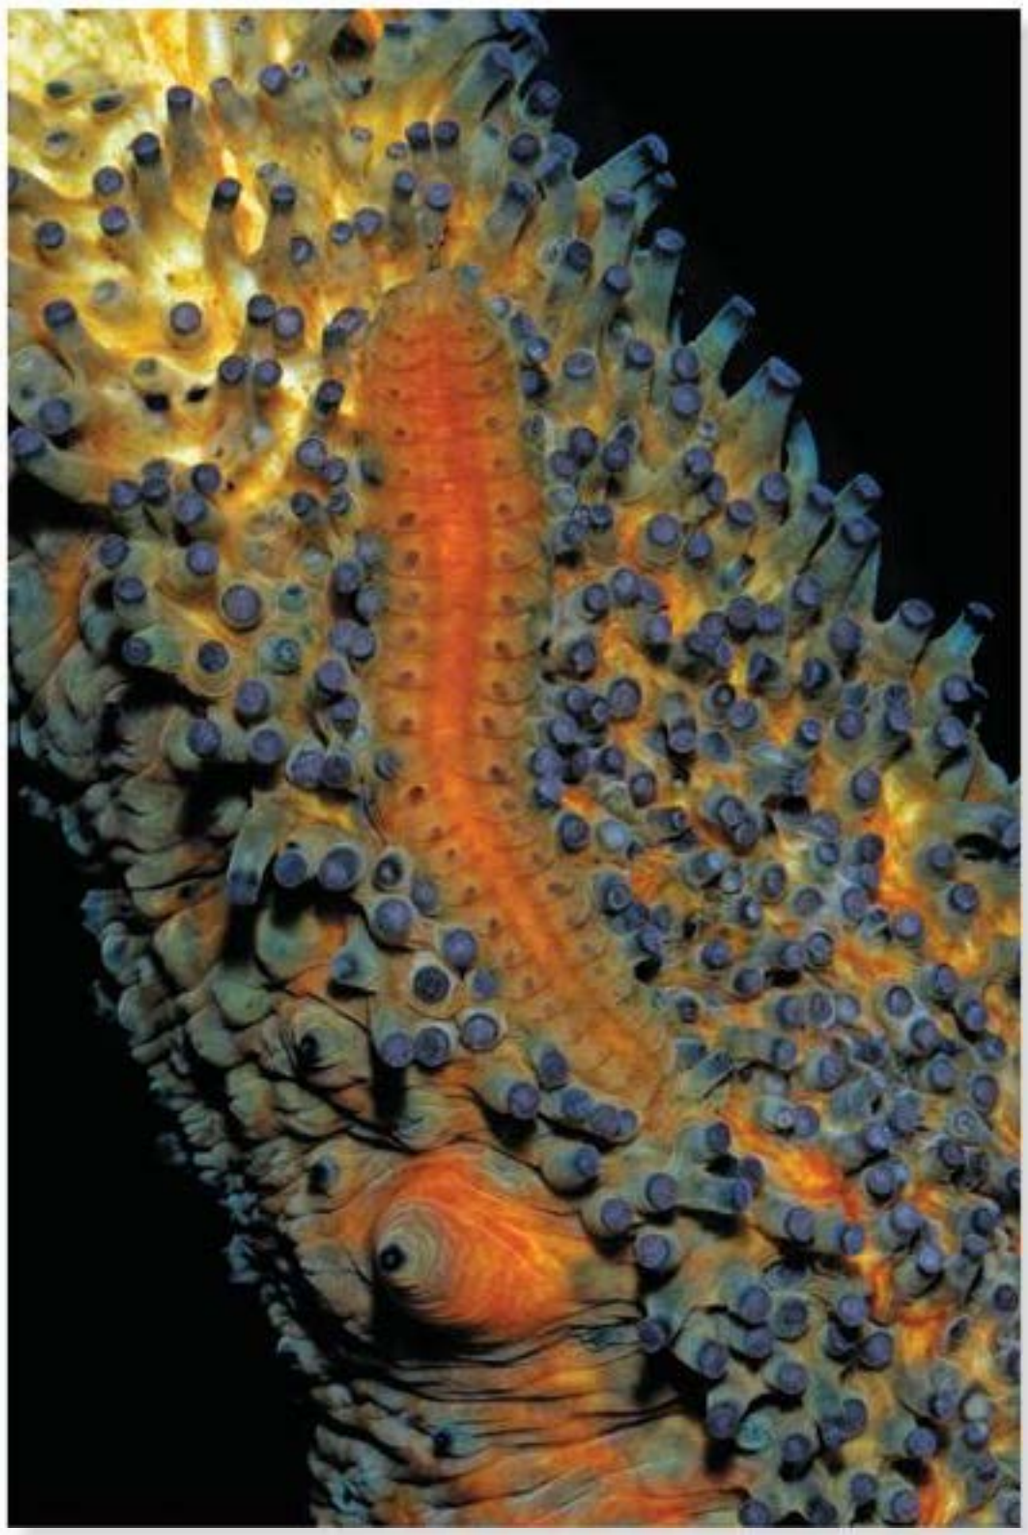
Geologic Time Scale

ERA	PERIOD		EPOCH	TIME (BEGINNING)
Cenozoic	Quaternary		Holocene	10,000 ybp
			Pleistocene	2.6 mya
	Tertiary	Neogene	Pliocene	5.3 mya
			Miocene	23 mya
		Paleogene	Oligocene	33.9 mya
			Eocene	56 mya
			Paleocene	66 mya
Mesozoic	Cretaceous			145 mya
	Jurassic			201 mya
	Triassic			252 mya
Paleozoic	Permian			299 mya
	Carboniferous		Pennsylvanian	323 mya
			Mississippian	359 mya
	Devonian			419 mya
	Silurian			444 mya
	Ordovician			485 mya
	Cambrian			541 mya
Precambrian	Ediacaran			635 mya
				4.57 bya

ybp = years before present; mya = million years ago; bya = billion years ago



A phylogenetic tree of the Animal Kingdom (Metazoa), reflecting a consensus view based primarily on recent molecular phylogenetic analyses. Radiation of the clade Spiralia is shown in red, that of Ecdysozoa in green. Uncertainty still exists in several regions, as shown by the "starburst" at the base of the spiralian clade, and by several other polytomies in the tree. The relative positions of the basalmost (non-bilaterian) phyla remain uncertain, especially Ctenophora. Further resolution of metazoan phylogeny is enthusiastically anticipated in the coming years. See Chapter 28 for additional details.

About the cover

The scale worm *Arctonoe pulchra* on the warty sea cucumber (*Apostichopus parvimensis*). Photo by Larry Jon Friesen. Dr Friesen's spectacular photographs were also part of the Second Edition of *Invertebrates* (including its cover), and over 130 of his photographs grace the pages of this Third Edition. The success of this project has been due, in no small part, to his contributions.

Larry Jon Friesen, PhD, completed his graduate research at the University of California, Santa Barbara, in Animal Communication. Dr Friesen is a Professor of Biological Sciences at Santa Barbara City College, teaching Cell Biology and Animal Diversity and incorporating his lifelong passion for nature photography

We dedicate this book to all our fellow teachers
and students of Invertebrate Zoology around the world.

Brief Contents

CHAPTER 1 ■ **Introduction** 1

CHAPTER 2 ■ **Systematics, Phylogeny, and Classification** 35

CHAPTER 3 ■ **The Protists:** Kingdom Protista 55

CHAPTER 4 ■ **Introduction to the Animal Kingdom:** Animal Architecture and Body Plans 135

CHAPTER 5 ■ **Introduction to the Animal Kingdom:** Development, Life Histories, and Origin 183

CHAPTER 6 ■ **Two Basal Metazoan Phyla:** Porifera and Placozoa 213

CHAPTER 7 ■ **Phylum Cnidaria:** Anemones, Corals, Jellyfish, and Their Kin 265

CHAPTER 8 ■ **Phylum Ctenophora:** The Comb Jellies 327

CHAPTER 9 ■ **Introduction to the Bilateria and the Phylum Xenacoelomorpha:** Triploblasty and Bilateral Symmetry Provide New Avenues for Animal Radiation 345

CHAPTER 10 ■ **Phylum Platyhelminthes:** The Flatworms 373

CHAPTER 11 ■ **Four Enigmatic Protostome Phyla:** Rhombozoa, Orthonectida, Chaetognatha, Gastrotricha 413

CHAPTER 12 ■ **Phylum Nemertea:** The Ribbon Worms 435

CHAPTER 13 ■ **Phylum Mollusca** 453

CHAPTER 14 ■ **Phylum Annelida:** The Segmented (and Some Unsegmented) Worms 531

CHAPTER 15 ■ **Two Enigmatic Spiralian Phyla:** Entoprocta and Cycliophora 603

CHAPTER 16 ■ **The Gnathifera:** Phyla Gnathostomulida, Rotifera (including Acanthocephala), and Micrognathozoa 613

CHAPTER 17 ■ **The Lophophorates:** Phyla Phoronida, Bryozoa, and Brachiopoda 635

CHAPTER 18 ■ **The Nematoida:** Phyla Nematoda and Nematomorpha 669

CHAPTER 19 ■ **The Scalidophora:** Phyla Kinorhyncha, Priapula, and Loricifera 693

CHAPTER 20 ■ **The Emergence of the Arthropods:** Tardigrades, Onychophorans, and the Arthropod Body Plan 709

CHAPTER 21 ■ **Phylum Arthropoda:** Crustacea: Crabs, Shrimps, and Their Kin 761

CHAPTER 22 ■ **Phylum Arthropoda:** The Hexapoda: Insects and Their Kin 843

CHAPTER 23 ■ **Phylum Arthropoda:** The Myriapods: Centipedes, Millipedes, and Their Kin 895

CHAPTER 24 ■ **Phylum Arthropoda:** The Chelicerata 911

CHAPTER 25 ■ **Introduction to the Deuterostomes and the Phylum Echinodermata** 967

CHAPTER 26 ■ **Phylum Hemichordata:** Acorn Worms and Pterobranchs 1007

CHAPTER 27 ■ **Phylum Chordata:** Cephalochordata and Urochordata 1021

CHAPTER 28 ■ **Perspectives on Invertebrate Phylogeny** 1047

Contents

CHAPTER 1
Introduction 1

Keeping Track of Life 4
Prokaryotes and Eukaryotes 7
Where Did Invertebrates Come From? 10
- The Dawn of Life 10
- The Ediacaran Period and the Origin of Animals 10
- The Paleozoic Era (541–252 Ma) 12
- The Mesozoic Era (252–66 Ma) 16
- The Cenozoic Era (66 Ma–present) 16

Where Do Invertebrates Live? 17
- Marine Habitats 17
- Estuaries and Coastal Wetlands 20
- Freshwater Habitats 22
- Terrestrial Habitats 22
- A Special Type of Environment: Symbiosis 23

Biodiversity Patterns 24
New Views of Invertebrate Phylogeny 25
Some Comments on Evolution 26
A Final Introductory Message to the Reader 32

CHAPTER 2
Systematics, Phylogeny, and Classification 35

Biological Classification 36
Nomenclature 36
Systematics 39
Monophyly, Paraphyly, and Polyphyly 40
Characters and the Concept of Homology 41
Phylogenetic Trees 43
Pleisiomorphy and Apomorphy 44
Constructing Phylogenies and Classifications 44
Molecular Phylogenetics 51

CHAPTER 3
The Protists: Kingdom Protista 55

Taxonomic History and Classification 59
Overviews of the Major Clades, or Groups 62
The General Protistan Body Plan 64
The Protist Phyla 70
Group 1: Amoebozoa 70
Phylum Amoebozoa: Amebas 70
Group 2: Chromalveolata 76
Phylum Dinoflagellata: Dinoflagellates 76
Phylum Apicomplexa: Gregarines, Coccidians, Haemosporidians, and Their Kin 81
Phylum Ciliata: The Ciliates 87
Phylum Stramenopila: Diatoms, Brown Algae, Golden Algae, Slime Nets, Oomycetes, etc. 97
Phylum Haptophyta: Coccolithophores 101
Phylum Cryptomonada: Cryptomonads 103

Group 3: Rhizaria 104
Phylum Chlorarachniophyta: Chlorarachniophyte Algae 104
Phylum Granuloreticulosa: Foraminiferans and Their Kin 105
Phylum Radiolaria: Radiolarians 108
Phylum Haplosporidia: Haplosporidians 111
Group 4: Excavata 112
Phylum Parabasalida: Trichomonads, Hypermastigotes, and Their Kin 112
Phylum Diplomonadida: Diplomonads 115
Phylum Heterolobosea: Heterolobosids 117
Phylum Euglenida: Euglenids 118
Phylum Kinetoplastida: Trypanosomes, Bodonids, and Their Kin 120
Group 5: Opisthokonta 124
Phylum Choanoflagellata: Choanoflagellates 124

Protist Phylogeny 125
The Origin of the Protista 125
Relationships among the Protists 127

CHAPTER 4

Introduction to the Animal Kingdom: Animal Architecture and Body Plans 135

Body Symmetry 136
Cellularity, Body Size, Germ Layers, and Body Cavities 138
Locomotion and Support 140
Feeding and Digestion 148
Excretion and Osmoregulation 157
Circulation and Gas Exchange 162
Nervous Systems and Sense Organs 168
Bioluminescence 174

The Tunicate Body Plan 1041
Chordate Phylogeny 1041

CHAPTER 28

Perspectives on Invertebrate Phylogeny 1047

Illustration Credits 1053

Index 1061

Preface to the Third Edition

For this edition of *Invertebrates*, Wendy Moore and Stephen M Shuster joined as co-authors. In addition, 22 other contributing authors graciously agreed to revise selected chapters or chapter sections. And two dozen reviewers were kind enough to critically read various chapters of the book. There is likely no way *Invertebrates*, Third Edition could have the depth and accuracy it has without the help of these wonderful professionals and specialists, and we are deeply indebted to them.

An information explosion has occurred since the Second Edition of this book, especially in the fields of molecular biology and phylogenetics. Just as the Second Edition of *Invertebrates* was going into production, the beginning framework of a new metazoan phylogeny was starting to appear in the scientific literature, although at that time it was based almost entirely on ribosomal gene trees and considerable disagreement existed. In the intervening decade, this new phylogeny was refined although many details still remain to be worked out. Most importantly, Protostomia and Deuterostomia have been redefined, and the long-standing Articulata group (based upon a hypothesized sister-group relationship between Annelida and the Panarthropoda) has been disarticulated with annelids now being placed among the Spiralia, and arthropods among the Ecdysozoa. The phyla Echiura and Sipuncula have been subsumed into Annelida. The basal, diploblastic phyla have been shuffled about near the base of the Metazoa tree, and they might continue to shuffle about for a bit longer; as this edition goes to press. We predict that, by the Fourth Edition of *Invertebrates*, the phylogenetic positions of all (or at least most) of the metazoan phyla will be stabilized—a lofty goal long sought by zoologists.

As in the Second Edition, important new terms are printed in boldface when first defined (and these are noted in the Index). Specific gene names, like species names, are italicized (though note that names for classes of genes, e g , Hox and ParaHox genes, are not italicized). We have again included the protists in the book, because instructors teaching Invertebrate Zoology usually cover the "kingdom Protista" and have asked for it. Our knowledge of protistan biology and phylogeny has expanded so much since the Second Edition that the amount of new information, even briefly presented, is substantial. The ICZN (International Code for Zoological Nomenclature) eschews use of diacritical marks in formal taxonomic names, and we follow that recommendation. However, for other terms we generally retain the original spellings and diacritics. So for example, there are archoöphoran and neoöphoran flatworms (the terms describing modes of egg development), but there are also the (now largely abandoned) taxa Archoophora and Neoophora.

Much of the art for this edition has been updated. However, we continue to include diagrams that will be useful to students in the laboratory, including for animal dissections. We also continue to provide rather detailed classifications and taxonomic synopses within each phylum. We don't expect these to read in the same way as the rest of the chapter, but rather to be used as a reference to look up taxonomic names, understand the traits that distinguish groups, or get an overall sense of the scope of the higher taxa in a phylum.

To say this book is a "labor of love" would be an understatement Without a deep passion for invertebrates, on the part of all the contributors, it would not have been possible. Hope fully this book elevates in its readers their own passion and enthusiasm for that 96% of the animal kingdom that has so successfully flourished without backbones.

R.C.B., W.M., S.M.S.
Tucson, Arizona
December 2015

Preface to the Second Edition

It is not now nor will it ever be given to one man to observe all the things recounted in the following pages.

WALDO L. SCHMITT
Crustaceans, 1965

During the revision of *Invertebrates* my brother Gary passed away. For a while the project was stalled. But, buoyed by the support of family, friends, and colleagues, I eventually returned to the task, which, at times, seemed overwhelming. The field of invertebrate biology is so vast, and cuts across so many disciplinary lines, that even in a book of this size it is necessary to generalize about some topics and to slight others. As university instructors, my brother and I realized early on that the teaching of invertebrate zoology should not be compartmentalized. Thus, in planning this book we were concerned about two potential dangers. First, the text might become an encyclopedic list of "facts" about one group after another, the sort of "flash card" approach that we wanted to avoid. Second, the book might be a rambling series of stories or vignettes about randomly selected animals (or "model organisms") and their ways of life. The first book would be dull, would encourage rote memorization instead of understanding, and might give the misconception that there is little left to discover. The second book might be full of interesting "gee whiz" stuff but would seem disorganized and without continuity or purpose to the serious student. Either approach could fail to present the most important aspects of invertebrates their phenomenal diversity, their natural history, and their evolutionary relationships. We also held to the belief that what we *know* about these animals is not as important as how we *think* about them. You should be prepared to assimilate much new material, but you should also be prepared for a great deal of uncertainty and mystery, as much remains to be discovered.

To avoid the pitfalls noted above, and to establish threads of continuity in our discussions about invertebrates, we developed our book around two fundamental themes: unity and diversity. The first theme we approach by way of functional body architecture, or what we call the bauplan concept. The second theme we approach through the principles of phylogenetic biology. Our hope was that weaving the book tightly to these themes would provide a meaningful flow as readers move from one phylum to the next. The first five chapters provide background for these themes and thus provide an important foundation upon which the rest of the book rests Please read these chapters carefully and refer back to them throughout your study.

The bulk of this book is devoted to a phylum by-phylum discussion of invertebrates. Fairly detailed classifications or taxonomic synopses for each phylum are included in separate sections of each chapter to serve as references. A consistent organization is maintained throughout each chapter, although we did yield to the important and sometimes different lessons to be learned by investigating the special attributes of each group of animals. In addition, because of their size and diversity, some taxa receive more attention than others although this does not mean that such groups are more "important" biologically than smaller or more homogeneous ones. (Five chapters are devoted to the arthropods and their kin.) In certain chapters more than one phylum is covered. In some cases the phyla covered are thought to be closely related to one another; in other cases the phyla merely represent a particular grade of complexity and their inclusion in a single chapter facilitates our comparative approach.

Certain aspects of this book have, of course, been influenced by our own biases; this is especially true of the discussions on phylogeny. We use a combination of phylogenetic trees (cladograms) and narrative discussions to talk about animal evolution. Cladograms are used when appropriate, because they provide the least ambiguous statements that can be made about animal relationships. We always knew that some of you, professors and students both, would disagree with our methods and ideas to various degrees at least we *hoped* that you would. Never placidly accept what you see in a textbook, or anyplace else for that matter, but try to be critical in your reading.

The book's final chapter is a phylogenetic summary of the animal kingdom. It reinforces the point that

much remains to be explored and learned about the evolutionary relationships of invertebrates Like all scientific knowledge, we are dealing here with provisional, transient "truths" that always remain open to chal lenge and revision. And, of course, scientists disagree. It is this disagreement and the constant challenging of hypotheses that enliven the field and push the frontiers of knowledge forward.

There are a few other things you should know about this book. A brief historical review of the classification of each major group is provided. We felt this material was not only interesting but also served to imbue students with a sense of the dynamic nature of taxonomy and the development of our understanding of each group. Unless otherwise indicated, the Classification section in each chapter deals only with extant taxa. Descriptions of taxa in these annotated classifications are written in somewhat telegraphic style to save space; we never expected these sections to be "read"—they are for reference. Important new words, when first defined, are set in boldface type. These boldfaced terms are also indicated by boldfaced page references in the index; thus the index can also be used as a glossary. We tried hard to be consistent in our usage of zoological terminology, but the existence of similar terms for entirely different structures in certain groups is notoriously troublesome—these are noted in the text.

For this Second Edition of *Invertebrates*, of course, we have tried to be as current as possible with the research literature, but even as this book goes into production important new publications appear daily. It has been estimated that the volume of scientific information is doubling about every 10 years (or faster). A half million nonclinical biology papers are published annually. As Professor George Bartholomew noted, "If one equates ignorance with the ratio between what one knows and what is available to be known ...each biological investigator becomes more ignorant with every passing day." My goal has been to provide sufficient reference material to lead the interested student quickly into the heart of the relevant literature. Most of the references cited in the text will be found at the end of the corresponding chapter. However, to conserve space and eliminate redundancy, in a number of cases (especially in figure citations) references of a general nature may be listed only once, usually in the introductory chapters. You will also notice citations of a fair number of references that are quite old, some from the nineteenth century. These are included not out of whimsy, but because many of these are benchmark research papers or they stand out as some of the best available descriptions for the subject at hand. (It is surprising how many of the illustrations in modern biology texts can be traced back to origins in nineteenth century publications.) It is distressing to see how commonplace it has become for researchers to ignore the excellent (and important) work of past decades. For example, many phylogenetic research papers completely ignore 150 years of careful embryological research that was published, largely in the German and American literature, in the nineteenth and twentieth centuries. For some scientists, biological research seems to be little more than "sound bites" from the past decade. Sadly, today, this "sound bite research culture" is often imbued in graduate students—a shocking and dangerous trend that encourages dilettantes. To understand animals requires a thorough understanding of their overall biology, and the dedication of a career, not just dabbling.

Since the first edition of this book, there has been an explosion of research in the field of molecular biology. Much of this has been in molecular phylogenetics, but huge strides are also being made in the area of molecular developmental biology. Papers in these fields now appear at such a pace that it is difficult to write about them in a textbook, for fear the ideas will be obsolete in six months. There have been many new phylogenetic hypotheses proposed on the basis of DNA sequence analyses since the fist edition of this book. Many of the molecular phylogenetic trees that were published before 2000 were quirky and troublesome, due to the simple fact that the field is still new and emerging. Because most of these trees are relatively new and still await rigorous testing with independent data, we do not discuss them all. However, we do discuss molecularbased hypotheses that have a growing body of support or have received widespread attention. But, in general we have taken a conservative approach in this regard—we are only just beginning to discover which genes are appropriate for different levels of phylogenetic analysis, and how best to analyze them.

These things being said, I hope you are now ready to forge ahead in your study of invertebrates. The task may at first seem daunting, and rightly so. I hope that this book will make this seemingly overwhelming task a bit more manageable. If I succeed in enhancing your enjoyment and appreciation of invertebrates, then my efforts will have been worthwhile.

Acknowledgments

This edition of *Invertebrates* has again benefitted greatly from conscientious reviews provided by many specialists, and we extend to these wonderful professionals our utmost gratitude. A very special note of appreciation goes to Gonzalo Giribet, who not only revised several chapters and sections for this edition, but also graciously took the time to review several other chapters; a more informed invertebrate zoologist does not exist today and we deeply appreciate the help he provided. Rebecca Rundell read the entire text—a daunting undertaking—providing critical scientific and instructor-oriented feedback; we were fortunate that she was willing to undertake this formidable task and we thank her profusely! Other colleagues who went above and beyond in providing assistance include Larry Jon Friesen, Jens Høeg, Reinhardt Kristensen, Brian Leander, Sally Leys, Claus Nielsen, and Martin Sørensen, to whom we owe a great debt of gratitude. Larry Friesen's photographic contributions to this edition of *Invertebrates* tremendously enhanced the book.

Invertebrates is in four languages and enjoys a broad readership, especially in Europe and Latin America. Many students have written over the years expressing their support and encouragement and sending photographs or other material, especially from Mexico and South America, but none has been as creative or inspirational as Lorena Viana and her friends from the University of São Paulo. *Muito obrigado, Lorena.*

Most of the original artwork in this text was done from our own sketches or from other sources by the award winning scientific illustrator Nancy Haver, supported by our publisher, Sinauer Associates. We have been incredibly fortunate to have Nancy working with us on all three editions of *Invertebrates*. The highly talented production staff at Sinauer has always been a joy to work with, and for this edition we once again had the skills of Janice Holabird, Martha Lorantos, David McIntyre, Marie Scavotto, and Chris Small. We are especially grateful to Production Editor Martha Lorantos, who led the team for this edition, doing so with extraordinary technical skill, patience, and good humor. Martha somehow managed to keep this locomotive on the tracks no matter how many twists, turns, and switches it took. Andy Sinauer has been part of this project since the mid-1980s, and he has been unwavering in his wise council, patience, and great insight. We are deeply indebted to Andy for his consistent support and personal interest in this text throughout its history. As a book publisher (and book lover) Andy's dedication to quality and professionalism is unequaled.

Media and Supplements to accompany *Invertebrates*, Third Edition

eBook

Invertebrates, Third Edition is available for purchase as an eBook, in several different formats, including VitalSource, Yuzu, BryteWave, and RedShelf The eBook can be purchased as either a 180-day rental or a permanent (non-expiring) subscription All major mobile devices are supported. For details on the eBook platforms offered, please visit www.sinauer.com/ebooks.

For the Instructor

(Available to qualified adopters)

Instructor's Resource Library

The *Invertebrates*, Third Edition Instructor's Resource Library includes an extensive collection of visual resources for use in preparing lectures and other course materials. The IRL includes the following:

Textbook Figures and Tables: All of the textbook's figures and tables are included as both high- and low-resolution JPEGs, for easy use in presentation software, learning management systems, and assessments. New for the Third Edition, this now includes all of the textbook's photographs.

Supplemental Photo Collection: Expanded for the Third Edition, this collection of over 1,000 photographs depicts organisms that span the entire range of phyla covered in the textbook.

PowerPoint Presentations: Two ready-to-use PowerPoint presentations are provided for each chapter of the textbook: one that contains all of the textbook figures and tables, and one that contains all of the relevant photos from the supplemental photo collection.

CHAPTER 1

Introduction

The incredible array of extant (= living) invertebrate species on Earth is the outcome of hundreds of millions of years of evolution. Indirect evidence of the first life on Earth, prokaryotic organisms, has been found in some of the oldest sedimentary rocks on the planet, suggesting that life first appeared in Earth's seas almost as soon as the planet cooled enough for it to exist. The Earth is 4.57 billion years old, and the oldest rocks found so far are about 4.3 billion years old. Although the precise date of the first appearance of life on Earth remains debatable, there are tantalizing 3.8 billionyear old trace fossils from Australia that resemble prokaryotic cells although these have been challenged, and opinion is now split on whether they are traces of early bacteria or simply mineral deposits. However, good evidence of prokaryotic life has been found in pillow lava that formed on the seabed 3 5 billion years ago, now exposed in South Africa. And 3 4billion year old fossil cells (probably sulfur bacteria) have been found among cemented sand grains on an ancient beach in Australia.[1]

The next big step in biological evolution came about when prokaryotic cells began taking in guests Around 2 to 2.5 billion years ago, one of these primitive cells took in a freeliving bacterium that established permanent residency, giving rise to the organelles we call mitochondria and this was the origin of the eukaryotic cell. Mitochondria, you will recall, generate energy for their host cells by oxidizing sugars, and in this case they also equipped early life to survive in Earth's increasing oxygen levels. Evidence suggests that mitochondria evolved just once, from a

---

[1]There are three popular theories on how life first evolved on Earth. The classic "primeval soup" theory, dating from Stanley Miller's work in the 1950s, proposes that self replicating organic molecules first appeared in Earth's early atmosphere and were deposited by rainfall into the ocean, where they reacted further to make nucleic acids, proteins, and other molecules of life More recent y, the idea of the first synthesis of biological molecules by chemical and thermal activity at deep-sea hydrothermal vents has been suggested. Hydrothermal vents also spew out compounds that could have been incorporated into the first life forms The third proposal is that organic molecules, or even prokaryotic life itself, first arrived on Earth from another planet (recentl y Mars has been at the forefront), or from deep space, on comets or meteorites Meteorites that fall to Earth contain amino acids and organic carbon molecules such as formaldehyde. Clearly, raw materials were not the issue—the trick was assembling the organic compounds to create a living, reproducing system.

TABLE 1.1 Numbers of Described Living Species in the 32 Animal Phyla (~1,382,402 total; ~1,324,402, or 96% are invertebrates)[a]

Taxon	Number of Described Species	Percent of Total Described Animal Species
Phylum Porifera	9000	0.65
Phylum Placozoa	1 (or 2)	0.0001
Phylum Cnidaria	13,200	0.95
Phylum Ctenophora	100	0.007
Phylum Xenacoelomorpha	400	0.03
Phylum Platyhelminthes	26,500	1.92
Phylum Chaetognatha	130	0.009
Phylum Gastrotricha	800	0.06
Phylum Rhombozoa (= Dicyemida)	70	0.005
Phylum Orthonectida	21	0.002
Phylum Nemertea	1300	0.09
Phylum Mollusca	80,000	5.79
Phylum Annelida	20,000	1.45
Phylum Entoprocta	200	0.014
Phylum Cycliophora	2	0.0001
Phylum Gnathostomulida	100	0.007
Phylum Micrognathozoa	1	0.0001
Phylum Rotifera	2000	0.14
Phylum Phoronida	11	0.0008
Phylum Bryozoa (= Ectoprocta)	6000	0.43
Phylum Brachiopoda	400	0.03
Phylum Nematoda (= Nemata)	25,000	1.81
Phylum Nematomorpha	360	0.03
Phylum Kinorhyncha	200	0.014
Phylum Priapula	20	0.001
Phylum Loricifera	35	0.003
Phylum Tardigrada	1200	0.087

Phylum Arthropoda		
Subphylum Myriapoda	16,360	1.18
Phylum Arthropoda TOTAL	**1,126,685**	**81.48**

symbiotic α-proteobacterium, and then subsequently diversified broadly. Modern free-living relatives of this bacterium harbor about 2,000 genes across several million bases, but their mitochondrial descendants have far fewer, sometimes as few as three genes. And human mitochondrial DNA harbors only about 16,000 bases. On the other hand, some plants have greatly expanded their mitochondrial genome, the largest so far discovered in the genus *Silene*, with around 11 million bases. Another prokaryotic intracellular guest, a cyanobacterium, became the ancestor of chloroplasts through the same symbiogenic process; chloroplasts, of course, are the photosynthesizing organelles that made plants and algae possible. In some plant and algae lines, the original chloroplast was lost, and a new one was picked up when a host cell took in an alga and co-opted its chloroplast in another kind of symbiogenic event (see Chapter 3 for a detailed discussion of these symbiogenic events).

Controversial hydrocarbon biomarkers suggest that the first eukaryotic cells might have appeared as early as 2.7 billion years ago (late Archean), although the earliest fossils that have been proposed to be eukaryotes—based on cell surface features and their large size—are about 1.8 billion years old (early Proterozoic). Multicelled algae (protists) date as far back as 1.2 billion years. Eukaryote-like microfossils have been described from 1-billion-year-old freshwater deposits, suggesting that the eukaryotes might have left the sea and invaded the terrestrial realm long ago. Even though the eukaryotic condition appeared early in Earth's history, it took a few hundred million more years for multicellular organisms to first evolve.

Disputed trace fossils have led some to suggest that the earliest

TABLE 1.1 (Continued)

Phylum Chordata TOTAL	**61,030**	**4.41**

*Estimated numbers of described (living) species of Prokaryota = 10,300; Protista = 200,000; Plantae = 315,000; and Fungi = 100,000.

animals (Metazoa) might have originated a billion years ago, but recent molecular clock estimates put the origin of Metazoa at 875 to 650 million years ago. The oldest generally accepted metazoan fossils are from the Ediacaran period, found in the Fermeuse Formation of Newfoundland (~560 Ma) and the Doushantuo Formation of southern China (600–580 Ma). A 560 million-year-old likely cnidarian (named *Haootia quadriformis*) has been described from Newfoundland, with quadraradial symmetry and clearly preserved bundled muscular fibers. *Haootia* appears to be a nearly 6 cm-long polyp, or perhaps an attached medusa it resembles modern species of Staurozoa. Cnidarians and other apparent diploblastic animals have been reported from the Doushantuo deposits, although these have been met with skepticism in some quarters. However, in 2015, a seemingly reliable 600 million year old fossil sponge (*Eocyathispongia qiania*) was described from the Doushantuo Formation. In 2009, Jun Yuan Chen and colleagues reported on embryos of reputed bilaterians (triploblasts) in the Doushantuo deposits (dated 600–580 Ma)—32-cell stage embryos with micromeres and macromeres, apparent anterior-posterior and dorsoventral patterning, and ectoderm like cells around part of their periphery. This finding was challenged, and the fossils were variously declared as prokaryotes or protists by other workers. However, further discoveries of additional embryos seemed to support the view of these being bilaterian embryos and, in some cases, perhaps diapause embryos ("resting eggs") of bilaterians. Good trace fossils (tracks) of a minute wormlike bilaterian animal, possibly with legs, have also been described from 585 million year old rocks in Uruguay. These fossil records put the appearance of "higher metazoans" (i.e., bilaterians) millions of years before the beginning of the Cambrian period.

There is no argument that Metazoa are monophyletic (i.e., a clade), and the animal kingdom is defined by numerous synapomorphies, including: gastrulation and embryonic germ layer formation; unique modes of oogenesis and spermatogenesis; a unique sperm structure; mitochondrial gene reduction; epidermal epithelia with septate junctions, tight junctions, or zonula adherens; striate myofibrils; actin-myosin contractile elements; type IV collagen; and the presence of a basal lamina/basement membrane beneath epidermal layers (of course, some of these features have been secondarily lost in some groups). Evidence is strong that Metazoa arose out of the protist group Choanoflagellata, or a common ancestor, and the two comprise sister groups in almost all recent analyses. They are, in turn, part of a larger clade known as Opisthokonta that also includes the fungi and several small protist groups (see Chapter 3).

The three great lineages of life on Earth—Bacteria, Archaea, Eukaryota are very different from one another. Bacteria and Archaea have their DNA dispersed throughout the cell, whereas in Eukaryota the DNA is enclosed within a membrane-bound nucleus. The cell lineages that gave rise to the Eukaryota are still unknown. The many millennia between the origin of Eukaryota and the explosive radiation that apparently began in the Ediacaran is sometimes called the "boring billion years," but the fossil record is fairly sparse for that time period, so we're not sure how "boring" it actually was. A popular hypothesis suggests that oxygen levels were too low during that time for larger organisms to evolve (see below).

Today, there are an estimated 2,007,702 described and named living species. About 58,000 of these are vertebrates and 1,324,402 are invertebrates (Table 1.1). In addition, about 200,000 protists have been described, 315,000 plants (290,000 seed plants), and 100,000 fungi. And 15,000 to 20,000 new species are described every year. It seems likely that a significant portion of Earth's biodiversity, at the level of both genes and species, resides in the "invisible" prokaryotic world, and we have come to realize how little we know about this hidden world. About 10,300 species of prokaryotes have been described, but there are an estimated 10 million (or perhaps more) undescribed prokaryote species on Earth. An estimated 135,000 more plant species remain to be described. Overall, estimates of undescribed eukaryotes range from lows of 3–8 million to highs of 100 million or more.

Keeping Track of Life

For a gentleman should know something of invertebrate zoology, call it culture or what you will, just as he ought to know something about painting and music and the weeds in his garden.

Martin Wells
Lower Animals, 1968

How can we possibly keep track of all these species names and information about each of them, and how do we organize them in a meaningful way? We do so with classifications. Classifications are lists of species, ranked in a subordinated fashion that reflects their evolutionary relationships and phylogenetic history. Classifications summarize the overarching aspects of the tree of life. At the highest level of classification, we can recognize two superkingdoms: Prokaryota (containing the kingdoms Archaea and Bacteria) and Eukaryota (containing the kingdoms Protista, Fungi, Plantae, and Animalia/Metazoa). Because "Protista" is not a monophyletic group, the protists are sometimes broken up into several kingdoms, or other classificatory ranks, but the relationships among the protists are still being debated (see Chapter 3).

One of the earliest and best-known evolutionary trees of life published from a Darwinian (genealogical) perspective was by Ernst Haeckel in 1866 (Figure 1.1). Haeckel coined the term "phylogeny," and his famous trees codified what became a tradition of depicting phylogenetic hypotheses as branching diagrams, a tradition that has persisted since that time. However, a hand drawn sketch in Charles Darwin's field notebook (1837) clearly depicts his view of South American mammal evolution in a branching tree of extant and fossil species. And in his book, *On the Origin of Species* (1859), Darwin presented an abstract branching diagram of a theoretical tree of species as a way of illustrating his concept of descent with modification. Jean Baptiste Lamarck probably presented the first historical trees of animals in his *Philosophie Zoologique* in 1809, and the French botanist Augustin Augier published a tree showing the relationships among plants in 1801 (perhaps the first tree ever published)—although both Lamarck's and Augier's trees were produced before the modern concept of evolution had been clearly articulated. We discuss various ways in which phylogenetic trees are developed in Chapter 2.

Since Haeckel's day, many names have been coined for the branches that sprout from these trees, and in recent years a glut of new names has been introduced to label various molecularly based clades nested within the tree of life. We will not burden you with all of these names, but a few of them need to be defined here before we launch into our study of the invertebrates. Some of these names refer to groups of organisms that are thought to be natural phylogenetic lineages (i.e., groups that include all the descendants of a stem species, known as **monophyletic groups**, or **clades**). Examples of such natural, or monophyletic groups are the superkingdom Eukaryota, kingdom Metazoa (the animals), and kingdom Plantae (the lower and higher plants).[2] All three of these large groupings are thought to have had a single origin, and they each include all of the species descended from that original ancestor. Monophyletic groups comprise a cluster of terminal branches (with a single origin) embedded within a much larger tree. Some other named groups are natural, having a single evolutionary origin, but the group *does not contain all of the members* of the lineage. Such groups are said to be **paraphyletic**, and they are often the basal or ancestral lineages in a much larger clade. Paraphyletic groups comprise some, but not all descendants of a stem species. The Protista are paraphyletic because the grouping excludes three large multicelled lineages that evolved out of it (e.g., Metazoa, Plantae, Fungi). Another well-known paraphyletic group is Crustacea (which excludes the Hexapoda/Insecta, a clade that evolved out of it). The clade that includes both Crustacea and Hexapoda is known as Pancrustacea. Classifications of life are derived from evolutionary or phylogenetic trees, and thus generally include only monophyletic groups. However, sometimes paraphyletic taxa are also used because, if they are unambiguous, they can be important in facilitating meaningful communication among scientists and between the scientific community and society (e.g., Protista and Crustacea).

Some names refer to unnatural, or composite, groupings of organisms, such as "microbes" (i.e., any organism that is microscopic in size, such as bacteria, archaeans, yeasts, unicellular fungi, and some protists). These unnatural groups are **polyphyletic**. For example, yeasts are unicellular fungi that evolved several times independently from multicellular filamentous ancestors; today they are assigned to one of three higher fungal phyla, so the concept of "yeast" represents a polyphyletic, or unnatural grouping. The name "slugs"

---

[2]For decades, taxonomists have debated the boundary between protists and Plantae. We accept the view that it should be placed just prior to the evolutionary origin of chloroplasts and that Plantae should comprise all eukaryotes with plastids directly descending from the initially enslaved cyanobacterium, i.e., Rhodophyta (red algae), Glaucophyta (glaucophyte algae), and Viridiplantae ("green plants"), but exclude those like chromists that obtained their chloroplasts from plants secondarily by subsequent eukaryote to eukaryote lateral transfers. The structure of plastid genomes and the derived chloroplast protein-import machinery support a single origin of these closely related groups. Thus, Plantae is a monophyletic clade containing two subkingdoms, Biliphyta (phyla Glaucophyta and Rhodophyta) and Viridiplantae (the phyla Chlorophyta, Charophyta, Anthocerotophyta, Bryophyta, Marchantiophyta, and Tracheophyta). In the past, some workers have restricted Plantae to land plants (embryophytes or higher plants) and included the other Viridiplantae with the Protista in a larger group called Protoctista (which also included the lower fungi).

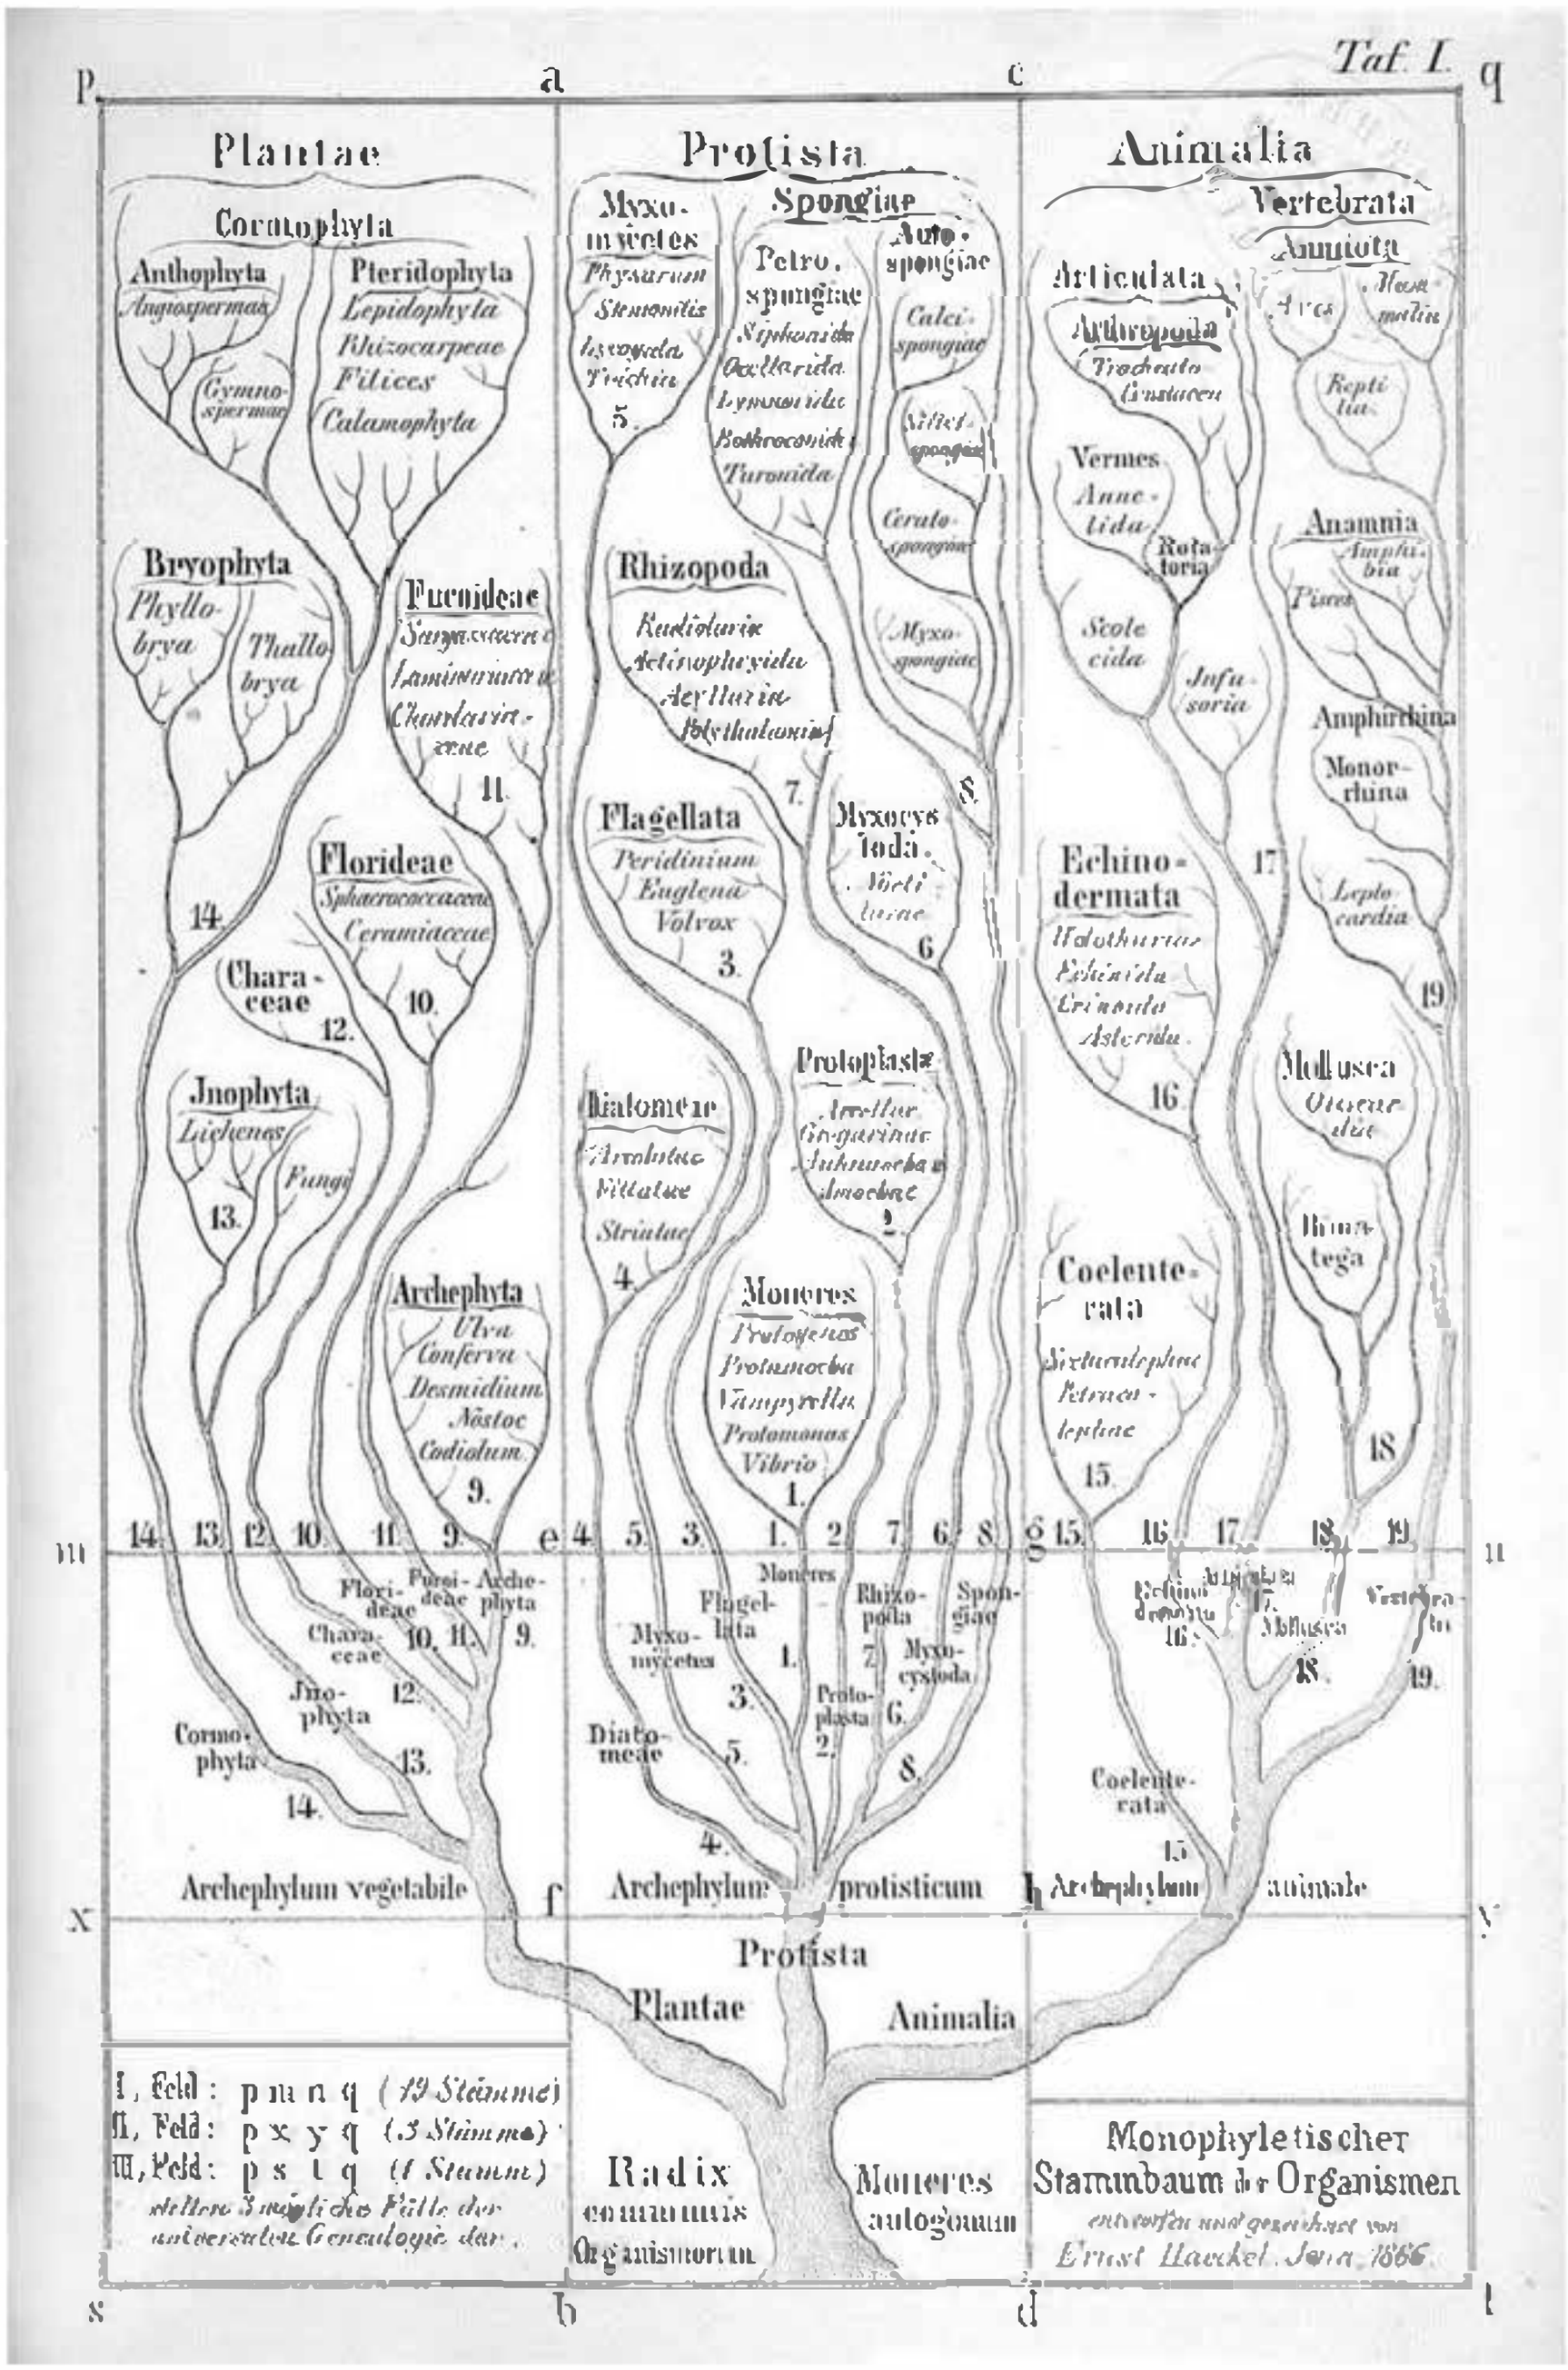

Figure 1.1 Haeckel's Tree of Life (1866).

(or "sea slugs") also refers to a group of animals that do not share a single ancestry (the slug form has evolved many times among gastropod molluscs), so slugs are polyphyletic (see chapter opener photo of a Spanish shawl slug, *Flabellina iodinea*). We explore these concepts more fully in Chapter 2

We know approximately how many genes are in organisms from yeast (about 6,000 genes) to humans (about 25,000 genes), but we don't know how many living species inhabit our planet and the range in estimates is surprisingly broad. How many undescribed species are lingering out there, waiting for names? However derived, predictions of global species diversity rely on extrapolations from existing real data. Methods of estimation have included rates of past species descriptions, expert opinion, the fraction of undescribed species in samples collected, and ratios between taxa in the taxonomic hierarchy Each method has its limitations. Two recent estimates of undescribed marine animals (Mora et al. 2011 and Appeltans et al. 2012) reached the conclusion that 91% vs. 33–67% (respectively) of the world's eukaryotic marine fauna is still undescribed. More recently, a large research program sampling the Western Australian upper continental slope for Crustacea and Polychaeta found 95% of the species to be undescribed (with the rate of new species obtained by the sampling program not even leveling off). Given the vast extent of the poorly-sampled world's continental slopes, not to mention the deep sea, rainforests, and other little-sampled habitats, these data suggest that estimates of over 90% undescribed eukaryotes on Earth are not unreasonable.

Our great uncertainty about how many species of living organisms exist on Earth is unsettling and speaks to the issue of priorities and funding in biology. At our current rate of species descriptions, it might take us 10,000 years or more to describe just the rest of Earth's eukaryotic life forms. Not all of the species remaining to be described are invertebrates between 1990 and 2002 alone, 38 new primate species were discovered and named. And if prokaryotes are thrown into this mix, the numbers become even larger. Recent gene-sequence surveys of the world's oceans (based largely on DNA "barcodes"—16S ribosomal gene sequences for Bacteria and Archaea, 18S ribosomal gene sequences for eukaryotes) have revealed a massive undescribed biota of microbes in the sea. Similar discoveries have been made with genetic searches for soil microbes. For example, there are about 30,000 formally named bacterial varieties that are in pure culture, but estimates of undescribed species range from 10 million to a billion or more! And we now know that thousands of bacterial species inhabit the human body, almost all of which are not yet even named and described. Viruses still lack a universal molecular identifier, and the world scope of viral biodiversity is essentially unknown.

There are currently several attempts to compile a list of all known species on Earth. The United States Geological Service (USGS) hosts ITIS—the Integrated Taxonomic Information System. The goal of ITIS is to create an easily accessible database with reliable information on species names and their classification. Recently, ITIS and several other initiatives turned their data over to the Catalogue of Life (CoL) project, which is building the species list (up to 1.5 million species as this book went to press) and maintaining a "consensus classification" of all life (see www.catalogueoflife.org, and Ruggiero et al. 2015). The Encyclopedia of Life (EOL) project is building a website that offers not just species names, but also ecological information about each species; it currently contains more than 175,000 vetted species pages. WoRMS (The World Register of Marine Species), an open-access online database with the goal of listing all described eukaryotic marine species, predicts the completed inventory will catalog 222,000 to 230,000 species.

However, at our current rate of anthropogenically driven extinction a majority of Earth's species will go extinct before they are ever described. In the United States alone, at least 5,000 named species are threatened with extinction, and an estimated 500 known species have already gone extinct since people first arrived in North America. Globally, the United Nations Environment Programme estimates that by 2030 nearly 25% of the world's mammals could go extinct, and recent counts indicate 322 vertebrate species have already become extinct since 1500. Some workers now refer to the time since the start of the Industrial Revolution as the Anthropocene—a period marked by humanity's profound global transformation of the environment. More than half of Earth's terrestrial surface is now plowed, pastured, fertilized, irrigated, drained, bulldozed, compacted, eroded, reconstructed, mined, logged, or otherwise converted to new uses. Human-driven deforestation removes 15 billion trees per year. E. O. Wilson once estimated that about 25,000 species are going extinct annually on Earth (we just don't know what they are!).

Pimm et al. (2014) calculated extinction rates as fractions of species going extinct over time—extinctions per million species years (E/MSY). For example, 1,230 bird species have been described since 1900, and 13 of these are now extinct. This cohort accumulated 98,334 species-years, meaning an average species has been known for 80 years. The extinction rate is thus $13/98{,}334 \times 10^6 = 132$ E/MSY. They calculated that, before *Homo sapiens* arrived on the scene, the overall background animal extinction rate was 0.1 E/MSY; today it is about 100 E/MSY (a thousand times higher). Proportionally speaking, larger animals (e.g., vertebrates), higher in the food chain and fewer in number, are more likely to go extinct than invertebrates. This means invertebrates (and protists), which already run

the world, will play even more important ecosystem roles in the future.

Even though invertebrates make up 96% of the described animal kingdom (Table 1.1), they account for a mere 38% of the 500 or so species now under protection by the U.S. Endangered Species Act. NatureServe has argued that more than 1,800 invertebrate species need protection, while the IUCN Red List of Threatened Species documents the extinction risk of nearly 50,000 species of animals and plants. In 2002, the U.N. Convention on Biological Diversity committed nations to significantly reduce rates of biodiversity loss by 2010, and in 2010 this call was renewed with a set of specific targets for 2020. However, several recent studies have shown that the convention has so far failed and rates of biodiversity loss do not appear to be slowing at all. Further, the Convention has crippled scientific fieldwork around the world by instilling in many nations a fear of outside researchers "stealing their genetic biodiversity."

The single greatest threat to species survival for the past 200 years has been habitat loss. Although we hear mostly about deforestation, 30 to 50% of the Earth's coastal environments have been degraded during past decades, at rates exceeding those of tropical forest loss. Looking forward, the damaging effects of habitat loss will likely be matched (and escalated) by anthropogenically driven global climate change. The concentration of carbon dioxide (CO_2) in Earth's atmosphere has risen by about 38% since the start of the industrial era as a result of fossil fuel burning and land use change, and a quarter to a third of all the CO_2 emitted through human activities has been absorbed by the ocean, resulting in acidification of surface waters. In fact, the oceans overall are now about 30% more acidic than they were 100 years ago. The drop in ocean pH is creating hardships on animals with calcium carbonate skeletons, and damage has been documented in everything from corals to sea butterflies (pteropod molluscs). In May 2013, the concentration of CO_2 in the atmosphere reached 400 ppm, the highest it has been over the past 2 million years. Never before has such a rapid global-scale increase in CO_2 (and temperature) occurred during the history of human civilization. Rising concentrations of greenhouse gasses in the atmosphere are leading to increasing global temperatures and changes in precipitation regimes, and these changes are impacting the distribution of biota across the planet. Globally, average air temperatures have risen about 0.8°C since 1880, mean land surface temperature has warmed 0.27°C per decade since 1979, and projections from global climate models predict global atmospheric temperatures to increase by about 4°C by the end of this century. Melting polar ice and glaciers, combined with expansion of warming ocean waters, are driving up sea level, which is expected to be as much as four feet higher by the end of this century.

Prokaryotes and Eukaryotes

The discovery that organisms with a cell nucleus constitute a natural (monophyletic) group divided the living world neatly into two categories, the **prokaryotes** (Archaea and Bacteria: those organisms lacking membrane-enclosed organelles and a nucleus, and without linear chromosomes), and the **eukaryotes** (those organisms that do possess membrane-bound organelles, a nucleus, and linear chromosomes). Investigations by Carl Woese and others, beginning in the 1970s, led to the discovery that the prokaryotes themselves comprise two distinct groups, called **Bacteria** (= Eubacteria) and Archaea (= Archaebacteria), both quite distinct from eukaryotes (Box 1A). Bacteria correspond more or less to our traditional understanding of bacteria. Archaea strongly resemble Bacteria, but they have genetic and metabolic characteristics that make them quite unique. For example, Archaea differ from both Bacteria and Eukaryota in the composition of their ribosomes, in the construction of their cell walls, and in the kinds of lipids in their cell membranes. Some Bacteria conduct chlorophyll-based photosynthesis, a trait that is never present in Archaea (photosynthesis is the harvesting of light to produce energy/sugars and oxygen). Current thinking favors the view that prokaryotes ruled Earth for about a billion years before the eukaryotic cell appeared.

As the prokaryotes evolved, they adapted to colonize every conceivable environment on Earth. During the early evolution of prokaryotes, Earth's air had almost no oxygen, consisting primarily of CO_2, methane, and nitrogen. The metabolism of the earliest prokaryotes relied on hydrogen, methane, and sulfur, and did not produce oxygen as a byproduct. It was the appearance of the first oceanic photosynthesizing prokaryotes that led to increased atmospheric oxygen concentrations, setting the stage for the evolution of complex multicellular life. And aquatic species were probably able to colonize land only because the oxygen helped create the ozone layer that shields against the sun's ultraviolet radiation. Just *when* oxygen producing photosynthesis began is still being debated, but when it happened, most of the early chemoautotrophic prokaryotes were likely poisoned by the "new gas" in the environment. A large body of evidence points to a sharp rise in the concentration of atmospheric oxygen between 2.45 and 2.32 billion years ago (this is sometimes called the "great oxidation event"), around the same time the eukaryotic cell first appeared. This evidence includes red beds or layers tinged by oxidized iron (i.e., rust) and oil biomarkers that may be the remains of Cyanobacteria (true Bacteria). However, in western Australia, thick shale deposits that are 3.2 billion years old have bacterial remains that hint at oxygen-producing photosynthesis. These ancient oxygen levels might have reached around 40% of present atmospheric levels. There is

BOX 1A The Six Kingdoms of Life*

PROKARYOTES (Superkingdom Prokaryota)*

Kingdom Bacteria (= Eubacteria)
The "true" bacteria, including Cyanobactera (blue green algae), Proteobacteria, Spirochaetae, and numerous other phyla; never with membrane enclosed organelles or nucle , or a cytoskeleton; none are methanogens; some use chlorophyll-based photosynthesis; with peptidoglycan in cell wal ; with a single known RNA polymerase

Kingdom Archaea (= Archaebacteria)
Anaerobic or aerobic, largely methane-producing microorganisms; never with membrane-enclosed organelles or nucle , or a cytoskeleton; none use chlorophyll-based photosynthesis; without peptidoglycan in cell wall; with several RNA polymerases.

EUKARYOTES (Superkingdom Eukaryota)

Cells with a variety of membrane-enclosed organelles (e.g., mitochondria, lysosomes, peroxisomes) and with a membrane-enclosed nucleus. Cells gain structural support from an internal network of fibrous proteins called a cytoskeleton.

Kingdom Protista
Largely unicellular eukaryotes that do not undergo tissue formation through the process of embryological layering. A paraphyletic grouping of many phyla, including euglenids, diatoms and some other brown algae, ciliates, dinoflagellates, foraminiferans, amoebae, and others (Chapter 3). Protists descended from bacteria by the acquisition of a nucleus, endomembrane, cytoskeleton, and mitochondria. The 200,000 or so described living species probably represent about 10% of the actual protist diversity on Earth today.

Kingdom Fungi
The fungi. Probably a monophyletic group that includes molds, mushrooms, yeasts, and others. Saprobic, heterotrophic, multicellular organisms. We view the demarcation between Protists and Fungi as lying immediately before the origin of the chitinous wall around vegetative fungal cells and the associated loss of phagotrophy. The earliest fossil records of fungi are from the Middle Ordovician, about 460 million years ago. The 100,000 described species are thought to represent only a small percent of the actual diversity, and estimates of total fungal biodiversity range from 3 to 10 million.

Kingdom Plantae (= Archaeplastida)
Unicellular and multicellular, photosynthetic, chlorophyll-bearing eukaryotes with plastids directly descended from an intracellularly ensaved cyanobacterium. Includes Glaucophyta (glaucophyte algae), Rhodophyta (red algae), and Viridiplantae (green plants). Viridiplantae includes the phyla Chlorophyta (green algae), Charophyta (freshwater green algae), Anthocerotophyta (hornworts and their kin), Marchantiophyta (liverworts), Bryophyta (other nonvascular plants), and Tracheophyta (the vascular plants, about 260 000 of which are flowering plants). Tracheophytes develop through embryonic tissue layering, in a manner analogous to animal embryogeny. The described species of Plantae are thought to represent about half of Earth's actual plant diversity.

Kingdom Animalia (= Metazoa)
The multicellular animals. A monophyletic taxon, containing 32 phyla of ingestive, heterotrophic, multicellular organisms that develop by tissue layering during embryogenesis. About 1,382,402 species of living metazoans have been described; estimates of the number of undescribed animal species range from lows of 3–8 million to highs of over 100 million.

---

*Portions of the old "Kingdom Monera" are now included in the Bacteria (Eubacteria) and the Archaea. Viruses (about 5 000 described "species") and subviral parasites such as viroids and prions, which are all regarded as laterally transmissible parasitic genetic elements, are not included in this classification. Prions are infectious proteins, devoid of a nucleic acid genome but subject to mutation and thus evolution. Viruses comprise an ancient, polyphyletic group of stripped down parasitic genetic fragments. Recent work suggests that they might have played important roles in major evolutionary transitions, such as the invention of DNA and DNA replication mechanisms, the formation of the major "superkingdoms" of life, and perhaps even the origin of the eukaryotic nucleus. Viral classification is standardized by the ICTV (International Committee on Taxonomy of Viruses).

also evidence in the geological record that atmospheric oxygen did not steadily increase, but fluctuated wildly, dropping at times to a mere 0.1% of current levels. It may not have been until around 800 million years ago that high oxygen levels stabilized.

Terrestrial photosynthesis has little effect on atmospheric O_2 because it is nearly balanced by the reverse processes of respiration and decay. By contrast, marine photosynthesis is a net source of O_2 because a small fraction (~0.1%) of the organic matter synthesized in the oceans is buried in sediments. It is this small "leak" in the marine organic carbon cycle is responsible for most of our atmospheric O_2. Cyanobacteria are thought to have been largely responsible for the initial rise of atmospheric O_2 on Earth, and even today *Prochlorococcus* can be the numerically dominant phytoplankter in tropical and subtropical oceans, accounting for 20 to 48% of the photosynthetic biomass and production in some regions. Today most marine photosynthesis is performed by Cyanobacteria and single celled protists, such as diatoms and coccolithophores. Cyanobacteria are nearly unique among the prokaryotes in performing oxygenic photosynthesis, often together with nitrogen fixation, and thus they are major primary producers in both marine and terrestrial ecosystems.

Many Archaea live in extreme environments, and this pattern is often interpreted as a refugial lifestyle—in other words, such creatures tend to live in places where they have been able to survive without confronting dangerous environments or competition from more highly derived life forms. Many of these "extremophiles" are

anaerobic chemoautotrophs, and they have been found in a variety of habitats, such as deep-sea hydrothermal vents, benthic marine cold seeps, hot springs, saline lakes, sewage treatment ponds, in subglacial lakes beneath the ice of Antarctica (where the water is liquid due to a combination of geothermal heating and pressure), and in the guts of humans and other animals. One of the most astonishing discoveries of the 1980s was that extremophile Archaea (and some fungi) are widespread in the deep rocks of Earth's crust. Since then, a community of hydrogen-eating Archaea has been found living in a geothermal hot spring in Idaho, 600 feet beneath Earth's surface, relying on neither sunshine nor organic carbon. Archaea are known to grow at temperatures up to 121°C in deep sea hydrothermal vents, and one species has been shown to fix nitrogen at temperatures up to 92°C. Archaea have been found at depths as great as 28 km, living in igneous rocks with temperatures as high as 75°C. Recently, a diverse microbial biota (Bacteria, Archaea, and even Eukaryotes) has been found to live as deep as 2.5 km beneath the seafloor, in ancient buried sediments, and they are remarkably abundant in coalbed layers. And in the early part of this century, using new high throughput sequencing technologies, it was discovered that there are massively more species of prokaryotes in the environment than had been thought. Even deep within sediments, at least 800 m below the seafloor, huge populations of prokaryotes have been discovered.

We are now realizing that the 10,000 or so described species of Bacteria and Archaea are barely the tip of the iceberg. Extremophiles include halophiles (which grow in the presence of high salt concentrations, in some cases as high as 35% salt), thermophiles and psychrophiles (which live at very high or very low temperatures), acidiphiles and alkaliphiles (which are optimally adapted to acidic or alkaline pH environments), and barophiles (which grow best under pressure). Molecular phylogenetic studies now suggest that some of these extremophiles, particularly the thermophiles, may be very similar to the "universal ancestor" of all life on Earth.[3]

[3]One of the most striking examples of a thermophile is *Pyrolobus fumarii* a chemolithotrophic archaean that lives in oceanic hydrothermal vents at temperatures of 90° 113°C. (Chemolithotrophs are organisms that use inorganic compounds as energy sources.) On the other hand, *Polaromonas vacuolata* grows optimally at 4°C. *Picrophilus oshimae* is an acidiphile whose growth optimum is pH 0.7 (*P. oshimae* is also a thermophile, preferring temperatures of 60°C). The alkaliphile *Natronobacterium gregoryi* lives in soda lakes where the pH can rise as high as 12. Halophilic microorganisms abound in hypersaline lakes such as the Dead Sea, Great Salt Lake, and solar salt evaporation ponds, and the green alga *Dunaliella salina* lives in the Dead Sea at salinities of 23% salt. Such lakes are often colored red by dense microbial communities (e.g., *Halobacterium*). *Halobacterium salinarum* lives in the saltpans of San Francisco Bay and colors them red. Barophiles have been found living at all depths in the sea, and one unnamed species from the Mariana Trench (the deepest part of the ocean) has been shown to require at least 500 atmospheres of pressure in order to grow.

Courses and texts on invertebrates often include discussions of two eukaryotic kingdoms: the Animalia (= Metazoa) and certain protist phyla. Following this tradition, we treat 32 phyla of Metazoa and 17 phyla of protists in this book. In today's world of diminishing "ology" courses many students will find this to be their only detailed exposure to this very important group of organisms. The vast majority of kinds (species) of living organisms that have been described are animals. The kingdom Animalia, or Metazoa, is usually defined as the ingestive, heterotrophic, sexual, multicellular eukaryotes that undergo embryonic tissue formation.[4] The process of embryonic tissue formation takes place through a major reorganization and differentiation process called gastrulation. However, its members possess other unique attributes as well, such as an acetylcholine/cholinesterase-based nervous system, special types of cell-cell junctions, and a unique family of connective tissue proteins called collagens. Metazoans have also been shown to possess a distinctive set of insertions and deletions in genes coding for proteins in the mitochondrial genome. Among the Metazoa are some species that possess a backbone (or vertebral column), but most do not. Those that possess a backbone constitute the subphylum Vertebrata of the phylum Chordata, and account for only about 4% (about 58,000 species) of all described animals. Those that do not possess a backbone (the remainder of the phylum Chordata, plus 31 additional animal phyla) constitute the invertebrates. Thus we can see that the division of animals into invertebrates and vertebrates is based more on tradition and convenience, reflecting a dichotomy of interests among zoologists, than it is on the recognition of natural biological groupings. About 10,000 to 12,000 new species are named and described by biologists each year, most of them invertebrates (mainly insects).

Not only are invertebrates diverse and numerous, they span over 6 orders of magnitude in size. Many species are microscopic (even though they may have thousands of cells in their bodies). Some of the smallest are cycliophorans (350 µm, or 35 mm), loriciferans (as small as 85 µm, or .085 mm), and the coral reef nematode *Greeffiella minutum*, that is only 80 µm (.08 mm) long. However, species with bodies smaller than one millimeter occur in many other phyla. Invertebrates can also be quite large. Some jellyfish reach 25 m including the tentacles, the giant squid (*Architeuthis dux*) reaches 13 m including the tentacles, a sperm whale nematode parasite (*Placentonema gigantisima*) can exceed 8 m, and some earthworms can reach 3 m in length. There is a record of a nemertean reaching 60 m, but this lacks reliable verification. Giant clams (*Tridacna*) can exceed 400

[4]Heterotrophic organisms are those that derive their nutritional requirements from complex organic substances (i.e., by consuming other organisms or organic materials as food). In contrast, autotrophs are able to form nutritional organic substances from simple inorganic matter such as carbon dioxide (e.g., plants).

kg in weight, and the terrestrial coconut crab (*Birgus latro*) can exceed 4 kg perhaps the heaviest land invertebrate.

Where Did Invertebrates Come From?

Evolutionary analyses confirm that the ancestors of plants and animals (and fungi) were protists, and the phenomenon of multicellularity arose independently in these three groups, although in different ways. Genetic and developmental data confirm that the basic mechanisms of pattern formation and cell-cell communication during development were independently derived in animals and in plants. In animals, segmental identity is established by the spatially specific transcriptional activation of an overlapping series of master regulatory genes, the homeobox (Hox) genes. The master regulatory genes of plants are not members of the homeobox gene family, but belong to the MADS box family of transcription factor genes. There is no evidence that the animal homeobox and MADS box transcription factor genes are homologous.

Although the fossil record is rich with the history of many early animal lineages, many others have left few or no fossils. Many ancient animals were very small, many were soft-bodied and did not fossilize well, and others lived where conditions were not suitable for the formation of fossils. However, groups such as the echinoderms (sea stars, urchins), molluscs (clams, snails), arthropods (crustaceans, insects), corals, ectoprocts, brachiopods, and vertebrates have left rich fossil records. In fact, for some groups (e.g., echinoderms, brachiopods, ectoprocts, molluscs), the number of extinct species known from fossils exceeds the number of known living forms. Representatives of nearly all of the extant animal phyla were present in the Cambrian period. Life on land, however, did not appear until later, and terrestrial radiations probably began only about 470 million years ago. The following account briefly summarizes the early history of life and the rise of the invertebrates.

The Dawn of Life

It used to be thought that the Proterozoic eon, 2.5 billion years ago to 541 million years ago, was a time of only a few simple kinds of life; hence the name. However, recent discoveries have shown that life on Earth began early and had a very long history throughout the Proterozoic. As noted above, some of the oldest rocks known on Earth already have markings suspected to represent anaerobic sulfate-reducing prokaryotes and perhaps even cyanobacterial stromatolites. Undisputed cyanobacterial fossils 2.9 billion years of age are known. The first actual fossil traces of eukaryotic life (benthic algae) are 1.7 to 2 billion years old, whereas the first certain eukaryotic fossils (phytoplankton) are 1.4 to 1.7 billion years old. Together, these prokaryotes and protists appear to have formed diverse communities in shallow marine habitats throughout the Proterozoic. Living stromatolites (compact layered colonies of Cyanobacteria and mud) are still with us, and can be found in certain high evaporation/high salinity coastal environments in places as Shark Bay (Western Australia), Scammon's Lagoon (Baja California), salt ponds on islands in the Sea of Cortez, the Persian Gulf, the Paracas coast of Peru, the Bahamas, and Antarctica. Living stromatolites also occur in some isolated inland waters, such as the famous Cuatro Cienegas Oasis of Chihuahua, Mexico.

The end era of the Proterozoic (the Neoproterozoic, 1 billion years ago to 541 Ma) was a different world from today. Atmospheric oxygen levels were much lower. The deep ocean was especially oxygen poor. And three ice-covered Earth events are hypothesized to have occurred during the Neoproterozoic Era, based on the occurrence of multiple glaciations at sea level in low latitudes in the geological record. These "Snowball Earth" events, which might have each lasted up to 10 million years, are thought to have been interrupted by periods of rapid warming and global greenhouse conditions. The causes of these wide climatic swings during the Neoproterozoic are still unclear although there is evidence that the world oceans lacked the $CaCO_3$-based carbon stabilization chemistry we have today. Indeed, major carbon precipitators such as foraminiferans and coccolithophores had probably not yet evolved in the world's oceans. It seems likely that buildup of atmospheric CO_2 generated by massive volcanic eruptions drove the warming events. All these changes were taking place during the breakup of a supercontinent known as Rodinia (about 750 Ma)—the supercontinent that preceded Pangaea. It was against this backdrop that the Metazoa first arose, some time between 650 million years ago and 1 billion years ago (the exact timing is still uncertain). Aroumd 800 million years ago, atmospheric oxygen seems to have stabilized at a relatively high level, setting the stage for the more rapid evolution of eukaryotes and the Bilateria. Oxygen, of course, was critical to the diversification of large and metabolically active, complex life.

The prevailing view is that Metazoa arose in the Neoproterozoic (latest Precambrian) and began to diversify, and then radiated rapidly in the Cambrian the "Cambrian explosion." However, during the Neoproterozoic these early animal lineages must have survived some extreme climate swings on Earth, including profoumd changes in ocean and atmospheric chemistry and widespread global glacial events.

The Ediacaran Period and the Origin of Animals

One of the most perplexing unsolved mysteries in biology is the origin and early radiation of Metazoa (the an-

imal kingdom). Fossil (and molecular clock) evidence suggests that by the end Proterozoic Ediacaran period, a worldwide marine invertebrate fauna was already well established. Although the animals that existed during this time left few records, the fauna of the Ediacaran (635–541 Ma) contains the first evidence of many modern phyla. Living phyla thought to be represented among the Ediacaran fauna include Porifera, Cnidaria, Mollusca, possibly Annelida (including possible echiurids and pogonophorans), and others. Some authors have even suggested the presence of Onychophora, Arthropoda, and Echinodermata, although these are controversial. The Ediacaran *Dickinsonia* has been said to represent a "placozoan grade animal," *Kimberella* may be a mollusc, *Eoandromeda* a ctenophore, and *Thectardis* a sponge (although all of these classifications are debatable). Over 100 Ediacaran animal genera have been described from around the world. However, many Ediacaran animals cannot be unambiguously assigned to any living phylum, and these animals may represent phyla or other high-level taxa that went extinct at the Proterozoic–Cambrian transition.

Ediacaran fossils were first reported from sites in Newfoundland and Namibia, but the name is derived from the superb assemblages of these fossils discovered at Ediacara in the Flinders Ranges of South Australia. Most of the Ediacaran organisms were preserved as shallow-water impressions on sandstone beds, but some of the 25 or so worldwide sites probably represent deep-water and continental slope communities. The Ediacaran fauna was mostly soft bodied, and there have been no heavily shelled creatures reported from these deposits. Even the alleged molluscs and arthropod-like creatures from this fauna are thought to have had soft (unmineralized or lightly mineralized) skeletons. A few chitinous structures developed during this time, such as the jaws of some annelid like creatures (and the chitinous sabellid like tubes of others) and the radulae of early molluscs.[5] Siliceous spicules of hexactinellid sponges have been reported from Australian and Chinese Ediacaran deposits. In 2014, Ediacaran-age metazoan reefs were discovered in Namibia that were built by skeletonized creatures named *Cloudina*. Resembling cnidarians, these are the oldest known structural reef building organisms although their phylogenetic affinities are uncertain.

Many of these Ediacaran animals appear to have lacked complex internal organ structures. Many were small and possessed radial symmetry. However, at least by the late Ediacaran, large animals with bilateral symmetry seem to have appeared, and some almost certainly had well-developed internal organs (e.g., the segmented, sheetlike *Dickinsonia*, which reached a meter in length; Figure 1.2). Some workers have questioned whether or not Ediacaran life even included any animals, suggesting that it might represent only protists, algae, fungi, lichens, and microbial colonies and mats. However, some Ediacaran fossils seem to be unmistakably Porifera and Cnidaria, and others (e.g., *Kimberella*) show strong similarity to molluscs. *Kimberella* has been associated with scratch marks reminiscent of radula scrapings. Still others are thought to possess bilateral symmetry, an idea once controversial but now gaining traction. Among the bilaterian fossils are *Kimberella*, the annelid- or arthropod-like *Spriggina*, "small shelly fossils" (e.g., the enigmatic *Cloudina*), and bilaterian embryos from the Doushantuo Formation of south China, although these bilaterian records have their detractors. Other evidence of bilaterians in these deposits include what appear to be predatory bore holes in the small shelly fossils, and a variety of horizontal and vertical burrows that were perhaps made by motile animals. An entire group of species called Proarticulata, appear to possess both segmentation and bilateral symmetry (e.g., *Dickinsonia*, *Vendia*, *Onega*, *Praecambridium*).

The beginning of the Ediacaran period coincides with the end of the last "Snowball Earth" event of the Precambrian, when most of Earth's land, and perhaps much of its ocean, was frozen over. And at the end of the Ediacaran (the end of the Precambrian) many living creatures seem to have gone extinct[6] The Ediacaran period was followed by the Cambrian period (541–485 Ma) and the great "explosion" of skeletonized metazoan life associated with that time (see below). Life quickly got very interesting and very complicated in the Cambrian! Why large, skeletonized animals appeared at that particular time, and in such great profusion, remains a mystery, but the fossil record clearly informs us that by the early Cambrian most of the major animal phyla we recognize today had come into being. Certainly, great changes were occurring at the end of the Precambrian and the start of the early Cambrian—the breakup of the supercontinents, rising sea levels, a possible nutrient crisis, fluctuations in atmospheric composition (including oxygen and CO_2 levels), changes in ocean chemistry and these likely

[5]Chitin is a cellulose like family of compounds that is widely distributed in nature, especially in invertebrates, fungi, and many protists, but it is apparently uncommon in deuterostome animals and higher plants, perhaps due to the absence of the chitin synthase enzyme.

[6]The largest mass extinctions recorded in the fossil record occurred at the ends of the Precambrian (the Ediacaran–Cambrian transition), Ordovician, Devonian, and Permian, and in the Early Triassic, Late Triassic, and end-Cretaceous. Most of these extinction events were experienced by both marine and terrestrial organisms. The Triassic events and the end Devonian event have recently been shown to be less severe extinction events than once thought. And a relatively little-studied mass extinction event in the late Permian, about 260 million years ago, has recently begun to emerge as a much larger extinction event than previously thought, with perhaps 56% of plant species and 58% of marine invertebrate genera disappearing.

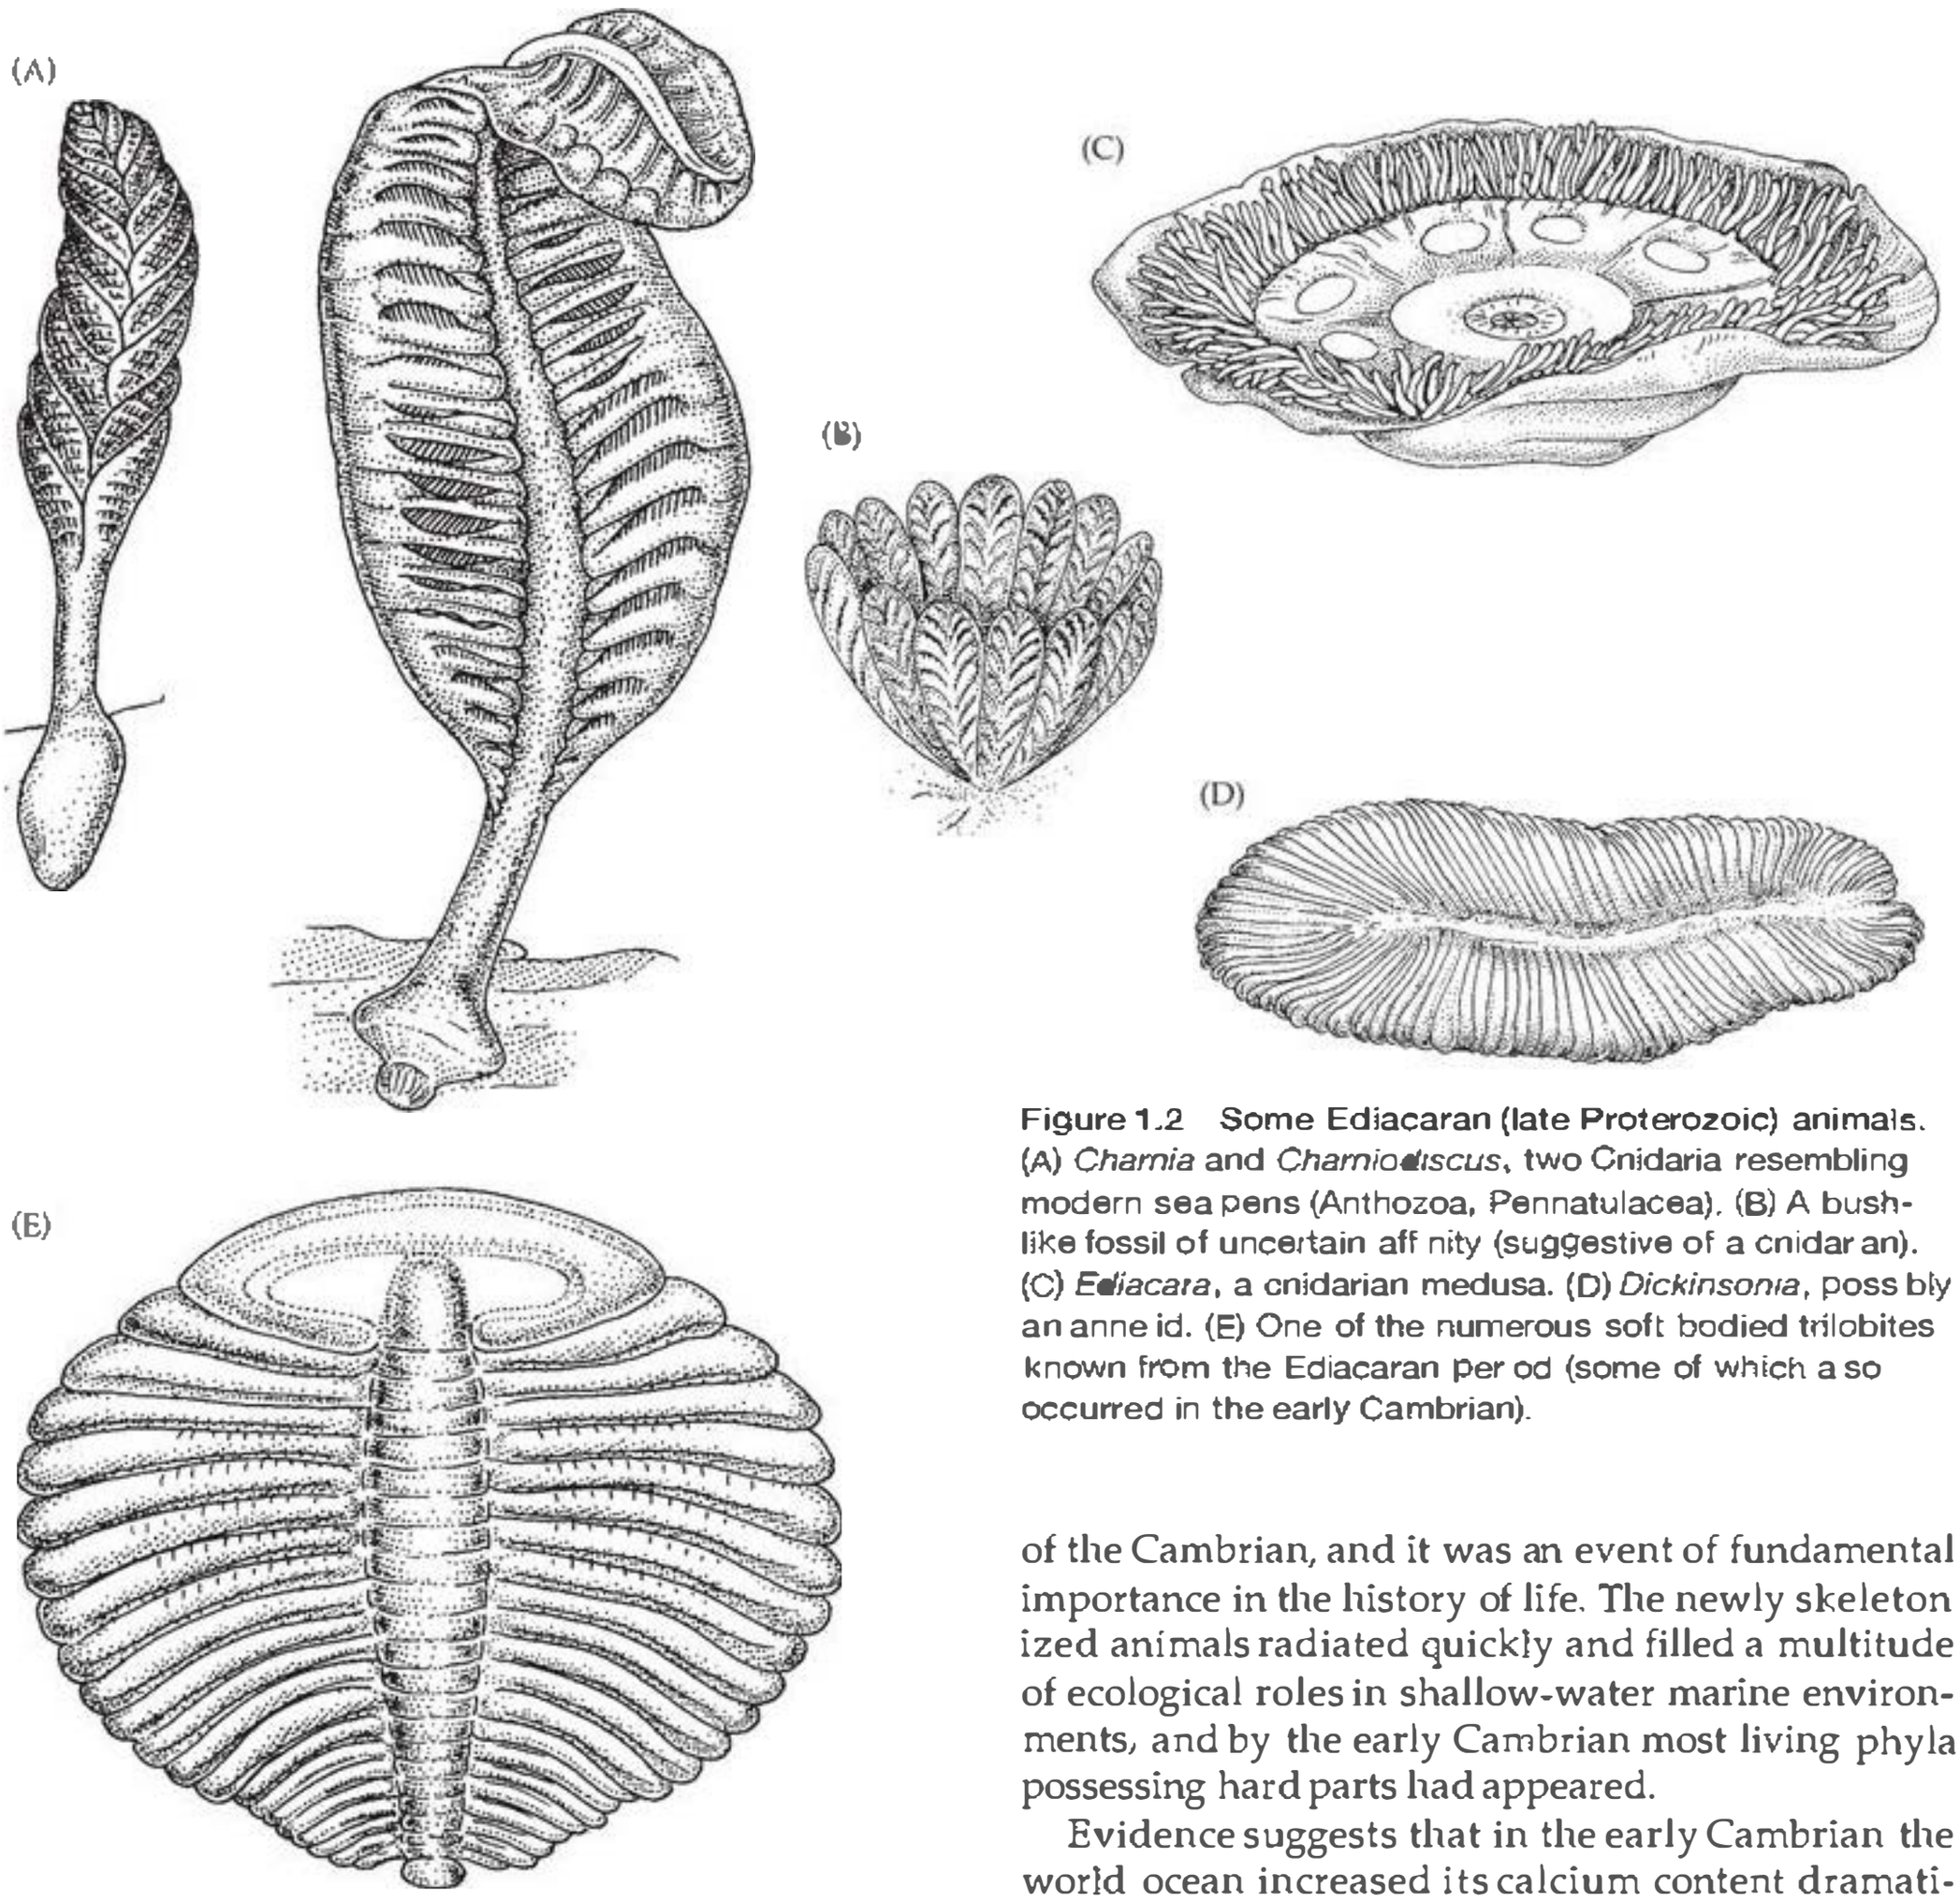

Figure 1.2 Some Ediacaran (late Proterozoic) animals. (A) *Charnia* and *Charniodiscus*, two Cnidaria resembling modern sea pens (Anthozoa, Pennatulacea). (B) A bush-like fossil of uncertain affinity (suggestive of a cnidarian). (C) *Ediacara*, a cnidarian medusa. (D) *Dickinsonia*, possibly an annelid. (E) One of the numerous soft bodied trilobites known from the Ediacaran period (some of which also occurred in the early Cambrian).

played a role the demise of the Ediacaran fauna and the rise of Cambrian life.

The Paleozoic Era (541–252 Ma)

The Phanerozoic eon (the time of abundant life on Earth that encompasses the Paleozoic, Mesozoic and Cenozoic eras) was ushered in with the almost simultaneous appearance in the lower Cambrian of well-developed, large, calcareous body skeletons in numerous groups, such as archaeocyathans (coral like organisms that were probably early sponges), molluscs, bryozoans, brachiopods, crustaceans, and trilobites. Shelled animals (molluscs, etc.) first appear among the "small shelly fossils" of the earliest Cambrian, and chaetognaths (represented by protoconodonts) are known from the same period. The appearance of well-mineralized animal skeletons thus defines the beginning of the Cambrian, and it was an event of fundamental importance in the history of life. The newly skeletonized animals radiated quickly and filled a multitude of ecological roles in shallow-water marine environments, and by the early Cambrian most living phyla possessing hard parts had appeared.

Evidence suggests that in the early Cambrian the world ocean increased its calcium content dramatically, which coincided with a proliferation of skeletonized animals. Climates were warm, and shallow epicontinental seas covered broad regions of Paleozoic continents. The explosion of bilaterally symmetrical animals, the Bilateria, also began around the Proterozoic-Cambrian transition. Seed ferns and other gymnosperms also arose during the Paleozoic, perhaps about 400 million years ago, whereas angiosperms may have arisen around 200 million years ago, as suggested by molecular data (although the oldest undisputed angiosperm fossils arose about 130 Ma).

Did all these metazoan lineages arise quickly, during the first 10 million years or so of the Cambrian? Or were many (or most) of them already getting established in the Ediacaran, but we have yet to find evidence of this, perhaps because they lacked hard skeletons or were very small. This latter idea, sometimes called the "phylogenetic fuse" hypothesis, is supported by the discovery

of undisputed and modern appearing crustaceans in the earliest Cambrian, as well as many creatures from the Ediacaran that resemble modern phyla. Given that advanced phyla like arthropods were already well established in the earliest Cambrian, it seems likely that earlier derived phyla of ecdysozoans must have been alive and well during the Ediacaran. Indeed, apparent phosphatized bilaterian animal embryos from the Ediacaran provide evidence of the cryptic roots of Metazoa and the likelihood that the evolutionary fuse of modern animal phyla was lit well before the Cambrian began. A recent, large phylogenetic analysis by Omar Rota-Stabelli and colleagues used 67 fossil calibration points to date a molecular timetree of ecdysozoan phyla, concluding that the clade originated in the Ediacaran.

Geological evidence tells us that Earth's earliest atmosphere lacked free oxygen, and the radiation of the animal kingdom could not have begun under those conditions. Free oxygen probably accumulated over many millions of years as a by product of photosynthetic activity in the oceans, particularly by the cyanobacterial (blue-green algae) stromatolites. A long-standing hypothesis suggests that the beginning of an oxygenated atmosphere was around 2.4 billion years ago, and it was then that "modern life" began to evolve (at the beginning of the Proterozoic). However, evidence for free oxygen levels in the Proterozoic is still unclear, and there are some data that suggest an oxygenated atmosphere might have evolved even earlier than that. Proterozoic seas might have been oxic near the surface, but anoxic in deep waters and on the bottom. Some workers suggest that the absence of metazoan life in the early fossil record is due to the simple fact that the first animals were small, lacked skeletons, and did not fossilize well. The discovery of highly diverse communities of metazoan meiofauna in the Proterozoic strata of south China and in deposits from the middle and upper Cambrian (e.g., the Swedish Orsten fauna) lends support to the idea that many of the first animals were microscopic.[7] However, large animals also are not uncommon among the Ediacaran and early Cambrian faunas.

It has also been proposed that the advent of predatory lifestyles, early in the Cambrian, was the key that favored the first appearance of animal skeletons (as defensive structures), leading to the "Cambrian explosion." The rapid appearance and spread of diverse metazoan skeletons in the early Cambrian certainly heralded the beginning of the Phanerozoic (i.e., all time after the Precambrian; the Paleozoic Mesozoic Cenozoic eras). The Ediacaran fauna seems to have included primarily passive suspension and detritus feeders; very few of these animals appear to have been active carnivores or herbivores. Early Cambrian animal communities, on the other hand, included most of the trophic roles found in modern marine communities, including giant predatory arthropods.

Much of what we know about earliest Cambrian life comes from the lower Cambrian Chengjiang fossil deposits of the Yunnan Province in southern China, and similarly aged (although less well preserved) deposits spread across China and the Siberian Platform. The Chengjiang deposits are the oldest Cambrian occurrences of well preserved soft bodied and hard bodied animals, and although they are dominated by arthropods they also include a rich assemblage of exquisitely preserved onychophorans, medusae (Cnidaria), and brachiopods, many of which appear closely related to Ediacaran species.

In the middle Cambrian (e g , the Burgess Shale fauna of western Canada and similar deposits elsewhere; Figures 1 3 and 1.4), annelids and tardigrades made their first positive appearance in the fossil record, and the first complete echinoderm skeletons appear. Twelve million years younger than the Chengjiang fauna, the Burgess Shale material is also dominated by arthropods (and their allies), including the infamous *Opabinia* and *Anomalocaris*. Most of the Burgess Shale fauna can also be assigned to living phyla. There are numerous other (less famous) Cambrian fossil sites, such as the Sirius Passet fauna in Greenland, the Emu Bay Shale in Australia, the Sinsk biota in Russia, and the Kaili and Guanshan biotas in China. In the upper Cambrian (e g., the Orsten deposits of southern Sweden and similar strata), the first pentastomid Crustacea and the first agnathan fishes make their appearances. By the end of the Cambrian, nearly all of the major, modern animal phyla had appeared. The Burgess Shale-like assemblage in Lower Ordovician rocks of Morocco tells us that many of the Cambrian lineages survived for tens of millions of years (Figure 1.4).

The driving force for this Cambrian explosion has perplexed scientists since Darwin's day. In fact, it has been referred to as "Darwin's dilemma," because he could not reconcile such rapid origination and diversification of major animal groups with his view of gradual evolution driven only by natural selection. Some analyses have suggested that rates of phenotypic and genomic evolution might have been many times faster during the Cambrian than in the rest of the Paleozoic. One popular notion is that atmospheric oxygen reached a critical level around 580 million years ago, in the Ediacaran, that allowed for larger animals and skeletonized animals to begin to evolve. This might have led to the appearance of large carnivores, which rely on oxygen for high-energy pursuits. Once the carnivores

[7] "Orsten"-type preservation entai s the phosphatization of cuticles with almost no deformation. It preserves the finest details of organisms, ncluding setae, and such deposits have yielded three dimensional fossils at the scale of 0 120 mm. First discovered in Sweden, Orsten-type deposits are now known from several continents, from the early Cambrian (520 Ma) to the middle Cretaceous (100 Ma). Most of the earliest "Orsten fossils" are undisputed arthropods

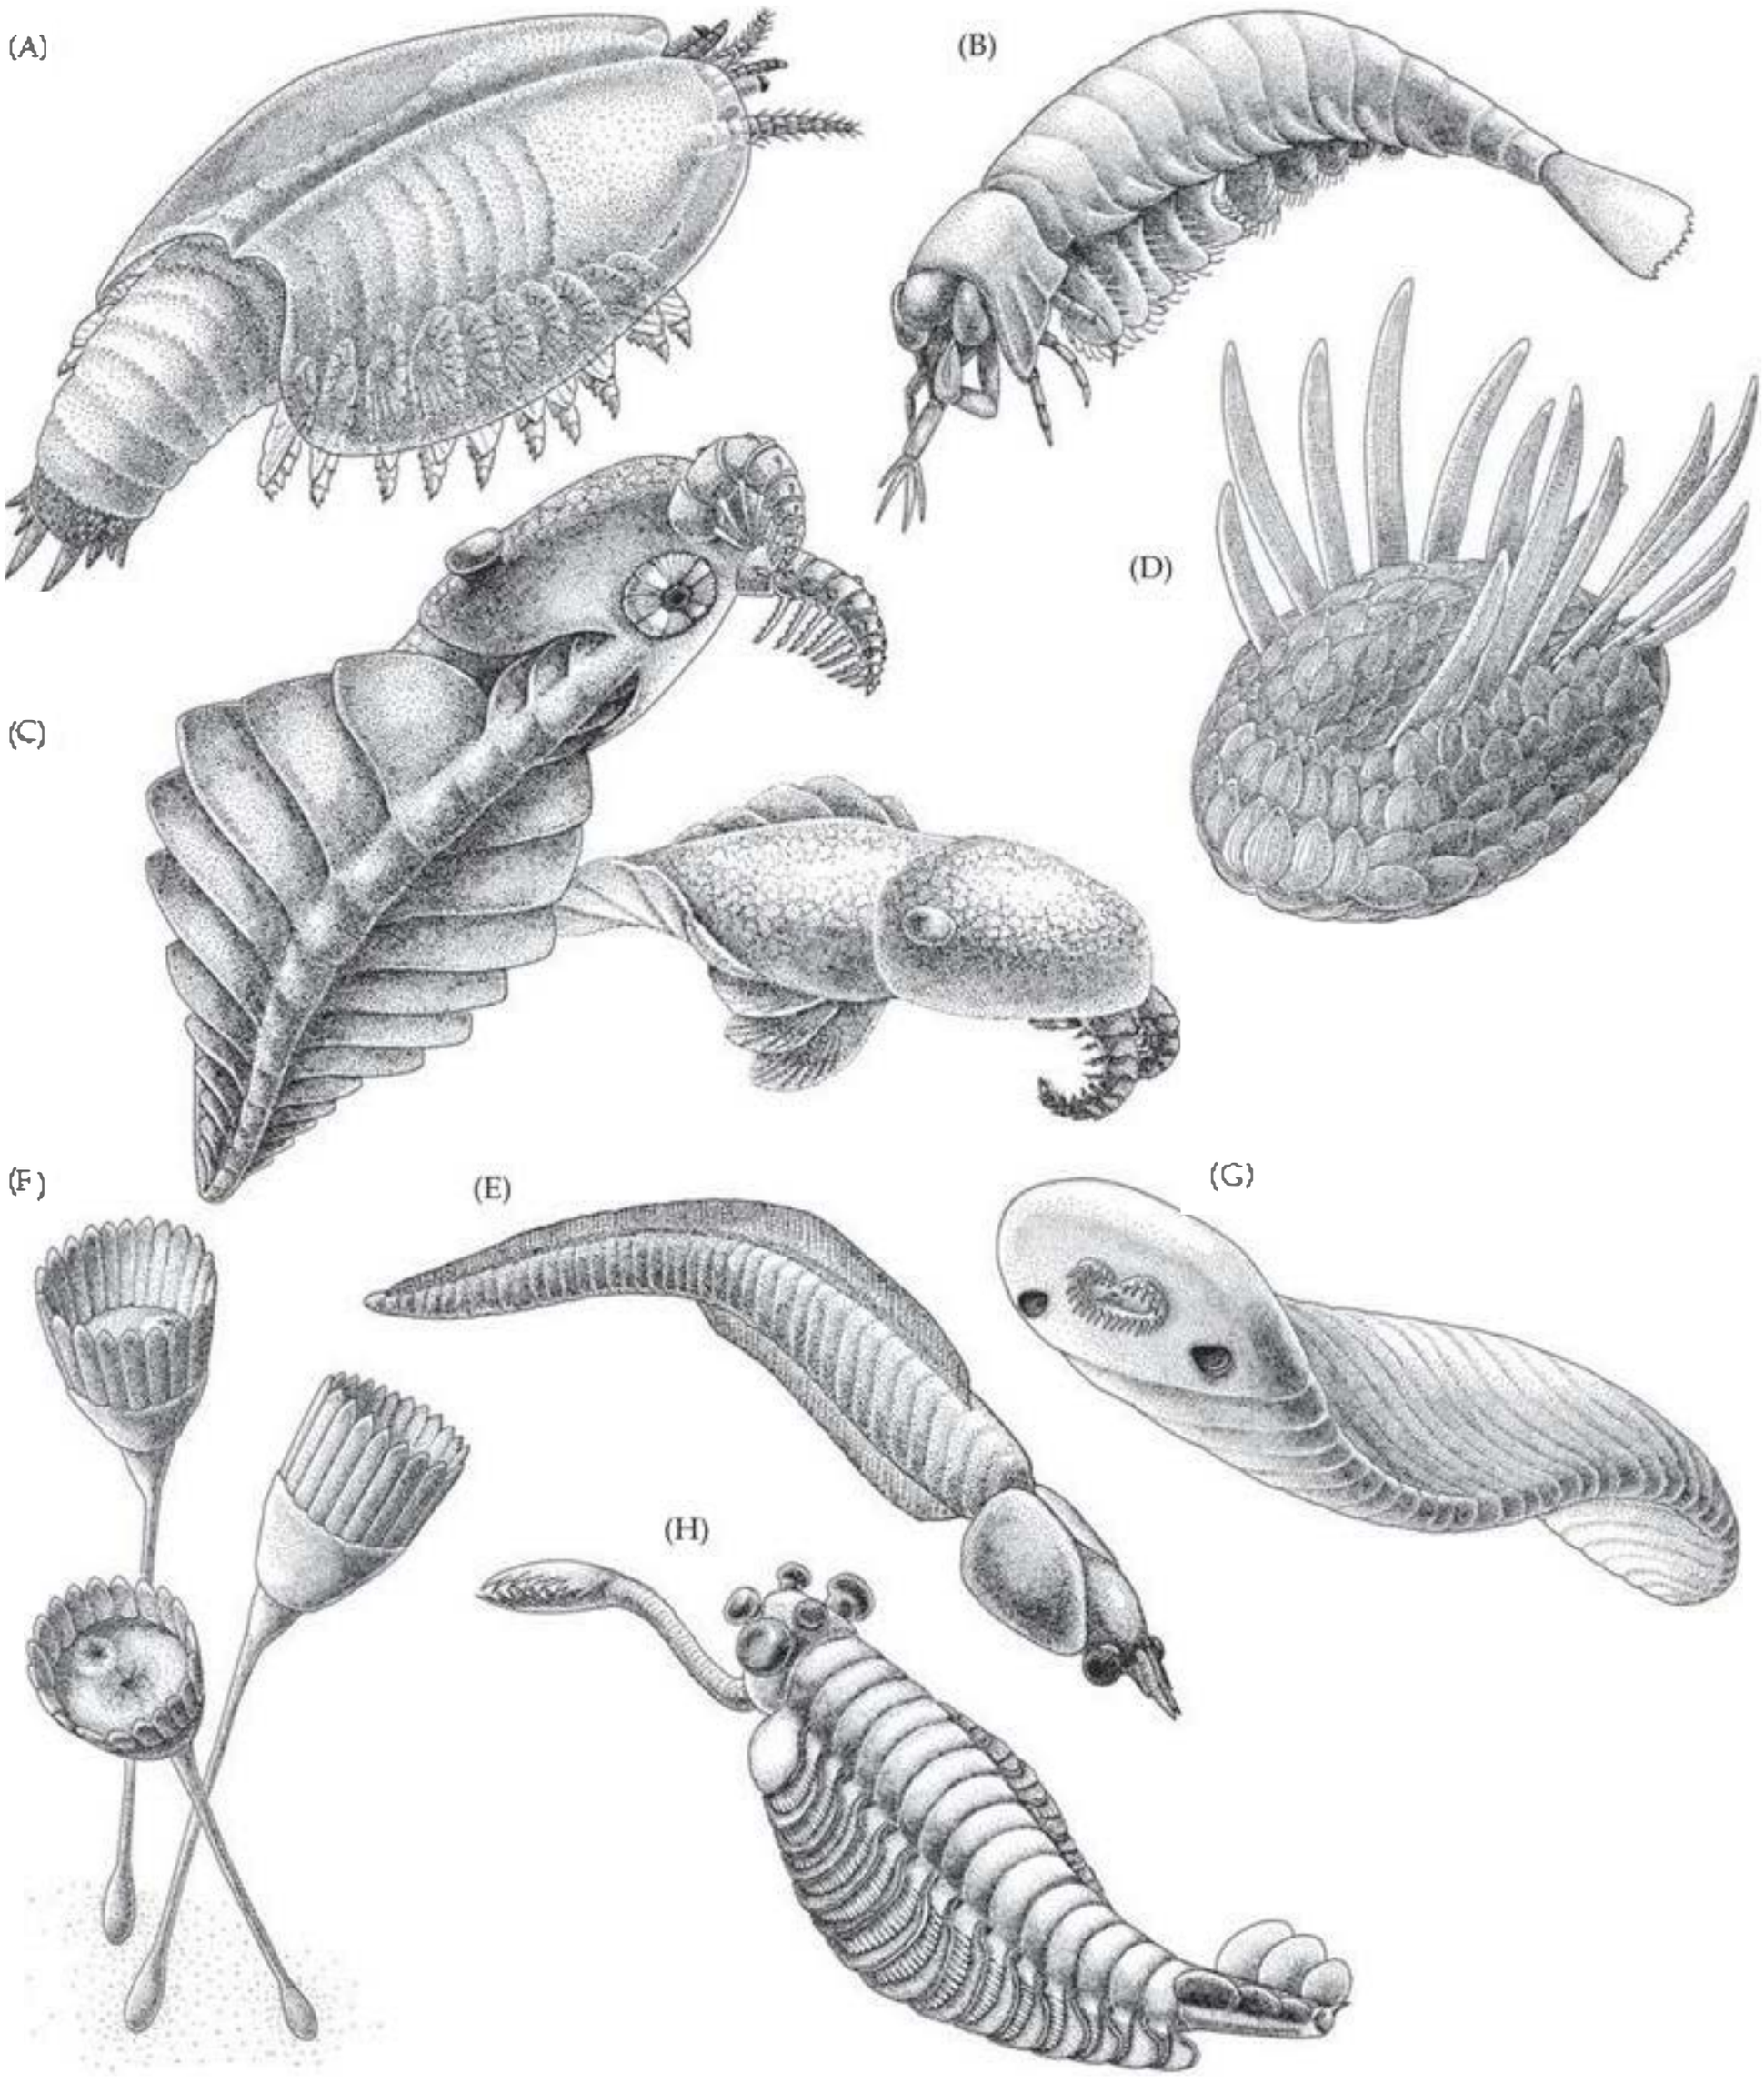

Figure 1.3 Some Cambrian life forms from the Burgess Shale deposits of Canada. (A) *Canadaspis*, an early malacostracan crustacean. (B) *Yohoia*, an arthropod of uncertain classification. (C) Two species of *Anomalocaris*, *A. nathorsti* (above) and *A. canadensis*. Anomalocarids were once thought to represent an extinct phylum of segmented animals, but are now regarded by many workers as primitive arthropods dating back to the Ediacaran. (D) *Wiwaxia*, a Burgess Shale animal with no clear affinity to any known metazoan phylum (although some workers regard it as a free-living annelid). (E) *Nectocaris*, another creature that has yet to be classified into any known phylum (despite its strong chordate like appearance). (F) *Dinomischus*, a stalked creature with a U shaped gut and with the mouth and anus both placed on a radially symmetrical calyx. Although superficially resembling several extant phyla, *Dinomischus* is now thought to belong to an unnamed extinct phylum of sessile Cambrian animals. (G) The elusive *Odontogriphus*, an appendageless flattened vermiform creature of unknown affinity (H) One of the more enigmatic of the Burgess Shale animals, *Opabinia*; this segmented creature was probably an ancestral arthropod. Notice the presence of five eyes, a long prehensile "nozzle," and gills positioned dorsal to lateral flaps.

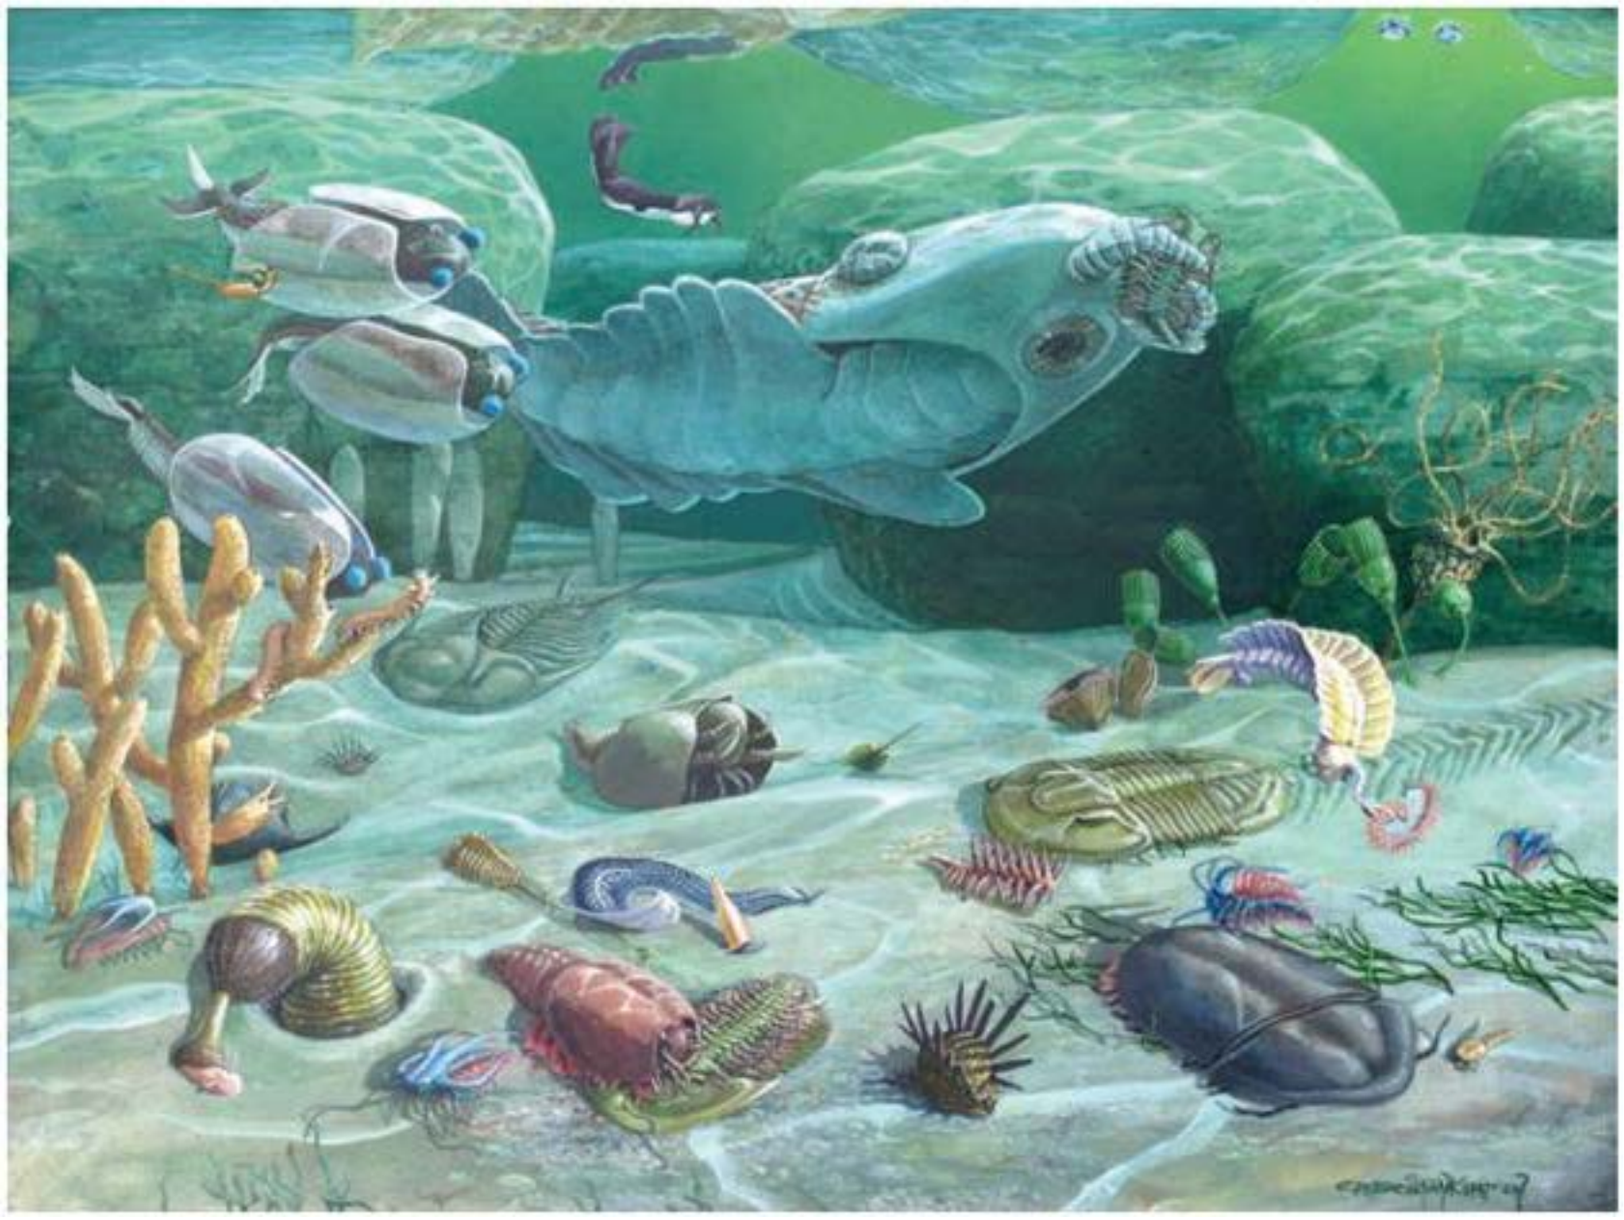

Figure 1.4 "Fauna of the Burgess Shale," Carel Brest von Kempen. Acrylic on illustration board. Depicted are stromatolites, *Leptomitus, Vauxia, Billingsella Hallucigenia Aysheaia, Anomalocaris, Opabinia, Leiopyge, Olenoides, Asaphiscus, Elrathia, Modocia, Naraoia, Habellia, Burgessia, Plenocaris, Sarotrocercus, Odaraia, Pseudoarctolepis, Canadaspis, Marrella, Branchiocaris, Ottoia, Hyolithes, Canadia Gogia, Pikaia, Wiwaxia, Dinomischus,* and *Amiskwia*.

proliferated, a predator–prey arms race ensued, driving the rapid evolution of never-ending new body forms. However, some other evidence suggests that high oxygen levels existed well before that date.

Another explanation for the explosive radiation of Metazoa in the Cambrian is a rapid increase in nutrient supplies to the world's oceans, especially phosphorus (P) and potassium (K). This is hypothesized to have occurred as the Earth cooled enough for subducting mantle to hydrate with seawater about 600 million years ago, thus moving water from the oceans into the lower mantle and lowering sea level, which in turn exposed great swaths of new landmasses that underwent erosion of P and K, which in turn were transported to the sea as fertilizers. In addition, massive uplift of mountains and plume driven dome up of landmasses also might have added new nutrient erosion sources around the Precambrian-Cambrian transition.

The early Paleozoic also saw the first xiphosurans, eurypterids, trees, and teleost fishes (in the Ordovician). The first land animals (arachnids, centipedes, myriapods) appeared in the Upper Silurian. By the middle Paleozoic (the Devonian period), life on land had begun to proliferate. Forest ecosystems became established and began reducing atmospheric CO_2 levels (eventually terminating an earlier Paleozoic greenhouse environment). The first insects also appeared in the early Paleozoic era (see chapter 22). Insects probably developed flight in the Early Devonian (~406 million years ago), and they began their long history of coevolution with plants shortly thereafter (at least by the mid-Carboniferous, when tree fern galls first appeared in the fossil record).[8] During the Carboniferous period, global climates were generally warm and humid, and extensive coal producing swamps existed.

The late Paleozoic witnessed the formation of Earth's most recent supercontinent Pangaea, in the Permian period (about 270 Ma). The end of the Paleozoic era/Permian period (252 Ma) was marked by the largest mass extinction known, in which about 90% of Earth's marine species (and 70% of the terrestrial vertebrate genera) were lost over a brief span of a few million years. The Paleozoic reef corals (Rugosa and Tabulata) went extinct, as did the once dominant trilobites, never to be seen again. The driving force of the massive Permian extinction is a hotly debated subject, and hypotheses range from rapid global warming to rapid global cooling! Either might have been driven by a huge asteroid impact, perhaps coupled with

[8]Coevolution is the reciprocal adaptation that occurs over time between closely interacting species. One classic example is plants and their pollinators, which have evolved in lockstep since the late Paleozoic era to form remarkably finely tuned anatomies, physiologies, and behaviors, among willing (or unwilling) partners.

massive Earth volcanism, and perhaps also degassing of methane from stagnant ocean basins. Evidence suggests that toxic waters decimated shallow bottom marine communities at that time. All of these might have created a large and rapid global warming (or cooling) event, depending on how things played out. The trillions of tons of carbon released into the atmosphere and oceans from enormous volcanism likely also led to ocean acidification and a drop in dissolved oxygen in the oceans, further possible causes of oceanic extinction events. This volcanism was likely the one that created the massive flood basalts known as the Siberian Traps in Asia, an event coincident in time that could have led to atmospheric "pollution" in the form of dust and sulfur particles that cooled Earth's surface and/or massive gas emissions that led to a prolonged greenhouse warming and ocean acidification.

The Mesozoic Era (252–66 Ma)

The Mesozoic era is divided into three broad periods: the Triassic, Jurassic, and Cretaceous. The Triassic began with the continents joined together as Pangaea. The land was high, and few shallow seas existed. Global climates were warm, and deserts were extensive. Although the Triassic is perhaps best known for the emergence of the dinosaurs, vertebrate diversity in general exploded during this period, as the first land mammals made their appearance. In Triassic seas, modern looking scleractinian corals appeared, and the diversity of predatory invertebrates and fishes increased dramatically, although the paleogeological data suggest that deeper marine waters might have been too low in oxygen to harbor much (or any) multicellular life. The end of the Triassic witnessed a global extinction event that resulted in the disappearance of around half of all the living species. This was perhaps driven by the combination of asteroid impact and widespread volcanism that created the Central Atlantic Magmatic Province of northeastern South America 200 million years ago, although there is considerable disagreement about the extent and cause of this extinction event. Recent studies suggest elevated atmospheric CO_2 was the culprit behind the end-Triassic extinction event, possibly caused by high rates of magmatic CO_2 degassing.

The Jurassic saw a continuation of warm, stable climates, with little latitudinal or seasonal variation and probably little mixing between shallow and deep oceanic waters. Pangaea split into two large landmasses, a northern Laurasia and southern Gondwana, separated by a circumglobal tropical seaway known as the Tethys Sea. Many tropical marine families and genera today are thought to be direct descendants of inhabitants of the pantropical Tethys Sea. On land, modern genera of many gymnosperms and advanced angiosperms appeared, and the first birds begin to evolve (*Archaeopteryx*, ~150 Ma). Leaf-mining insects (lepidopterans) appeared by the late Jurassic (150 Ma), and other leaf mining orders appeared through the Cretaceous, coincident with the radiation of the vascular plants.

In the Cretaceous, large-scale fragmentation of Gondwana and Laurasia took place, resulting in the formation of the Atlantic and Southern Oceans. During this period, landmasses subsided and sea levels were high; the oceans sent their waters far inland, and great epicontinental seas and coastal swamps developed. As land masses fragmented and new oceans formed, global climates began to cool and oceanic mixing began to move oxygenated waters to greater depths in the sea. The oldest fossil of modern birds dates from the early Cretaceous (*Archaeornithura meemannae*, ~130 Ma).

The end of the Cretaceous was marked by the Cretaceous Paleocene mass extinction, in which an estimated 50% of Earth's species were lost, including the (nonavian) dinosaurs and all of the sea's rich Mesozoic ammonite diversity. There is strong evidence that this extinction event was driven by a combination of two factors: massive Earth volcanism associated with the great flood basalts of western India known as the Deccan Traps, combined with a major asteroid impact (documented by the Chicxulub Crater in the Yucatán region of modern Mexico). The Deccan Traps flood basalts comprise an almost unimaginable 1.3 million cubic kilometers of erupted lava, 3,000 m thick in some places. The main eruptions initiated about 250,000 years before the Cretaceous-Paleocene boundary, and overall the lava flowed for over 750,000 years. However, an estimated 90% of the eruptive flow took place rapidly, over less than 1 million years, coincident with the Cretaceous Paleocene boundary. The sulfur dioxide gas injected into the atmosphere from this massive volcanic event would have converted to sulfate aerosols that caused climate cooling, and when these aerosols washed out (as acid rain) they would have acidified the oceans. The scale of biological turnover between the Cretaceous and Paleocene is nearly unprecedented in Earth history. All the nonavian dinosaurs, marine reptiles, ammonites, and rudistid clams went extinct. Planktonic foraminiferans and land plants were devastated. There is recent evidence suggesting that the full strength of the end-Cretaceous mass extinctions might not have kicked in until about 300,000 years after the Chicxulub impact. If comet impacts are beginning to sound like a recurring theme in the history of life on Earth, it's because so many large impact craters have been found (at least 70 that are larger than 6 km in diameter), and many of these coincide with major transitions in the fossil record.

The Cenozoic Era (66 Ma–present)

The Cenozoic era dawned with a continuing worldwide cooling trend. As South America decoupled from Antarctica, the Drake Passage opened to initiate the circum-Antarctic current, which eventually drove the for-

mation of the Antarctic ice cap, which in turn led to our modern cold ocean bottom conditions (in the Miocene). India moved north from Antarctica and collided with southern Asia (in the early Oligocene). Africa collided with western Asia (late Oligocene/early Miocene), separating the Mediterranean Sea from the Indian Ocean and breaking up the circumtropical Tethys Sea. Around 56 million years ago, the Earth warmed rapidly as greenhouse gasses spiked in the atmosphere and global oceans warmed all the way down to the deep sea. The cause of this Paleocene-Eocene Thermal Maximum is uncertain, but massive volcanic eruptions that could have cooked CO_2 out of organic seafloor sediments have been suggested, as have wildfires burning through Paleocene peat deposits, and a comet impact (that could have released large deposits of methane hydrate from the seafloor). Relatively recently (in the Pliocene), the Arctic ice cap formed, and the Panama isthmus rose, separating the Caribbean Sea from the Pacific and breaking up the last remnant of the ancient Tethys Sea about 3 million years ago (although recent work has proposed a much earlier date for the closure of the Panama Seaway, perhaps 15–13 Ma). Modern coral reefs (scleractinian based reefs) appeared early in the Cenozoic, reestablishing the niche once held by the rugose and tabulate corals of the Paleozoic.

This textbook focuses primarily on invertebrate life at the very end of the Cenozoic, in the Quaternary period (Pleistocene + Holocene). However, evaluation of the present day success of animal groups also involves consideration of the deeper history of modern lineages, the diversity of life over time (numbers of species and higher taxa), and the abundance of life in various environments. The predominance of certain kinds of invertebrates today is unquestionable. For example, of the 1,382,402 or so described species of animals (1,324,402 of which are invertebrates), 81.5% are arthropods (and 82% of those are insects). It would be hard to argue that insects are not the most successful group of animals on Earth today. And the fossil record tells us that arthropods have always been key players in the biosphere, even before the appearance of the insects. Table 1.1 conveys a general idea of the levels of diversity among the animal phyla today.

Where Do Invertebrates Live?

Marine Habitats

The global ocean is Earth's largest biome. In fact, it can be said that Earth is a marine planet—salt water covers 71% of its surface. The vast three dimensional world of the seas contains 99% of Earth's inhabited space. Life almost certainly evolved in the sea, and the major events described above leading to the diversification of invertebrates occurred in late Proterozoic and early Cambrian shallow seas. Many aspects of the marine world minimize physical and chemical stresses on organisms. The challenge of evolving gas exchange and osmotic regulatory structures that can function in freshwater and terrestrial environments are formidable, and relatively few lineages were able to do so and escape their marine origins. Thus, is not surprising to find that the marine environment continues to harbor the greatest diversity of higher taxa and major body plans—14 of the 32 living animal phyla are strictly marine (e g , Placozoa, Ctenophora, Chaetognatha, Rhombozoa, Orthonectida, Cycliophora, Gnathostomulida, Phoronida, Brachiopoda, Kinorhyncha, Priapula, Loricifera, Echinodermata, Hemichordata) and many others have barely penetrated the terrestrial or freshwater realm. Productivity in the world's oceans is very high, and this also probably contributes to the high diversity of animal life in the sea (the total primary productivity of the seas is about 48.7×10^9 metric tons of carbon per year). Perhaps the most significant factor, however, is the special nature of seawater itself.

Water is a very efficient thermal buffer. Because of its high heat capacity, it is slow to heat up or cool down. Large bodies of water, such as oceans, absorb and lose great amounts of heat with little change in actual water temperature. In fact, the oceans store over 90% of the excess heat accumulating in the world's atmospheric climate system today. Thus, oceanic temperatures are very stable in comparison with those of freshwater and terrestrial environments. Short-term temperature extremes occur only in intertidal and estuarine habitats, and invertebrates living in such areas must possess behavioral and physiological adaptations that allow them to survive these temperature changes, which are often combined with aerial exposure during low tide periods.

The saltiness, or salinity, of seawater averages about 3.5% (usually expressed as parts per thousand, 35‰). This property, too, is quite stable, especially in areas away from shore and the influence of freshwater runoff. The salinity of seawater gives it a high density, which enhances buoyancy, thereby minimizing energy expenditures for flotation. Furthermore, the various ions that contribute to the total salinity occur in fairly constant proportions. These qualities result in a total ionic concentration in seawater that is similar to that in the body fluids of most animals, minimizing the problems of osmotic and ionic regulation (see Chapter 4). The pH of seawater is also quite stable throughout most of the ocean. Naturally occurring carbonate compounds participate in a series of chemical reactions that buffer seawater at about pH 7.5–8.5. However, today's anthropogenic-driven increase in atmospheric CO_2 threatens to alter the carbonate buffering capacity of the world's seas. A large fraction (over 25%) of the CO_2 added to the atmosphere by burning of fossil fuels enters the ocean. Seawater reacts with CO_2 to form carbonic acid, decreasing the pH of ocean surface waters.

The lowering of sea surface pH disrupts formation of calcium carbonate skeletons in both animals and protists.

In shallow and nearshore waters, CO_2, various nutrients, and sunlight are generally available in quantities sufficient to allow high levels of photosynthesis, either seasonally or continuously (depending on latitude and other factors). Dissolved oxygen levels rarely drop below those required for normal respiration, except in stagnant waters such as might occur in certain estuarine or ocean basin habitats, or where anthropogenic activities have created eutrophic conditions that can result in oxygen minimum zones (OMZs), hypoxic regions, or even anoxic sea floor conditions. Hypoxia occurs when dissolved oxygen falls below <2 ml of O_2/liter. The size and number of OMZs, defined by O_2 concentrations below 20 μM and sometimes called "dead zones," in the world oceans have been growing rapidly in recent decades as a result of humans releasing huge quantities of organic waste and fertilizers into the sea. Deep sea ecosystems contain the largest hypoxic and anoxic regions of the Biosphere. Permanently anoxic conditions in the oceans are present in the subsurface seafloor and, among other areas, in the interior of the Black Sea[*] and in the deep (>3,000 m) hypersaline anoxic basins of the Mediterranean Sea, where it has long been thought that no metazoans could live. However, recently several species of Loricifera were discovered living in the anoxic Mediterranean basins (perhaps the only animals able to live permanently in anoxic conditions).

Because the marine realm is home to most of the animals discussed in this book, some terms that describe the subdivisions of that environment and the categories of animals that inhabit them will be useful. Figure 1.5 illustrates a generalized cross section through an ocean. The shoreline marks the littoral region, where sea, air, and land meet and interact (Figure 1.6A). Obviously, this region is affected by the rise and fall of the tides, and we can subdivide it into zones or shore elevations relative to the tides. The **supralittoral zone**, or splash zone, is rarely covered by water, even at high tide, but it is subjected to storm surges and spray from waves The **eulittoral zone**, or true intertidal zone, lies between the levels of the highest and lowest tides. It can be subdivided by its flora and fauna, and by mean monthly hours of aerial exposure, into high, mid-, and low intertidal zones. The **sublittoral zone**, or subtidal zone, is never uncovered, even at very low tides, but it is influenced by tidal action (e.g., by changes in turbulence, turbidity, and light penetration).

Organisms that inhabit the world's littoral regions are subjected to dynamic and often demanding conditions, and yet these areas commonly are home to exceptionally high numbers of species. Most animals and plants are more or less restricted to particular elevations along the shore, a condition resulting in the phenomenon of zonation. Such zones are visible as distinct bands or communities of organisms along the shoreline. The upper elevational limit of an intertidal organism is commonly established by its ability to tolerate conditions of exposure to air (e.g., desiccation, temperature fluctuations), whereas its lower elevational limit is often determined by biological factors (competition with or predation by other species). There are, of course, many exceptions to these generalizations.

Extending seaward from the shoreline is the **continental shelf**, a feature of most large landmasses. The continental shelf may be only a few kilometers wide, or it may extend up to 1,000 km from shore (50 to 100 km is average for most areas). It usually reaches a depth of 150200 m. These nearshore shelf areas are among the most productive environments of the ocean, being rich in nutrients and shallow enough to permit photosynthesis from surface to sea floor

The outer limit of the continental shelf—called the **continental edge** is indicated by a relatively sudden increase in the steepness of the bottom contour. The "steep" parts of the ocean floor, the **continental slopes**, actually have slopes of only 4–6% (although the slope is much steeper around volcanic islands). The continental slope continues from the continental edge to the deep ocean floor, which forms the expansive, relatively flat **abyssal plain**. The abyssal plain is an average of about 4 km below the sea's surface, but it is interrupted by a variety of ridges, seamounts, mountain ranges, trenches, and other formations. The bottoms of some deep-sea trenches exceed 10 km in depth.

Organisms that inhabit the water column are known as **pelagic organisms**, whereas those living on the sea bottom anywhere along the entire contour shown in Figure 1.5 are referred to as **benthic organisms**. Organisms living *near* the seafloor are **demersal**. Both the variety and the abundance of life tend to decrease with increasing depth, from the rich littoral and continental shelf environments to the deep abyssal plain. However, an overgeneralization of this relationship can be misleading. For example, although pelagic biomass declines exponentially with depth, both diversity and biomass increase again near the bottom, in a thick layer of resuspended sediments called the **benthic boundary layer**. Also, shelf and slope habitats in temperate regions are often characterized by low animal density but high species diversity. In many areas, benthic diversity increases abruptly below the continental edge (100 300 m depth), peaks at 1,000 to 2,000 m depth, and then decreases gradually. Species diversity in the benthic abyssal region itself may be surprisingly high. The first impression of early marine scientists—that the deep seabed was an environment able to sustain only a

[*]Despite its large surface area (423,500 km^2), the Black Sea has only a thin surface layer that supports eukaryotic life The water mass below about 175 m is devoid of dissolved oxygen making this the largest anoxic body of water in the world.

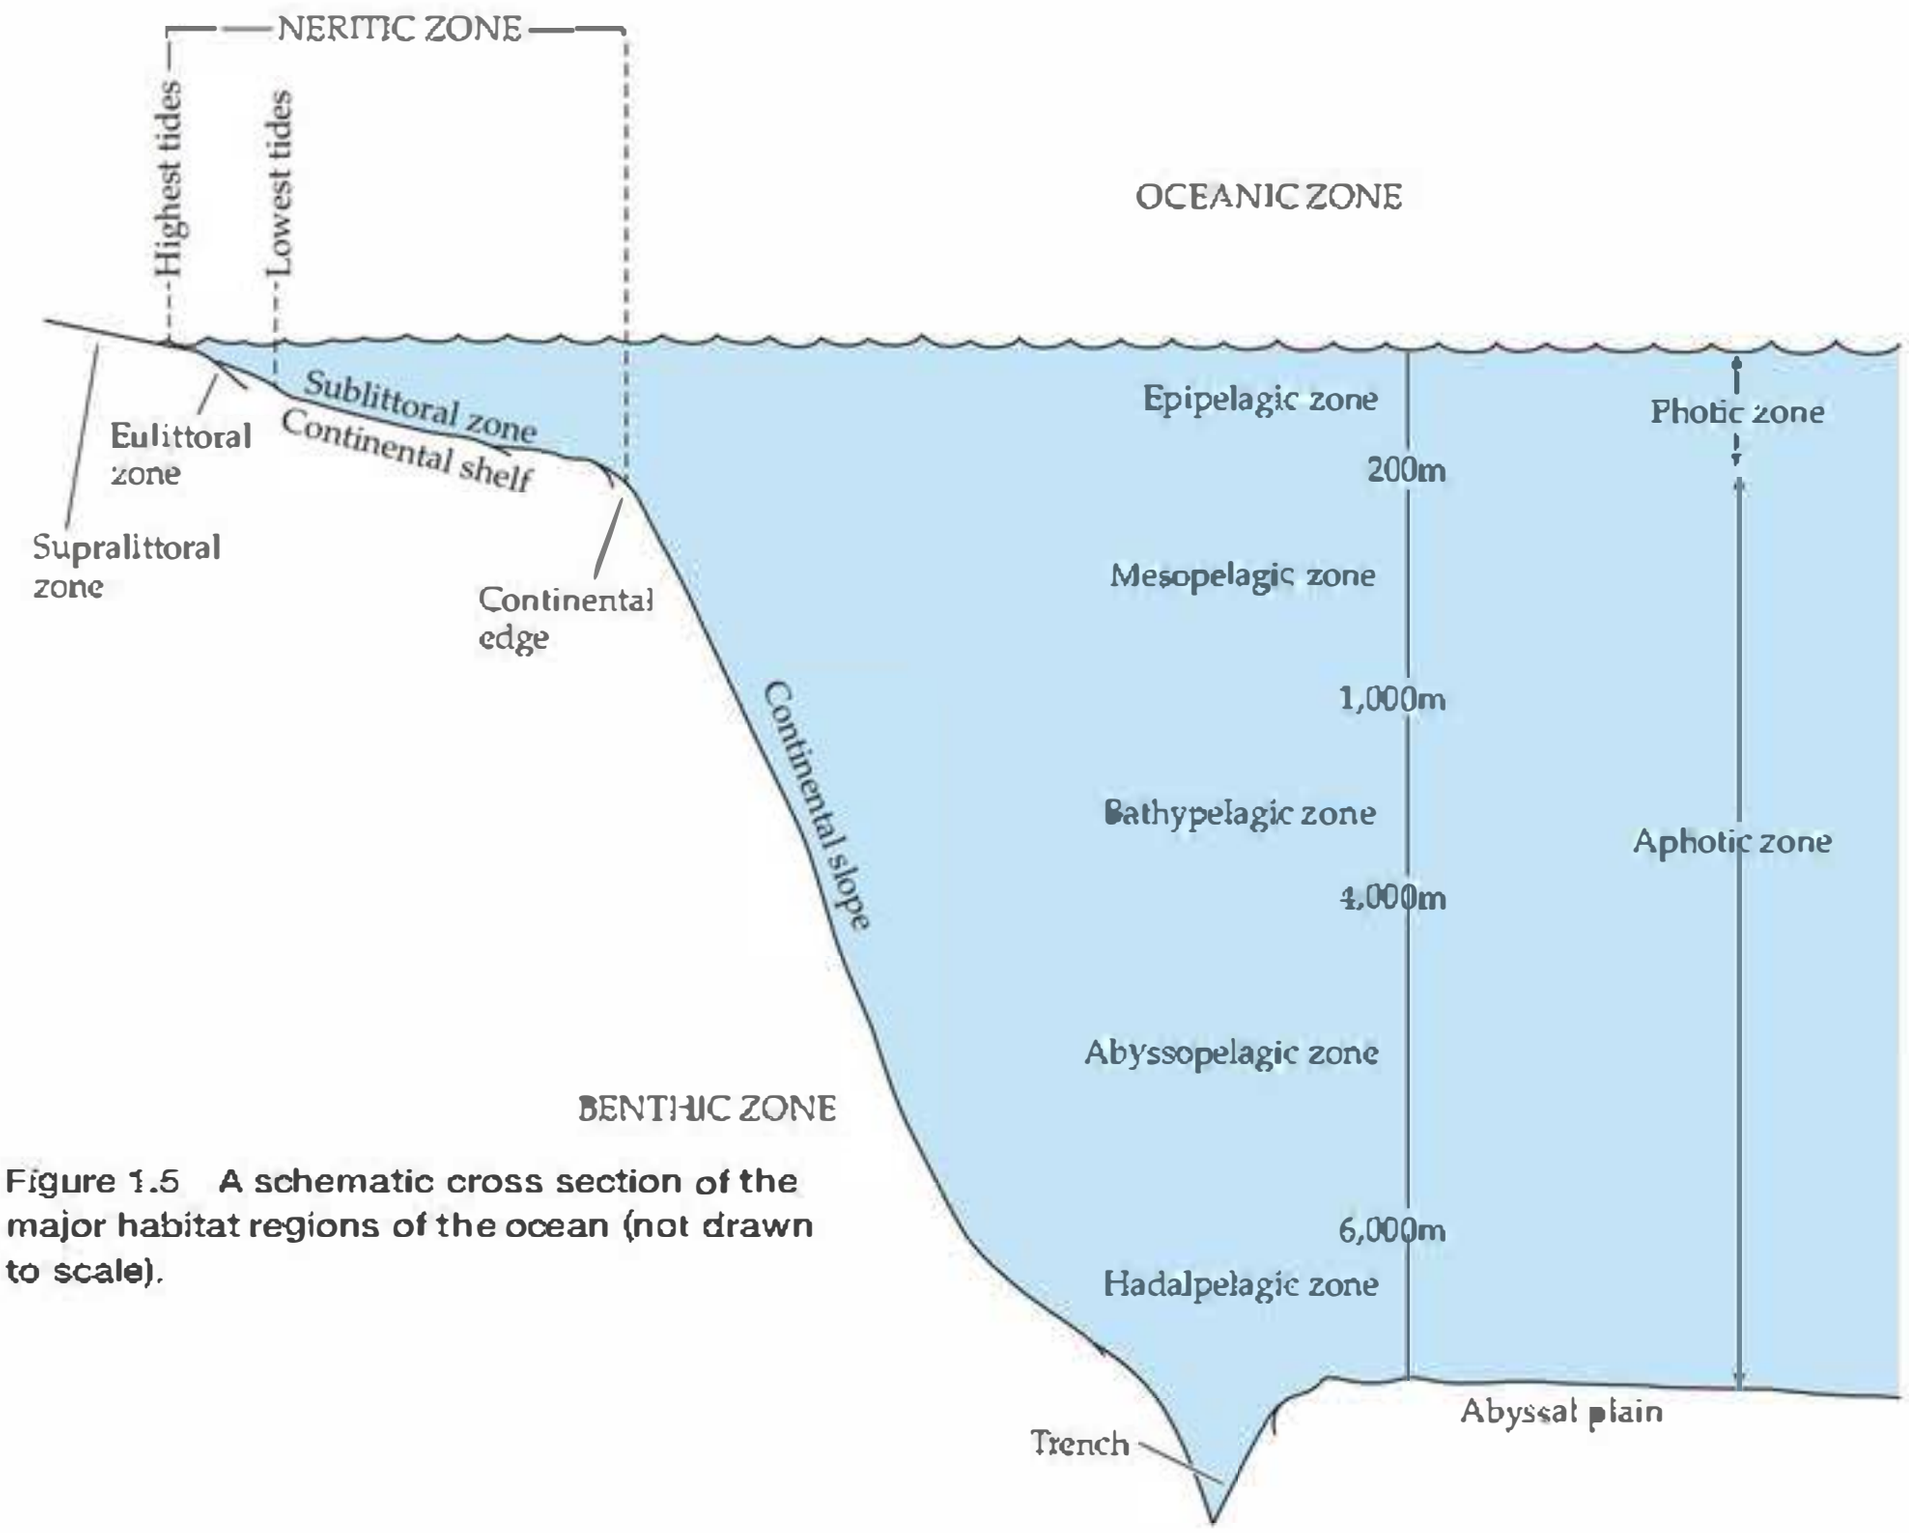

Figure 1.5 A schematic cross section of the major habitat regions of the ocean (not drawn to scale).

few species in impoverished simple communities—was long ago shown to be incorrect, and deep-sea biodiversity is now known to be quite high, in some areas even rivaling tropical rain forests. Additionally, the deep ocean covers more than half the planet!

Benthic animals may live on the surface of the substratum (**epifauna**, or **epibenthic** forms, such as most sea anemones, sponges, many snails, and barnacles) or burrow within soft substrata (infauna). Infaunal forms include many relatively large invertebrates, such as clams and various crustaceans and worms, as well as some specialized, very tiny forms that inhabit the spaces between sand grains, termed interstitial organisms (the smallest of which are **meiofauna**, usually defined as animals smaller than 0.5 mm). Six phyla of metazoans are exclusively meiobenthic in the sea: Gastrotricha, Gnathostomulida, Kinorhyncha, Loricifera, Micrognathozoa, and Tardigrada. Benthic animals may also be categorized by their locomotor capabilities. Animals that are generally quite motile and active are described as being errant (e.g., crabs, many worms), whereas those that are firmly attached to the substratum are **sessile** (e.g., sponges, corals, barnacles). Others are unattached or weakly attached, but generally do not move around much (e.g., crinoids, solitary anemones, most clams); these animals are said to be **sedentary**.

The region of water extending from the surface to near the bottom of the sea is called the **pelagic zone**. The pelagic region over the continental shelf is called the **neritic zone**, and that over the continental slope and beyond is called the **oceanic zone**. The pelagic region can also be subdivided into increments on the basis of water depth (Figure 1.5) or the depth to which light penetrates. The latter factor is, of course, of paramount biological importance. Only within the **photic zone** does enough sunlight penetrate that photosynthesis can occur, and (except in a few special circumstances) all life in the deeper, **aphotic zone** depends ultimately upon organic input from the overlying sunlit layers of the sea. Notable exceptions are the restricted deep-sea hydrothermal vent and benthic cold seep communities in which sulfur-fixing microorganisms serve as the basis of the food chain.[10] The photic zone can be up to 200 m deep in the clear waters of the open ocean, decreasing to about 40 m over continental shelves and to as little

[10]In addition to deep-sea hydrothermal vents, nonphotosynthetic chemoautotroph-based communities have recently been discovered in a cave, Movile Cave in Romania. The base of the food chain in this unique cave ecosystem is autotrophic microorganisms (bacteria and fungi) thriving in thin mats in and near geothermal waters that contain high levels of hydrogen sulfide. This community sustains dozens of microbial and invertebrate species. It is thought that the hydrogen sulfide originates from a deep magmatic source, similar to that seen in deep-sea vents.

as 15 m in some coastal waters. Phytoplankton in the photic zone of the world's oceans account for about half the production of organic matter on Earth. Note that some oceanographers restrict the term aphotic zone to depths below 1,000 m, where absolutely no sunlight penetrates; the region between this depth and the photic zone is then called the disphotic zone. Nearly 64% of the surface of planet Earth—over 200 million km^2—lies in the sea below the photic zone (below 200 m depth), and in this region it is estimated that 16 gigatons of carbon fixed by phytoplankton sink to the ocean interior ever year as the only food source for the majority of organisms in the deep sea (one gigaton is a billion tons).

Organisms that inhabit the pelagic zone are often described in terms of their relative powers of locomotion. Pelagic animals that are strong swimmers, such as fishes and squids, constitute the **nekton**. Those pelagic forms that simply float and drift, or generally are at the mercy of water movements, are collectively called **plankton**. Many planktonic animals (e.g., small crustaceans) actually swim very well, but they are so small that they are swept along by prevailing currents in spite of their swimming movements, even though those movements may serve to assist them in feeding or escaping predators. Both photosynthetic organisms (**phytoplankton**) and animals (**zooplankton**) are included among the plankton, the latter being represented by invertebrates such as jellyfishes, comb jellies, arrow worms, many small crustaceans, and the pelagic larvae of many benthic adults. Planktonic animals that spend their entire lives in the pelagic realm are called **holoplanktonic** animals; those whose adult stage is benthic are called **meroplanktonic** animals.

The oceans hold some unique habitats. Perhaps the most well known are coral reefs, which comprise one of the ocean's most diverse ecosystems. In 1997, Marjorie Reaka-Kudla estimated there were about 93,000 described animal species living in the world ocean's coral reefs, but that this was only 10% of the actual diversity (due to all of the undescribed species). Since then, some workers have suggested the number of coral reef animals might be three times, or more, than Reaka Kudla estimated.

Another well-known ocean ecosystem is the hydrothermal vent communities. These are abundant in the world's oceans, and tend to occur in areas where tectonic plates are moving apart and near plate hotspots (the land equivalents are geysers, fumaroles and hot springs). Oceanic hydrothermal vents have in common an abundance of reduced chemicals, such as sulfides and methane. Chemosynthetic bacteria and archaea form the base of the food chain in these areas. One of the signature animals of hydrothermal vents is the tubeworm annelid *Riftia pachyptila*, which has no mouth, gut or anus and cannot feed by normal means (see Chapter 14). Instead, *Riftia* depends on intracellular chemoautotrophic symbionts—which fill a large internal organ called the trophosome—for nutrition. The symbionts are Proteobacteria, which are functionally analogous to plant chloroplasts in that they generate organic carbon as a food source for their worm hosts.

Another unique marine habitat consists of large vertebrate carcasses that sink to the bottom in deep waters, especially cetaceans (whales, dolphins, and porpoises). Unlike in shallower waters, where a large carcass will be consumed by scavengers over a relatively short period of time, these "whale falls" can last for decades and allow for the establishment of an entire food web, characterized by a specific assemblage of species, especially crustaceans, annelids, and fishes. Some of the more famous members of the whale fall community are species of *Osedax*, the so called zombie worms, which consume the bones of dead cetaceans in these communities (see Chapter 14).

One of the most unusual marine environments inhabited by invertebrates are the pockets of concentrated brines that are encased in the ice matrix of Earth's polar regions (brines are generally considered to be 5% or more dissolved salts; ocean water is 3.4–3.5% salt). Living at very low temperatures (to −20°C) and light levels, a food web in miniature exists, including photosynthetic bacteria and protists (especially diatoms), heterotrophic protists, flatworms, small crustaceans, etc. These are highly-adapted, normally planktonic species that get trapped, and survive, when winter sea ice forms.

Estuaries and Coastal Wetlands

Estuaries usually occur along low lying coasts and are created by the interaction of fresh and marine waters, typically where rivers meet the sea. Here one finds an unstable blending of freshwater and saltwater conditions, moving water, tidal influences, and drastic seasonal fluctuations. Estuaries receive high concentrations of nutrients from terrestrial runoff in their freshwater sources and are typically highly productive environments. Temperature and salinity vary greatly with tidal activity and with season. Depending on tides and turbulence, the waters of estuaries may be relatively well mixed and more or less homogeneously brackish, or they may be distinctly stratified, with freshwater floating on the denser salt water below.

The amount of dissolved oxygen in an estuary may also change markedly throughout a 24 hour cycle as a function of temperature and the metabolism of autotrophic organisms. In many cases, hypoxic (very low oxygen) conditions may occur on a daily basis, especially in the early morning hours. Animals inhabiting these areas must be capable of migrating to regions of higher oxygen levels, be able to store oxygen bound to certain body fluid pigments, or be able to switch temporarily to metabolic processes that do not require oxygen-based respiration. Furthermore, vast amounts of silt borne by freshwater runoff are carried into the waters of estuaries; most of this silt settles out and creates

Figure 1.6 A few of Earth's major ecosystems. (A) Exposed rocks and algae in the intertidal zone, northern California. (B) A tidal flat in a salt marsh, New York. (C) A mangrove swamp at low tide, n Mexico. (D) A freshwater stream in a tropical wet forest ("rain forest"), Costa Rica. (E) Flowering trees in a trop cal dry forest, Costa Rica. (F) The Sonoran desert in Arizona. Fully a third of the land on our planet is desert or semi desert, and this ecosystem s predicted to grow with global warming.

extensive tidal flats or deltaic regions (Figure 1.6B). In addition to the natural stresses common to estuarine existence, the inhabitants of estuaries are also subject to stresses resulting from human activity—pollution, thermal additions from power plants, dredging and filling, excessive siltation resulting from coastal and upland deforestation and development, and storm drain discharges are some examples.

Most coastal wetlands and estuaries, such as salt marshes and mangrove swamps, are characterized by stands of halophytes (flowering plants that flourish in saline conditions; Figure 1.6B,C). Salt marshes and mangrove swamps are alternately flooded and uncovered by tidal action within the estuary, and are thus subjected to the fluctuating conditions described above. The dense halophyte stands and the mixing of waters of different salinities create an efficient nutrient trap. Instead of being swept out to sea, most dissolved nutrients entering an estuary (or generated within it) are utilized there, yielding some of the most productive regions in the world. This great productivity does eventually enter the sea in two principal ways: as plant detritus (mainly from halophyte debris), and via the nektonic animals that migrate in and out of the estuary. The contribution of estuaries to general coastal productivity can hardly be exaggerated. The organic matter produced by plants of the Florida Everglades, for example, forms the base of a major detritus food web that culminates in the rich fisheries of Florida Bay. Furthermore, 60–80% of the world's commercial marine fishes rely on estuaries directly, either as homes for migrating adults or as protective nurseries for the young. Estuaries and other coastal wetlands are also of prime importance to both resident and migratory populations of water birds.

A large number of invertebrates have adapted to life in these dynamic environments. In general, animals have but two alternatives when encountering stressful conditions: either they migrate to more favorable environments, or they remain and tolerate (accommodate to) the changing conditions. Many animals migrate into estuaries to spend only a portion of their life cycle, whereas others move in and out on a daily basis with the tides. Other species remain in estuaries throughout their lives, and these species show a remarkable range of physiological adaptations to the environmental conditions with which they must cope (Chapter 4).

Freshwater Habitats

Because bodies of fresh water are so much smaller than the oceans, they are much more readily and drastically influenced by extrinsic environmental factors, and thus are relatively unstable environments (Figure 1.6D). Changes in temperature and other conditions in ponds, streams, and lakes may occur quickly and be of a magnitude never experienced in most marine environments. Seasonal changes are even more extreme, and may include complete freezing during the winter and complete drying in the summer. Ponds that hold water for only a few weeks during and after rainy seasons are called **ephemeral pools** (or vernal pools). They typically contain a unique and highly specialized invertebrate fauna capable of producing resting, or diapause, stages (usually eggs or embryos) that can survive for months or even years without water. As stressful as this sounds, ephemeral pools contain rich communities of plant and animal life, especially endemic species of crustaceans. **Diapause** is a form of dormancy in which invertebrates in any stage of development before the adult, including the egg stage, cease their growth and development. Diapause is genetically determined. Some species are programmed to enter diapause when certain environmental conditions provide the proper cues (often a combination of temperature and length of daylight). Hibernation and aestivation are two other types of dormancy, but they are not genetically programmed and may occur irregularly, or not at all, during any stage of an animal's development **Hibernation** is a temporary response to cold, while **aestivation** is a temporary response to heat.

The very low salinity of fresh water (rarely more than 1‰) and the lack of constant relative ion concentrations subject freshwater inhabitants to severe ionic and osmotic stresses. These conditions, along with other factors such as reduced buoyancy, less stable pH, and rapid nutrient input and depletion produce environments that support far less biological diversity than the ocean does. Nonetheless, many different invertebrates do live in fresh water and have solved the problems associated with this environment. Special adaptations to life in fresh water are summarized in Chapter 4 and discussed in relation to the groups of invertebrates that have such adaptations in later chapters.

Stygobionts are aquatic obligates in subterranean ground waters, including streams and underground lakes that often connect to the sea. Aquatic creatures that inhabit subterranean alluvial waters and karst ecosystems also fall into this category.

Freshwater habitats are some of the most threatened environments on Earth. Throughout the United States, people destroy 100,000 acres of wetlands annually. Rare aquatic habitats such as ephemeral pools and subterranean rivers are disappearing faster than they can be studied. Underground, or hypogean, habitats are often aquatic, and these habitats are quickly being destroyed by pollution and groundwater overdraft.

Terrestrial Habitats

Life on land is in many ways even more rigorous than life in fresh water. Temperature extremes are usually encountered on a daily basis, water balance is a critical problem, and just physically supporting the body requires major expenditures of energy. Water provides a medium for support, for dispersing gametes, larvae, and adults, and for diluting waste products, and is a source of dissolved materials needed by animals. Animals living in terrestrial environments do not enjoy these benefits of water, and must pay the price.

Relatively few phyla have successfully invaded the terrestrial world. Invertebrate success on land is exemplified by the arthropods, notably the terrestrial

isopods, insects, and spiders, mites, scorpions, and other arachnids. These arthropod groups include truly terrestrial species that have invaded even the most arid environments (Figure 1.6F). Except for some snails and nematodes, all other land-dwelling invertebrates, including such familiar animals as earthworms, are largely restricted to relatively moist areas.

Terrestrial environments are commonly described in terms of moisture availability. **Xeric** habitats are dry, **mesic** environments have a moderate amount of moisture, and **hydric** habitats are very wet. Adaptations of terrestrial invertebrates to these various conditions are described in Chapter 4 and, for individual taxa, in subsequent chapters.

A Special Type of Environment: Symbiosis

Many invertebrates live in intimate association with other animals or plants. And, of course all animals share an ancient genetic relationship with prokaryotes. An intimate association between two different species is termed a symbiotic relationship, or symbiosis. Symbiosis was first defined in 1879 by German mycologist H. A. DeBary as "unlike organisms living together." In most symbiotic relationships, a larger organism (called the host) provides an environment (its body, burrow, nest, etc.) on or within which a smaller organism (the symbiont) lives. Some symbiotic relationships are rather transient—for example, the relationship between ticks or lice and their vertebrate host—whereas others are more or less permanent. Some symbionts are opportunistic (facultative), whereas others cannot survive without their host (obligatory). And, importantly, some symbioses evolve such intimacy that, over time, the genes of the smaller symbiont get incorporated into the genome of the "host."

Symbiotic relationships can be subdivided into several categories based on the nature of the interaction between the symbiont and its host (although in many cases the exact nature of the relationship is unknown). Perhaps the most familiar type of symbiotic relationship is **parasitism**, in which the symbiont (a parasite) receives benefits at the host's expense. Parasites may be external (**ectoparasites**), such as lice, ticks, and leeches; or internal (**endoparasites**), such as liver flukes, some roundworms, and tapeworms. Other parasites may be neither strictly internal nor strictly external; rather, they may live in a body cavity or area of the host that communicates with the environment, such as the gill chamber of a fish or the mouth or anus of a host animal (**mesoparasites**). Some parasites live their entire adult lives in association with their hosts and are permanent parasites, whereas temporary, or intermittent parasites, such as bedbugs, only feed on the host and then leave it. There are even nest parasites, such as ant-nest beetles (Carabidae: Paussini) that inhabit the nests of host ants and feed on them, apparently by tricking the ants into thinking they are one of them. In some of these cases, the line between parasitism and predation becomes blurred. Temporary parasites, such as mosquitoes and aegiid isopods, are often referred to as **micropredators**, in recognition of the fact that they usually "prey" on several different host individuals (that happen to be much larger than themselves).

Parasites that parasitize other parasites are **hyperparasitic**. **Parasitoids** are insects, usually flies or wasps, whose immature stages feed on their hosts' bodies, usually other insects, and ultimately kill the host. A **definitive host** is one in which the parasite reaches reproductive maturity. An **intermediate host** is one that is required for parasite's development, but in which the parasite does not reach reproductive maturity. Multiple hosts are more common than not in the world of parasites. Even most human pathogens circulate in animals (or else originated in nonhuman hosts), such as influenza, plague, and trypanosomiasis, which all transmit from animals to humans. Over half of all human pathogens are **zoonotic** (have animals hosts, other than humans, in their life cycle). Every species probably serves as host to several (or many) parasites. It has been suggested that parasitism is the most popular lifestyle on Earth! In fact, it has been estimated that 50 to 70% of the world's species are parasitic, making parasitism the most common way of life. Since insects are the most diverse group of organisms on Earth, and since all insects harbor numerous parasites, it is fair to say that the most common mode of life on Earth is that of an insect parasite. Most parasites have yet to be described, and as species go extinct, so, often, do their parasites (when the passenger pigeon was eliminated in 1914, it took two species of parasitic lice with it).

A few groups of invertebrates are predominantly or exclusively parasitic, and almost all invertebrate phyla have at least some species that have adopted parasitic lifestyles. Many texts and courses on parasitology pay particular attention to the effects of these animals on humans, crops, and livestock. Here we also try to focus on parasitism from "the parasite's point of view," that is, as a particular lifestyle suited to a specific environment, requiring certain adaptations and conferring certain advantages.

Mutualism is another form of symbiosis that is generally defined as an association in which both host and symbiont benefit. Such relationships may be extremely intimate and important for the survival of both parties; for example, the bacteria in our own large intestine are important in the production of certain vitamins and in processing material in our gut. In fact, beneficial associations with specific bacterial symbionts characterize many, if not all, animal species, although most of these relationships have not been well studied. Another example is the relationship between termites and certain protists that inhabit their digestive tracts and are

responsible for the breakdown of cellulose into compounds that can be assimilated by the insect hosts. Other mutualistic relationships may be less binding on the organisms involved. Cleaner shrimps, for example, inhabit coral reef environments, where they establish "cleaning stations" that are visited regularly by reef-dwelling fishes that present themselves to the shrimps for the removal of parasites. Obviously, even this rather loose association results in benefits for the shrimps (a meal) as well as for the fishes (removal of parasites). The mutualistic relationships between plants and their pollinators are essential to the survival of most flowering plants and their insect partners (and, in some cases, their bird or nectar-feeding bat partners). Mutualisms are some of the most threatened ecological relationships on earth. For example, as we loose pollinator species the plants they rely on suffer and begin to decline. In some cases, plants rely on single species for pollination. Imagine what will happen to the giant fig trees of the tropics (*Ficus* is the most widespread plant genus in the tropics) as they loose the single parasitic wasp varieties that pollinate each of the 900 or so species. Of immediate concern is Colony Collapse Disorder (CCD), a syndrome that is killing honeybees worldwide. Bees pollinate 71% of the crops that provide 90% of human food; but since 2006, U S. beekeepers have seen honeybee colony loss rates increase to 35% per year. The causes for CCD have yet to be elucidated, but overuse of pesticides in the environment appears to play a key role.

A third type of symbiosis is called **commensalism**. This category is something of a catchall for associations in which neither significant harm nor mutual benefit is obvious. Commensalism is usually described as an association that is advantageous to one party (the symbiont) but leaves the other (the host) unaffected. For instance, among invertebrates there are numerous examples of one species inhabiting the tube or burrow of another (**inquilism**); the former obtains protection, food, or both with little or no apparent effect on the latter. A special type of commensalism is **phoresis**, wherein the two symbionts "travel together," but there is no physiological or biochemical dependency on the part of either participant Usually one phoront is smaller than the other and is mechanically carried about by its larger companion.

There is a good deal of overlap among the categories of symbiosis described above, and many animal relationships have elements of two or even of all the categories, depending on life history stage or environmental conditions. Taken in its broad sense, the concept of symbiosis has profound implications for understanding Earth's biodiversity. It has been said that at least half the planet's species are symbionts and that all species have many symbiotic partnerships—concepts suggesting that every individual is an ecosystem.

Biodiversity Patterns

Biodiversity has been defined as the variety of genes, species, higher taxa, and ecosystems that constitute life on Earth. There are all kinds of biodiversity patterns on the Earth. At the species level, perhaps the best known pattern is the **latitudinal biodiversity gradient** ranging from low at the poles to high at the equator. This pattern is so general across so many taxa (though not all taxa) that it suggests the existence of a general explanation. Many hypotheses have been proposed to explain this pattern, but none have proven flawless. Some hypotheses focus on area relationships—for example, the tropics (roughly between the Tropics of Cancer and Capricorn) comprise the largest and most benign landscape scale region on the Earth and over time this might result in a great accumulation of species Other hypotheses focus on biology and ecology. For example, because of their latitude the tropics receive more sunlight and increased solar energy can drive higher productivity, which in turn can presumably support more species. One of the most studied hypotheses to explain biodiversity patterns is the humped back model (HBM; in reference to a curve often revealed when diversity is plotted against productivity), which suggests that plant diversity peaks in communities at intermediate productivity levels. At low productivity few species can tolerate the environmental stresses, and at high productivity a few highly competitive species dominate. Support for HBM has waxed and waned over the years; currently, it seems rather well supported by the evidence, at least in terrestrial environments. There are also ideas that suggest there may be faster speciation rates in warmer (tropical) climates leading to an accumulation of species. Other hypotheses focus on historical factors, such as climate stability in the tropics over Phanerozoic time. Still others explain the latitudinal biodiversity gradient on the basis of evolutionary ecology, suggesting that species competition, predation, and symbioses are stronger in the tropics and these interactions promote species coexistence and specialization, leading to greater speciation and/or niche specialization in the tropics. Paleontological studies of oceanic reef deposits support the idea that animals living in tropical reefs have high speciation rates (i.e , they are "cradles of evolution") and tend to export species to other, less biodiverse regions.

Within the marine realm today, the tropical West Pacific (especially the Indo-Australian Archipelago) has far and away the greatest biodiversity, especially associated with the coral habitats (both reefs and non-reefs) that dominate shallow seas in that region. This extraordinary diversity has been attributed to three possible mechanisms: (1) the coral habitats have served as refugia, preserving species from extinction during global cooling episodes, such as the 30 or so glacial cycles of the Pleistocene (i.e., these habitats are "species

sinks" where species accumulate over time); (2) these habitats have been sources of recruits and recolonization during favorable periods (i.e., they are "species pumps"); and (3) these habitats have exceptionally high speciation rates (i.e , they are "evolutionary cradles"). Of course, any or all of these explanations could be correct. The paleontological record tells us that the West Pacific biodiversity hotspot is much older than the Pleistocene, and also that over Earth's history, marine hotspots have moved about, probably as a result of changes in ocean basin geography.

Interestingly, research shows that there is a correlation between species diversity and the size of the areas being measured. For terrestrial species, some studies show that precipitation is most influential at small spatial scales, but cloud cover and area are more important at larger scales. At the local-to-landscape scale, fire, storm, and hurricane history often correlate to regional diversity. At global scales, processes such as tectonic plate movements and variations in sea level can account for differences in higher-level diversity (e g., mammal families).

New Views of Invertebrate Phylogeny

Significant changes in our view of animal phylogeny have come about over the past two decades, primarily from the rapidly expanding field of molecular phylogenetics, and also from new paleontological work and new ultrastructural and embryological studies. Broadly speaking, the 32 phyla of Metazoa are now divided into the four basal, or non-bilaterian phyla (Porifera, Cnidaria, Ctenophora, Placozoa) and the Bilateria (the triploblastic phyla). The Bilateria comprise two long-recognized clades, Protostomia and Deuterostomia, but four phyla once regarded as deuterostomes are now recognized as protostomes (Chaetognatha, Phoronida, Bryozoa, Brachiopoda), leaving only three phyla of Deuterostomia Echinodermata, Hemichordata, Chordata. The newly created phylum Xenacoelomorpha, housing taxa formerly allied with the Platyhelminthes (Acoela, Nemertodermatida, and *Xenoturbella*), remains enigmatic but most analyses place this group as basal bilaterians.

Among the protostomes, molecular phylogenetic research identifies two major clades, Ecdysozoa and Spiralia. However, five protostome phyla still remain elusive in their affinities: Chaetognatha, Platyhelminthes, Rhombozoa, Orthonectida, and Gastrotricha. And, despite great efforts to date, the specific relationships of the phyla within Ecdysozoa and Spiralia also remain somewhat evasive, although some strongly supported internal clades have been identified. For example, the Ecdysozoa comprises three well-supported clades—Scalidophora (Priapula, Loricifera, Kinorhyncha), Nematoida (Nematoda, Nematomorpha), and Panarthropoda (Onychophora, Tardigrada, Arthropoda). Relationships among the Spiralia have been more difficult to tease apart, although one well-supported internal clade is recognized, the Gnathifera, containing the phyla Gnathostomulida, Micrognathozoa, and Rotifera. Also, recent analyses suggest that the Lophotrochozoa might be a clade within Spiralia, containing (as the name suggests) the lophophorate phyla (Phoronida, Bryozoa/Ectoprocta, Brachiopoda) plus Nemertea, Annelida, and Mollusca (and possibly also Cycliophora, Entoprocta, and Platyhelminthes); however, this needs further testing. Some recent studies have suggested that ctenophores, not sponges, could be basal Metazoa, but this idea might be based on methodological artifacts (Pisani et al 2015).

Some phyla recognized in the last edition of this book are now known to be specialized lineages of other phyla, hence Echiura and Sipuncula are now viewed as specialized clades within the Annelida, and Acanthocephala are now seen as a parasitic lineage of Rotifera. Hexapoda (insects and their kin) now seem certain to have arisen from within the Crustacea, making the latter a paraphyletic group. And the Myxozoa, once thought to be protists, are now known to be highly derived and extraordinarily specialized, parasitic cnidarians.

Among the deuterostomes, Echinodermata and Hemichordata now appear to form a well supported clade (Ambulacraria), and this is the sister group to Chordata. Within Chordata, the long standing idea that lancelets (Cephalochordata) are the sister group to the Vertebrata (Craniata) has been overturned, and strong evidence now supports the tunicates (Urochordata) as the sister group to the vertebrates. The many phylogenetic ideas about these phyla and clades are presented in the following chapters. A summary classification is provided on the front inside cover, and a geologic time scale is on the back inside cover.

Not only have the phyla assigned to the old groups Protostomia and Deuterostomia been shuffled, but the meaning of these old names now rings only partly true New developmental research, especially gene expression studies, has revealed that many (perhaps most) members of Protostomia do not have "protostomous" development, but instead have idiosyncratic patterns or deuterostomous patterns.

Teasing apart the evolutionary relationships of the metazoan phyla has been challenging because of their ancient roots, and it has required finding informative phylogenetic markers for groups that are hundreds of millions of years old. The main obstacle has been that different regions of the genome have experienced different evolutionary histories, thus producing conflicting phylogenetic signals. Not only has this required using multiple genes, and even genome level analyses, it has also led to the development of sophisticated algorithms that model the evolution of individual amino

acids. Those phyla still stubbornly resisting phylogenetic understanding will probably requ re new and even more sophisticated analysis protocols. One of the important things that has been revealed over the past couple decades through the work of molecular phylogenet .cs and developmental biology is that there is far more homoplasy in the animal world than we suspected, even in such complex features as segmentation and nervous systems. For example, one surprising new discovery is that the annelids (now considered spiralians) and the Panarthropoda (Onychophora, Tardigrada, Arthropoda—now placed within Ecdysozoa) are far more distantly related than was previously thought. It might be hard to imagine the highly complex, multi level process of segmentation shared by annelids and arthropods evolving independently, and it seems more likely that they share some ancient bilaterian genes that predisposed them to a nearly identical embryological segmental patterning process. We still have much to learn about this surprising new twist in a n i mal phylogeny. Even spiral cleavage, once thought to be a largely immutable aspect of animal development (due to "developmental constraints"), has been shown to be flexible to the point of being greatly altered or possibly even lost in some lineages. Further, we now know that many genes once thought to be specific to particular innovations actually appeared in the tree of life much earlier than did the features themselves; so we can no longer necessarily expect to find novel genes associated with novel morphological or developmental features. For example, cellular adhesion and transcriptional regulation genes essential to anirnal multicellu larity also occur in the protistan ancestral line leading to Metazoa. And, we now know that many genes once thought to be specific to vertebrates can be found as far down the tree of life as Cnidaria (but have been lost in many lineages i n between). Many novel phenotypes have arisen by way of modification of gene fumction and by interactions between existing genes.

Legacy Names

As you might have guessed by now, some of the names in use today for higher taxa were created before biologists achieved their current understanding of animal phylogeny, and due to more recent reassignments of phyla these names are no longer fully descriptive. As noted above, the two great clades of Bilateria have long been called Protostomia and Deuterostomia. The name Protostomia was created for those animal phyla in which the blastopore gives rise to the mouth during embryogenesis (*proto* = first, *stoma* = mouth). In contrast, the name Deuterostomia was created for those animals that form the mouth not from the blastopore but elsewhere (*deutero* = second); in many of these groups, the the blastopore gives rise to the anus. However, over the past few years, we have discovered that some phyla with deuterostomous development actually belong in the clade called Protostomia (e.g., Chaetognatha, Pho ronida, Bryozoa, Brachiopods, Priapula, Arthropoda). Thus both names have been rendered less thanperfect ly descriptive Similarly, the name Spiralia was created by Waldemar Schleip in 1929, after the stereotypical spiral cleavage seen i n most member phyla, but even this name is not fully descriptive because several phyla of Spiralia lack this developmental pattern (e.g , Bryozoa, Brachiopoda, Gastrotricha, Orthonect:da). These kinds of names for higher taxa, that are no longer fully descrip tive based on their original intent, are legacy names. To fully appreciate them, one needs to understand a bit of their history, otherwise they can seem illogical.

Phylogenetics and Classification Schemes

As noted above, the rapidly growing number of molecular phylogenetic studies has changed many of our views on animal relationships and classif:cations. This work is also generating large and highly detailed phy logenetic trees, with long branching patterns depicting the history of life on Earth Such detail creates challenges for biologists who like to produce classifications that accurately reflect phylogeny, because the traditional Linnean hierarchical ranks are too few in number to capture the great depth and detail of these trees. Many of the new multigene or genomic trees have scores of branching points, or even hundreds of branches that appear as long comblike topologies. But the standard Linnean ranks number only 30 or so. There are a few solutions to this dilemma, such as using unranked classifications, but none of the solutions is perfect. We briefly discuss these in Chapter 2. In this book, we mostly use ranked classifications that mirror, or at least do not conflict with the phylogeny of the groups in question. In a few instances, we have had to use fully or partly unranked subordinated classifications (e.g, annelids and molluscs). Again, this is all explained in more detail in Chapter 2. But the upshot is, things are changing and the "traditional" classification schemes many students are used to seeing are beginning to look rather different these days.

Some Comments on Evolution

Fitness By Any Other Name
Would Be As Loose

A group inept
Might better opt
To be adept
And so adopt
Ways more apt
To wit, adapt.

John Burns
Biograffiti, 1975

This book takes evolution as its central theme. Although evolutionary biology has expanded rapidly over the past few decades, at its core remains the seminal and galvanizing concept of Charles Darwin and Alfred Russell Wallace—that natural selection and descent with modification are the agent and manifestation, respectively, of evolutionary change. Since the "molecular biology revolution" began in the 1980s, the paradigms that have guided evolutionary biology have expanded greatly. Molecular biology has produced dramatic discoveries and will no doubt continue to do so for many decades to come.

There are three fundamental patterns we see when we examine evolutionary history: anagenesis, speciation, and extinction. Anagenesis is the process by which a genetic or phenotypic character changes within a species over time, whether the change is random or nonrandom, slow or rapid. Anagenesis seems to be driven by those neo-Darwinian processes often referred to as microevolution the within-species, generation-by-generation evolution of populations and groups of populations over the "lifetime" of a species. Natural selection and adaptation are powerful driving forces at this level. Speciation is the "birth" of a species, and extinction is the "death" (termination) of a species. Speciation and extinction engage processes outside the natural selection/adaptation paradigm—processes often referred to as macroevolution. The mechanisms that initiate and sculpt each of these processes differ. Most college courses today focus primarily on microevolution, or anagenesis, and most students reading this book already know a great deal about population genetics and natural selection. Population genetics focuses on vertical transmission of genetic information. However, the view that all of evolution can be understood solely on the basis of microevolutionary phenomena is being reexamined in light of new ideas regarding evolutionary change. Consequently, we would like to introduce readers to some ideas with which they might be less familiar We will do so by first discussing within species processes (presented here under the term "microevolution"), and then speciation and extinction (grouped under the heading "macroevolution").

Microevolution

The neo Darwinian evolutionary model, or so-called "modern synthesis," that resulted from the integration of Mendelian genetics into Darwinian natural selection theory dominated evolutionary biology through the twentieth century. Basically, the neo Darwinian view holds that all evolutionary changes result from the action of natural selection on variation within populations (see John Burns's poem on page 26). This view has been called the "adaptationist paradigm." The theory focuses on adaptation and deals primarily with genes and changes in allelic frequencies within populations. These genetic variations come about primarily by recombination and mutation, although the random phenomena of genetic drift and founder effect are also part of the neo Darwinian synthesis.

Evolution by natural selection can be viewed as a deterministic process, even though certain elements of chance are accepted within the theory (e.g , mutation, random mating, the founder effect). The theory of natural selection implies that, given a complete understanding of the environment and genetics, evolutionary outcomes should be largely predictable. The theory of natural selection further implies that virtually all of the characteristics animals possess are products of adaptations leading to increased fitness (ultimately, to increased reproductive success). An adaptationist view might lead one to assume that every aspect of an animal's phenotype is the product of natural selection working to increase the fitness of a species in a particular environment. Microevolution is thus seen as a deterministic, within-species phenomenon that affects population genetics on a generation-to generation basis to produce changes and patterns in gene frequencies within and among populations.

Macroevolution

Macroevolution is the focus of some of the most interesting debates among biologists today. Macroevolutionary phenomena can include the origin of new species (cladogenesis), "explosive" adaptive radiations that appear to be linked to the opening up of new ecological arenas or niches, transgenic events, major shifts in developmental processes that might result in new body plans, various karyotypic alterations (e.g., polyploidy and polyteny), and mass extinction events (and the subsequent new biotic proliferations). One of the best examples of macroevolution is the origin and rise of birds from their massive bodied theropod dinosaur ancestors. The lineage leading to modern birds underwent rapid sustained miniaturization, with species evolving at a much faster rate than seen in other theropod lineages. Birds also rapidly developed new ecological and morphological innovations linked to smaller size, including a rate of skeletal adaptations four times faster than other dinosaurs. In part, the rapid radiation of birds was driven by the innovation of flight. Macroevolution asks the question, "what drives evolutionary innovation?"

Mass extinction events in Earth's history have played major roles in reshaping the directions of animal evolution in unpredictable ways. The largest of these extinction events wiped out a majority of life forms on Earth. In the Permian–Triassic extinction event, an estimated 90% of all marine species went extinct (although no phylum is known to have gone extinct since the start of the Cambrian) resulting in a worldwide reorganization of life. Mass extinctions are profound macroevolutionary events that can abruptly (in geological time) terminate millions of species and lineages.

In contrast to microevolution, macroevolution is evolutionary change, often rapid, that produces phylogenetic pattern formation above the species level (e.g., the patterns depicted on the phylogenetic trees in this book). The fossil record suggests that speciation events (one species giving rise to one or more new species) tend to be rapid, or geologically instantaneous. Analysis of the fossil record also shows that the number of species has increased gradually since the end of the Proterozoic, with this diversification periodically interrupted by mass extinctions. And mass extinctions have always been followed by periods of rapid speciation and radiation at higher taxonomic levels (i.e., macroevolution).

Newer views suggest that speciation might not be initiated by natural selection, but rather by processes outside the natural selection paradigm—perhaps most frequently by stochastic processes. Microevolution can be thought of as a within species process that maintains genomic continuity and continually "fine-tunes" populations and species to their changing environment. A reasonable analogy might be the basic metabolic activities that keep your own body "finetuned" to the environment a background process that is always at work maintaining a level of homeostasis (within your body, or within a species' gene pool). A macroevolutionary event, on the other hand, is typically a process that disrupts that genomic, or reproductive, continuity in a species and may thus initiate speciation events. Following the above analogy, macroevolutionary events disrupt the homeostasis of species' gene pools. Some examples of stochastic events that can lead to macroevolutionary change are described below.

The geneticist Richard Goldschmidt, the paleontologist Otto Schindewolf, and the zoologists René Jeannel and Claude Cuénot all maintained until the 1950s that neither evolution within species nor simple allopatric speciation could fully explain macroevolution. They advanced an idea called saltation theory—the sudden origin of wholly new types of organisms the "hopeful monsters" of Goldschmidt in great leaps of change. It has been proposed that one way such rapid changes might occur is through transgenic events, involving the lateral transfer of genetic material from one species to another. Proposed mechanisms of lateral genetic transfer include transposable genetic elements and symbiogenesis. The endosymbiont bacteria that gave rise to mitochondria and chloroplasts have been one major source of bacterial genes in eukaryotic nuclear genomes, and their ancestral lineages are the α-Proteobacteria and Cyanobacteria, respectively. Even in the human genome, it has been shown that dozens of genes have probably been transferred from bacteria to humans (or to one of our vertebrate ancestors) over the course of evolution.

Probably all phyla have some DNA in their genome that was "adopted" from other species in their distant past, especially from Eubacteria and Archaea. Two phyla that have been shown to have notably large percentages of their DNA derived from other life forms via horizontal transfer are rotifers and tardigrades. In the latter case, as much as one-sixth of their DNA might have been acquired by horizontal transfer (Chapter 20). A recent study by Thomas Boothby and others (2015) suggested that tardigrades (and rotifers, and perhaps other invertebrates) might be prone to integrating foreign genes into their genomes because they famously have the ability to survive extreme environmental stress. These researchers speculated that in conditions of extreme stress, such as desiccation, a tardigrade's DNA breaks into tiny pieces and then, when the cells rehydrate, the cell membranes and nucleus become temporarily leaky and DNA molecules can pass through, allowing an opportunity for the "host" to stitch in foreign DNA from the environment.

Transposable elements (TEs) are specialized DNA segments that move (transpose) from one location to another, either within a cell's DNA, between individuals in a species, or even between species. They were discovered in maize (*Zea mays*) by the Nobel laureate Barbara McClintock in the 1950s, but little was known about them until recently. With the growth of molecular genetics, hundreds of TEs now have been identified—over 40 different ones are known from the laboratory fruit fly *Drosophila melanogaster* alone. The mechanisms of TE transfer between organisms are not yet well understood. However, the transfer of genetic elements from one species to another is suspected to be by way of viruses, bacteria, arthropod parasites, or other vectors. There is strong evidence, for example, that parasitic mites have been responsible for the lateral transfer of genetic elements among *Drosophila* species.

The movement of a transposable element within a genome is mediated by a TE encoded protein called a "transposase," probably interacting in complex ways with certain cellular factors. A transposase recognizes the ends of the TE, breaks the DNA at these ends to release the TE from its original position, and joins the ends to a new target sequence. The transposition of some TEs from bacteria to bacteria, and from bacteria to plant cells, is partially understood, and we know that the introduction of these DNA segments can contribute powerful mutagenic qualities to the new host's genome. Recent work suggests that a great deal of such "gene swapping" took place during the early evolution of the prokaryotes. TEs have been best studied in prokaryotes, but they have been found in most organisms that have been examined, including insects, mammals, flowering plants, sponges, and flatworms. Although we lack specific evidence, there is reason to suspect that TEs could have been responsible for some of the major genetic innovations that have taken place in the history of life.

Aside from transposable elements, the duplication of a chromosomal segment that then becomes

separated from the original segment, ending up in a different chromosomal location, is now known to be a fairly common occurrence. A number of human genetic disorders are known to be associated with the increased expression of genes contained within such duplications. Duplicate genes provide a rich new substrate on which evolution can work. One member of the duplicate pair could take on a new function, or two duplicate genes could divide the multiple functions of the ancestral gene between them with natural selection then refining each copy separately to a more restricted set of tasks. Even single genes can duplicate, giving rise to redundancy that can provide the fodder for rapid evolution of new gene functions. For example, in the water flea (Crustacea: Branchiopoda: Diplostraca: *Daphnia*), tandem gene duplication has been extensive and is likely responsible for the extreme phenotypic plasticity of these creatures, as well as their extreme ecophysiological adaptability.

Rapid speciation by way of successful hybridization between two species is another example of macroevolution. Although most common in plants, and probably microbes, hybrid speciation does occur in animals as well, and it has been documented in African cichlids, cyprinid fishes, *Rhagoletis* fruit flies, and *Heliconius* butterflies The Appalachian tiger swallowtail, *Papilio appalachiensis* evolved from mixing between the eastern tiger swallowtail, *P. glaucus*, and the Canadian tiger swallowtail, *P canadensis*. The Appalachian species rarely reproduces with its parental species. Studies suggest the Appalachian tiger evolved about 100,000 years ago, and its genome is a mixture of the parental genomes.

Another way in which evolutionary novelties can arise is through symbiosis. The Russian biologist Konstantin Mereschkovsky (1855–1921) developed the "two-plasm" (cell within a cell) theory, claiming that chloroplasts originated from blue-green algae (Cyanobacteria). For this process, he invented the term symbiogenesis (today, this is often called the endosymbiotic theory). In Chapter 3, we describe the symbiogenic origin of the eukaryotic cell, which probably arose by way of incorporation of once free living prokaryotes that came to be what we recognize today as mitochondria, chloroplasts, cilia, flagella, and other organelles. Although symbiogenesis is an old idea, Lynn Margulis and others vigorously championed it in the twentieth century. Symbiogenesis is the permanent merger of two organisms from phylogenetically distant lineages into one radically more complex organism. Once thought to be rare, we now know that this phenomenon is common throughout life. Three examples are exceptionally important with regards to the evolution of the animal kingdom: (1) intracellular enslavement by an early eukaryote of an α proteobacterium by host protein insertion to make the first mitochondria, (2) later capture of a cyanobacterium by a heterotrophic protist to create the first chloroplast, thereby launching the kingdom Plantae, and (3) secondary enslavement of a red alga to yield more complex membrane topology in the phagophototrophic protist group known as the Chromalveolata. It has been estimated that over 50% of all formally described protists are chromalveolates. In addition to the enslavement of a red alga to give rise to the plastid ancestor of the Chromalveolata event, green algae have also been endosymbiotically captured, at least twice, to begin other new lineages of protists.

Beyond the origin of the eukaryotic cell, symbiogenesis has also been at work in many other systems, but we are just beginning to understand how pervasive this has been among Metazoa. In extremely intimate symbiotic partnerships, the two symbionts can have profound effects on each other's genetic evolution. Such partnerships are major sources of evolutionary innovation and they have driven rapid diversification of organisms, allowed hosts to harness new forms of energy, and resulted in profound modifications of Earth's nutrient cycles and geochemistry. Recent genomic studies have revealed the ubiquity of intimate symbioses. Many invertebrates are involved in such relationships, including the corals and other cnidarians that serve as hosts for symbiotic dinoflagellates (called zooxanthellae) that live within their tissues. Various animals that harbor (and exploit) tetrodotoxin-secreting bacteria (many chaetognaths, the blue ringed octopus, a sea star, a horseshoe crab, and certain tetraodontid fishes), squids with luminous bacteria, and lichens (an intimate association between fungi and Cyanobacteria or green algae) are other examples. Many insects harbor endosymbionts bacteria that live within the host's cells. Although separate organisms, they function as a metabolic unit. For example, species of mealy bugs depend on bacteria endosymbionts for nutrient provisioning, and the endosymbiont can in turn harbor its own endosymbiont. Endosymbionts can even speciate within their hosts, as has been shown in cicadas. That symbionts can affect the evolution of their hosts in unexpected ways can also be seen in parasites that enhance their own chances for survival by altering aspects of their host's lives—for example, parasites that increase the likelihood that their intermediate host will fall prey to their definitive host by changing the intermediate host's size, color, biochemistry, or behavior in ways that make it more vulnerable to predation. One common outcome of host-symbiont integration is a reduction in symbiont genome size. A species of leafhopper, *Macrosteles quadrilineatus*, harbors the endosymbiont *Nasuia deltocephalinicola*, the smallest bacterial genome sequenced to date.

Another revelation in our thinking about macroevolution has come from the discovery of homeobox (Hox) genes. These master regulatory genes encode proteins that regulate the expression of other genes. They modulate other sets of developmental genes and

in doing so "select" the developmental pathways that are followed by dividing cells. Hox genes have two functions in the early development of embryos: (1) they encode short regulatory proteins that bind to particular sequences of bases in DNA and either enhance or repress gene expression, and (2) they encode proteins that are expressed in complex patterns that determine the basic geometry of the organism. The term "Hox genes" refers specifically to those genes that are clustered in an array on the chromosome and function primarily in establishing regional or segmental identities. In all animal phyla that have been examined, regional or segmental specialization is controlled by the spatially localized expression of these genes, which play crucial roles in determining body patterns. They underlie such fundamental attributes as anterior posterior differentiation (in both invertebrates and vertebrates) and the positioning of body wall outgrowths (e.g., limbs). The pivotal role played in evolution by developmental genes and the processes they regulate has led to the emerging field of evolutionary developmental biology, or "EvoDevo" for short. EvoDevo is concerned with the generation of form within an individual and how developmental mechanisms evolve over time—that is, how evolutionary innovation comes about.

Hox genes have been conserved to a remarkable degree throughout the animal kingdom, and they are now known from all animal phyla that have been examined. Hox proteins regulate the genes that control the cellular processes involved in morphogenesis. In doing so, they demarcate relative positions in animals—they do not specify the precise nature of particular structures. For example, in arthropods, Hox genes regulate where body appendages form, and they can either suppress limb development or modify it (in concert with other regulatory genes) to create unique appendage morphologies. Mutations in Hox genes, and other developmental genes, can create gross mutations (homeotic mutations or homeosis).

Only a small fraction of all genes, fewer than 1%, are devoted to the construction and patterning of animal bodies during their development from fertilized egg to adult—the process of a single egg becoming a complex, multibillion- (or multitrillion-) celled organism that looks and functions properly. The rest are involved in the everyday tasks of cells within various organs and tissues. Thus, mutations or other changes in relatively few genes, a "toolkit" common to all animals, can have large embryological outcomes. There is a growing body of evidence suggesting that Hox genes (and other "master control genes") have played major roles in the evolution of new body plans among the Metazoa. The evolutionary potential of Hox genes lies in their hierarchical and combinatorial nature. We now know that a single Hox gene can modulate the expression of dozens of interacting downstream genes, the products of which determine developmental outcomes. Variation in the output of these multigene networks can arise at many levels simply through changes in the relative timing of developmental gene expression (i.e., by heterochrony; see Chapter 5), or through interactions between genes in the regulatory network. To understand the profound potential of Hox genes to drive evolutionary change, consider that within the genome of *Drosophila* 85–170 different genes are regulated by the product of the Hox gene *Ultrabithorax* (*Ubx*) alone. Changes in the *Ubx* protein could potentially alter the regulation of all these genes! In some families of sea spiders (Chelicerata: Pycnogonida), Hox gene mutations appear to have produced spurious segment/leg duplications, creating polymerous lineages.

There are now many examples of the extraordinary potential, and flexibility, of developmental genes. The potential of Hox genes is seen in the abdominal limbs of insects. Abdominal limbs ("prolegs") occur on larvae of various insects in several orders, and they are ubiquitous in the Lepidoptera (e.g., caterpillars). These limbs were probably present in insect ancestors, hence prolegs may have reappeared through the de-repression of an ancestral limb developmental program (i.e., they are a Hox gene mediated atavism). Proleg formation appears to involve a change in the regulation and expression of a single gene (*abd-A*) during embryogenesis. Another fundamental feature of animals is eyes, and these come in an enormous variety of styles, from the sophisticated camera-type eyes of vertebrates and cephalopods, to the simple light-sensitive eyespots of flatworms, to the compound faceted eyes of arthropods. It has been estimated the eyes have been "invented" independently dozens of times in Metazoa. Yet we now know that the gene required for eye formation in fruit flies (the *Pax-6* gene) is the exact counterpart of the gene required for eye formation in humans and squids and many other animals. Major innovations, macroevolution, can come about by "teaching old genes new tricks." And, most recently, it has been discovered that new genes can arise *de novo*, from ancestrally nongenic sequences. Since early in the twenty first century, *de novo* genes have been identified in *Drosophila*, rodents, rice, yeast and humans

In summary, the processes of microevolution (e.g., natural selection) act on individuals and populations, maintain genomic continuity, and create anastomosing patterns of relationship over time (Figure 1.7). Macroevolutionary processes (e.g., speciation and extinction), on the other hand, act on species and lineages, disrupt genomic continuity, and create ascending, bifurcating patterns of relationship over time (Figure 1.7). In a cladogram of species, the line segments represent the places where anagenesis (microevolution) is taking place within a given species. The nodes in the cladogram represent macroevolutionary events, speciation, and extinction. Although Darwin titled his book *On the Origin of Species*, he dealt primarily with the maintenance of adaptations. In fact, the nature of

Microevolution (Within-species evolution)

1. Individuals and populations linked by gene flow (e.g., reproductive ties, dispersion)
2. Process produces pattern of reticulation
3. Acts on individuals (e.g. natural selection)
4. Works to maintain genomic continuity (i.e. evolutionary homeostasis)
5. Creates an anastomosing network
6. Explains anagenesis

Macroevolution (Species/clade evolution)

1. Species linked by speciation events
2. Process produces pattern of bifurcation ("dendrogram")
3. Acts on species
4. Disrupts genomic continuity
5. Creates hierarchical, diverging network
6. Explains cladogenesis (origin of clades: species and species groups)

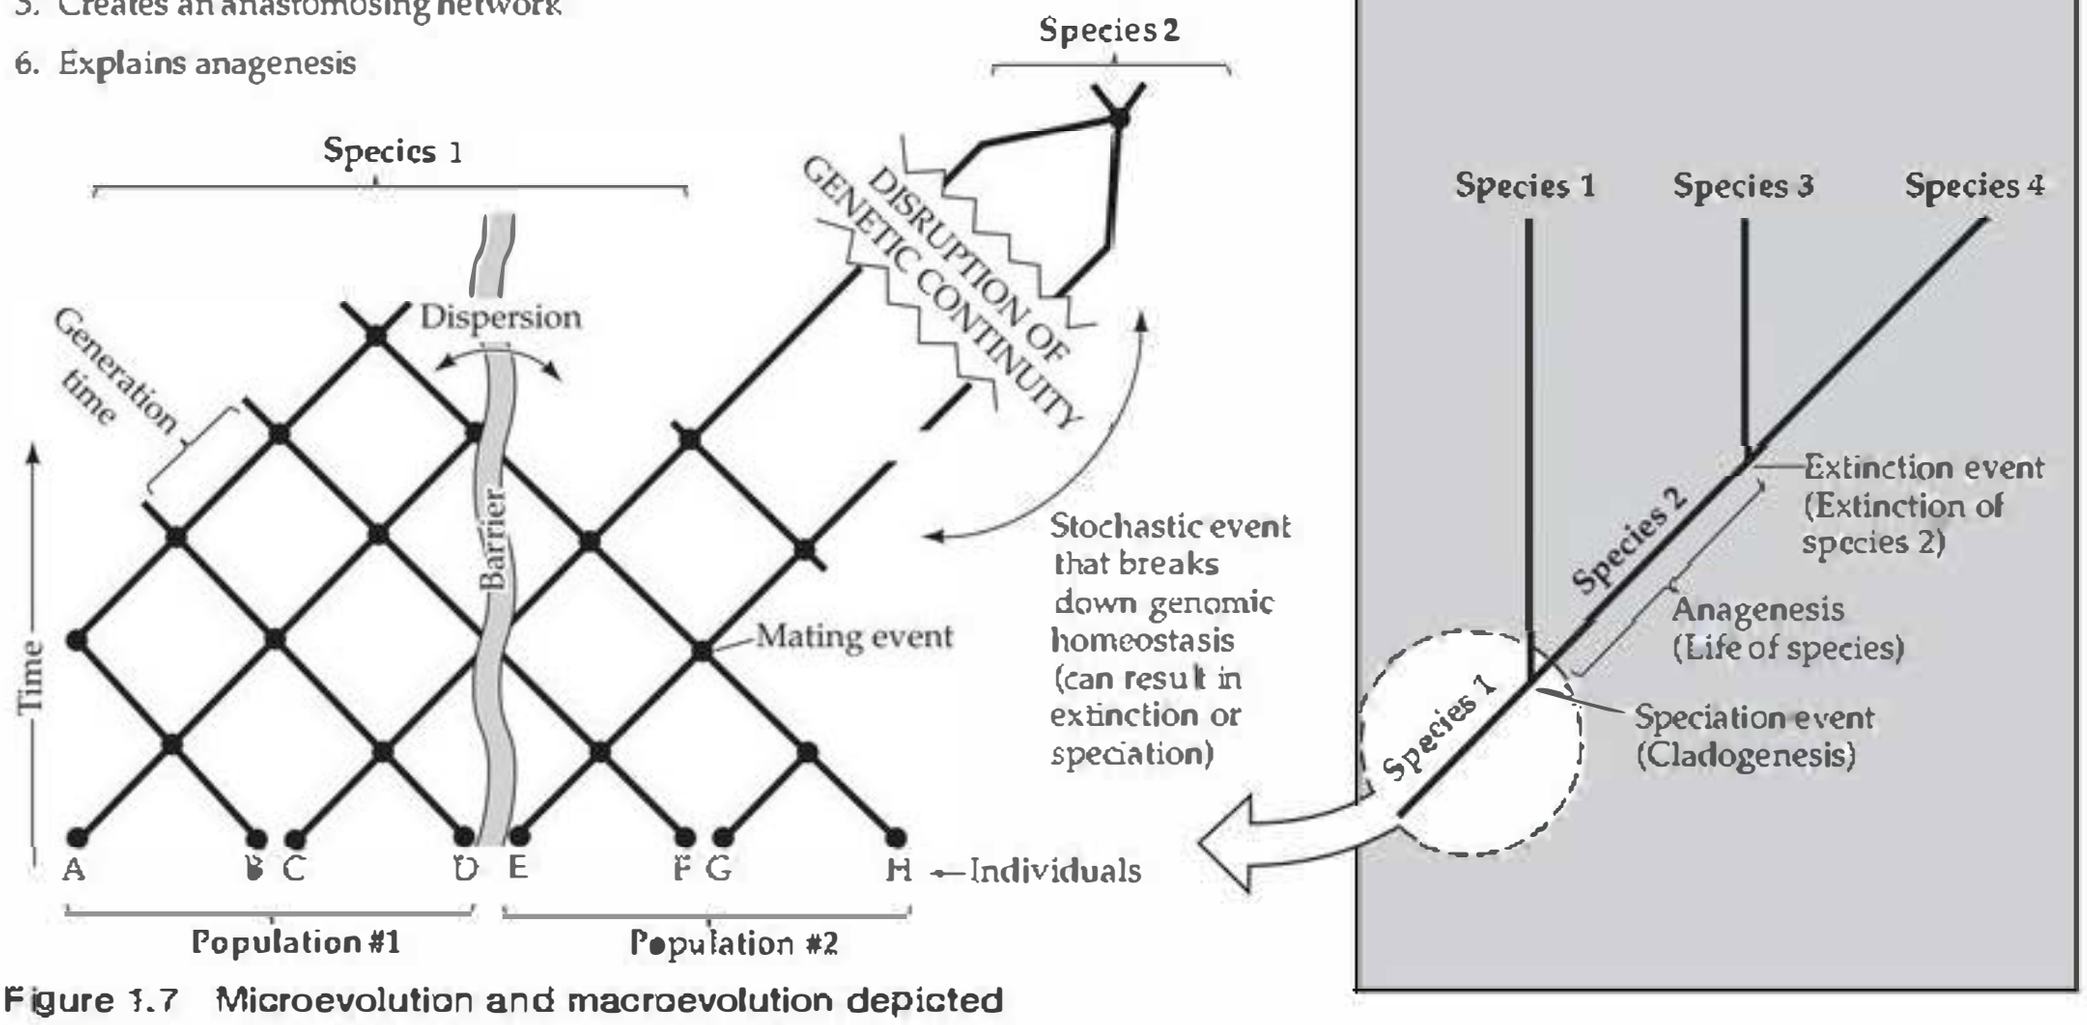

Figure 1.7 Microevolution and macroevolution depicted graphically. The highlighted portion of the cladogram (on the right) is shown in detail in the drawing to the left.

the relationship between anagenesis and cladogenesis is still not well understood. Evidence for the disengagement of natural selection and speciation comes from the fossil record, which suggests that most species do not change significantly throughout their existence; rather, they remain phenotypically stable for millions of years, then undergo a rapid change in which they essentially "replace themselves" with one or more new and different species. These new species, in turn, remain phenotypically static for millions more years. The fossil record suggests that most species of marine invertebrates persist more or less unchanged for 5–10 million years, whereas the time required for significant anatomical change seems to be only a few thousand years or less. The pattern of speciation in rapid bursts, sandwiched between long periods of species stasis, was presented in the famous punctuated equilibrium model of Niles Eldredge and Stephen Jay Gould (1972).

Biologists are still a long way from understanding all the causes and mechanisms of the evolutionary process, although we are developing excellent methods for analyzing the patterns of the history of evolution (e.g., molecular phylogenetics). The current debates concern the process—the nature of the evolutionary mechanisms themselves. It seems probable that different processes, working at different levels, have created the patterns we see in the world today. Despite the many evolutionary questions currently being discussed, and despite whatever evolutionary processes are at work, biologists are able to continue their efforts at reconstructing the evolutionary history of life on Earth, because the processes of evolution result in new organisms that are distinct by virtue of the unique new characters or attributes that they have acquired. Their descendants retain these attributes and in time acquire still others, which are retained by their descendants. In this fashion, the living world provides us with an analyzable hierarchical pattern consisting of nested sets of features recognizable both in fossils and in living organisms. Those features, in turn, are the data (i.e., the "characters") with which we can reconstruct a history of the ascent of life. We will have much more to say regarding this reconstruction process in the following chapter, because understanding what characters are and how they are evaluated is fundamental to comparative biology and to an appreciation of the invertebrate world.

A Final Introductory Message to the Reader

Because of our comparative approach, it is critical that you become familiar with Chapters 1, 2, 4, and 5 before attempting to study and comprehend the sections dealing with individual animal groups. These four chapters are designed to accomplish several goals: (1) to define some basic terminology, (2) to introduce a number of important concepts, and (3) to describe in detail the themes that we use throughout the rest of the book.

The fundamental theme of this book is evolution, and we approach invertebrate evolution primarily through the field of comparative biology. In Chapter 2 we provide an explanation of how biologists derive evolutionary schemes and classifications, how theories about the phylogeny of animal groups grow and change, and how the information presented in this text has been used to construct theories on how life evolved on Earth. In Chapters 4 and 5 we lay out the fundamental anatomical and morphological designs and developmental strategies of metazoans. Like the features of organisms, these designs and strategies are not random, but form patterns. Recognition and analysis of these patterns constitute the basic building blocks of this book. We then proceed in the "animal chapters" to explore the evolution of the invertebrates in light of various combinations of these basic functional body plans and lifestyles. With this background, you should be able to follow the evolutionary changes and branchings among the invertebrate phyla, their body systems, and their various pathways to success on Earth. Note that chapters treating large phyla (e.g., molluscs, annelids, the arthropods) have rather lengthy taxonomic synopses sections. We don't expect students to read every word of these synopses; they are provided more as a source reference for readers to look up taxa within the context of our current state of knowledge for the groups.

Through our approach, we hope to add continuity to the massive subject of invertebrate zoology, which is often covered (in texts and lectures) by a sort of "flash-card" method, in which the primary goal is to have the student memorize animal names and characteristics and keep them properly associated, at least until after the examination. Thus, we urge you to look back frequently at these first few chapters as you read ahead and explore how invertebrates are put together, how they live, and how they evolved.

CHAPTER 2

Systematics, Phylogeny, and Classification

This book deals with the field of comparative biology, or what may be called the science of the diversity of life. Scientists may use comparative biology for many reasons, but evolutionary biologists use it to study the characteristics of organisms in ways that allow them to estimate the history of life. Biologists have been undertaking comparative studies of anatomy, morphology, embryology, physiology, and behavior for over 150 years. And for the past 20 years or so, comparative molecular phylogenetics and evolutionary-developmental biology ("EvoDevo") have played critically important roles. Because we cannot directly observe the history of life (aside from the paleontological record), we must rely on the strength of the scientific method to reconstruct it, or infer it. This chapter provides an overview of this process. Comparative biology, then, in its attempt to understand diversity in the living world, deals with three distinguishable elements: (1) descriptions of organisms, particularly in terms of similarities and differences in their attributes (including their genetic characteristics); (2) the phylogenetic history of organisms through time; and (3) the distributional history of organisms in space. Many comparative biologists think of themselves as systematists. Systematics is the science of documenting Earth's biological diversity, reconstructing the history of that biodiversity, and developing natural classifications that reflect its evolutionary history.

The field of biological systematics has experienced a revolution in its theory and application in the past 40 years, especially with regard to phylogenetic reconstruction. Some philosophical aspects and operating principles of this exciting field are described in this chapter. It is essential that biology students have a basic grasp of how classifications are developed and phylogenetic relationships inferred, and we urge you to reflect carefully on the ideas presented in this introductory chapter.

Today, our classifications of life are built upon careful phylogenetic analyses of morphological, developmental, and genetic characteristics of species that we hypothesize reflect their evolutionary history. More and more,

---

The chapter opener photo shows representatives of two phyla that are only distantly related, deeply in time: sponges (Porifera) and crabs (Arthropoda). Both are ancient phyla that arose in Precambrian seas more than 550 million years ago.

we rely on molecular sequence data from genes as our basis for these analyses. But this process is not always straightforward. Genes (and morphology) can trick us in many ways. Similarities can come about in indirect ways, characters can be lost or transformed in ways that are not always obvious, and many long held ideas about animal development have recently been altered (or even overturned). In this chapter, we will help you understand the underpinnings of comparative biology as it relates to phylogenetic analysis and the construction of classifications.

Biological Classification

> *And you see that every time I made a further division, up came more boxes based on these divisions until I had a huge pyramid of boxes. Finally you see that while I was splitting the cycle up into finer and finer pieces, I was also building a structure. This structure of concepts is formally called a hierarchy and since ancient times has been a basic structure for all Western knowledge.*
>
> Robert M. Pirsig
> *Zen and the Art of Motorcycle Maintenance*, 1974

The term **biological classification** has two meanings. First, it means the *process* of classifying, which consists of delimiting, ordering, and ranking organisms in groups. Second, it describes the *product* of this process, or the classification scheme itself. The living world has an objective structure that can be empirically documented and described. One goal of biology is to discover and describe this structure, and classifications are one way of doing this. Carrying out the process of biological classification constitutes one of the principal tasks of the systematist.

The construction of a classification may at first appear straightforward; basically, the process consists of analyzing patterns in the distribution of characters among organisms. On the basis of such analyses, specimens are grouped into species (the word "species" is both singular and plural); related species are grouped into genera (singular, genus); related genera are grouped to form families; and so forth. The grouping process creates a system of subordinated, or nested, taxa (singular, taxon) arranged in a hierarchical fashion following basic set theory. If the taxa are properly grouped according to their degree of shared similarity (that is, on the basis of shared derived characteristics), the hierarchy will reflect patterns of evolutionary descent—the "descent with modification" of Darwin and Wallace.

The concept of similarity is fundamental to taxonomy, the classificatory process, and comparative biology as a whole. Similarity, evaluated on the basis of characteristics shared among organisms, is generally accepted by biologists to be a measure of biological (evolutionary) relatedness among individuals and taxa. The concept of relatedness, or genealogical kinship, lies at the core of systematics and evolutionary biology. Patterns of relatedness are usually displayed by biologists in branching diagrams called **trees** (e.g., phylogenetic, genealogical, or evolutionary trees). Once constructed, such trees can then be converted into classification schemes, which are a dynamic way of representing our understanding of the history of life on Earth. Thus, trees and classifications are actually hypotheses of the evolution of life and the natural order it has created.

Classifications are necessary for several reasons, not the least of which is to efficiently catalog the enormous number of species of organisms on Earth. Nearly two million species of prokaryotes and eukaryotes have been named and described (and a great many more remain undescribed). The insects alone comprise nearly a million named species, and over 350,000 of those are beetles! Classifications provide a detailed system for storage and retrieval of these names. Second, and most important to evolutionary biologists, classifications serve a descriptive function. This function is served not only by the descriptions that define each taxon, but also, as noted above, by the detailed hypotheses of evolutionary relationships among the organisms that inhabit Earth. In other words, classifications are (or should be) constructed from evolutionary relationships; that is, from the patterns of ancestry and descent depicted in phylogenetic trees.

If biological classification schemes summarize the hypotheses defined by phylogenetic trees, then classifications, like other hypotheses in science, have a third function—prediction. And like all hypotheses, the more precise and less ambiguous the classification, the greater its predictive value. Predictability is another way of saying testability, and it is testability that places an endeavor in the realm of science rather than in the realm of art, faith, or rhetoric. Like other hypotheses (or theories), classifications are always subject to refutation, refinement, and growth as new data become available. These new data may be in the form of newly discovered species or characteristics of organisms, new tools for the analysis of characters, or new ideas regarding how characteristics are evaluated. Changes in classifications reflect changes in our view and understanding of the natural world.

Nomenclature

The names employed within classifications are governed by rules and recommendations that are analogous to the rules of grammar that govern Western languages. The most fundamental goals of **biological nomenclature** are the creation of classifications in which (1) any single kind of organism has one and only one correct

name, and (2) no two kinds of organisms bear the same name. All of the codes of nomenclature for the various groups of life address these two fundamental requirements. Nomenclature is an important tool of biologists that facilitates communication and stability.[1]

Prior to the mid-1700s, animal and plant names consisted of one to several words or often simply a descriptive phrase. In 1735, at the age of just 28, the great Swedish naturalist Carl von Linné (Carolus Linnaeus, in the Latinized form he preferred) established a system of naming organisms now referred to as binomial nomenclature. Linnaeus's system required that every organism have a two-part scientific name, that is, be a **binomen**. The two parts of a binomen are the generic, or genus name and the specific name, or specific epithet. For example, the scientific name for one of the common Pacific coast sea stars is *Pisaster giganteus*. These two names together constitute the binomen; *Pisaster* is the animal's generic (genus) name, and *giganteus* is its specific epithet. The specific epithet is never used alone, but must be preceded by the generic name, and the animal's "species name" is thus the complete binomen. Use of the first letter of a genus name preceding the specific epithet is also acceptable once the name has appeared spelled out on the page or in a short article (e.g., *P. giganteus*).

The 1758 version of Linnaeus's system was the tenth edition of his famous *Systema Naturae*, in which he listed all animals known to him at that time and included critical guidelines for classifying organisms. Linnaeus distinguished and named over 4,400 species of animals, including *Homo sapiens*. Linnaeus's *Species Plantarum* (in which he named over 8,000 species) did the same for the plants in 1753. Linnaeus was one of the first naturalists to emphasize the use of similarities among species (or among other taxa) in constructing a classification, rather than using differences between them. In doing so, he unknowingly began classifying organisms by virtue of their genetic, and hence evolutionary, relatedness. Linnaeus produced his *Systema Naturae* 100 years prior to the appearance of Darwin and Wallace's theory of evolution by natural selection (1859), and thus his use of similarities in classification foreshadowed the subsequent emphasis by biologists on evolutionary relationships among taxa. Linnaeus was granted nobility in 1761 (and became Carl von Linné); he died in 1778.

[1]We generally avoid using common, or vernacular, names in this book, simply because they are frequently misleading. Most invertebrates have no specific common name, and those that do typically have more than one name. For example, several dozen different species of sea slugs are known as "Spanish dancers." All manner of creatures are called "bugs," most of which are not true bugs (Hemiptera) at all, e.g., "ladybugs," "sowbugs," "potato bugs," and so on. Recently, there has been a movement to codify common names, in an attempt to establish a single preferred vernacular for any given species. This movement is taking place mainly among vertebrate specialists, and there is, as yet, no widely accepted initiative to do this for invertebrates.

Binomens are Latin (or Latinized) because of the custom followed in Europe prior to the eighteenth century of publishing scientific papers in Latin, the universal language of the educated people of the time. For several decades after Linnaeus, names for animals and plants proliferated, and there were often several names for any given species (different names for the same species are called **synonyms**). The name in common use was usually the most descriptive one, or often it was simply the one used by the preeminent authority of the time. In addition, some generic names and specific epithets were composed of more than one word each. This lack of nomenclatural uniformity led, in 1842, to the adoption of a code of rules formulated under the auspices of the British Association for the Advancement of Science, called the Strickland code. In 1901 the newly formed International Commission on Zoological Nomenclature adopted a revised version of the Strickland code, called the **International Code of Zoological Nomenclature (ICZN)**. Botanists had adopted a similar code for plants in 1813, the Théorie Elémentaire de la Botanique, which became in 1930 the International Code of Botanical Nomenclature (there is also a separate, but complementary code for cultivated plants). Since then, it has been revised as the International Code of Nomenclature for Algae, Fungi, and Plants. There is also an International Code of Nomenclature of Bacteria.

The ICZN established January 1, 1758 (the year the tenth edition of Linnaeus's *Systema Naturae* appeared) as the starting date for modern zoological nomenclature. Any names published the same year, or in subsequent years, are regarded as having appeared after the *Systema*. The ICZN also slightly changed the description of Linnaeus's naming system, from binomial nomenclature (names of two parts) to **binominal nomenclature** (names of two names). However, one still sees the former designation in common use. This subtle change implies that the system must be truly binary; that is, both generic and trivial names can be only one word each. Although the system is binary, it also accepts the use of subspecies names, creating a **trinomen** (three names) within which is contained the mandatory binomen. For example, the sea star *Pisaster giganteus* is known to have a distinct form occurring in the southern part of its range, which is designated as a subspecies, *Pisaster giganteus capitatus*.

All codes of biological nomenclature share the following five basic principles:

1. Botanical, bacterial, and zoological codes are independent of each other. It is therefore permissible, although not recommended, for a plant genus and an animal genus to bear the same name (e.g., the name *Cannabis* is used for both a plant genus and a bird genus).

2. A taxon can bear one and only one correct name.
3. No two genera within a given code can bear the same name (i.e , generic names are unique); and no two species within one genus can bear the same name (i.e., binomens are unique).
4. The correct or valid name of a taxon is based on priority of publication (first usage).
5. For the categories of superfamily in animals and order in plants, and for all categories below these, taxon names must b e based on type specimens, type species, or type genera.[2]

When strict application of a code results in confu sion or ambiguity, problems are referred to the appropriate commission for a "legal" decision. Rulings of the International Commission on Zoological Nomenclature are published regularly in its journal, the Bulletin of Zoological Nomenclature. Note that the international commissions rule only on nomenclature or "legal" matters, not on questions of scientific or biological interpretation; these latter problems are the business of systematists. Obviously, the correct name of a species (and any future changes in that name) has great importance to all fields of biology (e.g., ecology, conservation biology, physiology) because scientists must know the correct names of their study organisms in order to communicate about them.

The hierarchical categories recognized by the ICZN are as follows:

Kingdom
  Phylum
    Class
      Cohort
        Order
          Family
            Tribe
              Genus
                Species
                  Subspecies

The above names represent categories; the actual ani mal group that is placed at any particular categorical level forms a taxon. Thus, the taxon Echinodermata is placed at the hierarchical level corresponding to the category phylum Echinodermata is the taxon, phy lum is the category. All categories (and taxa) above the species level are referred to as the higher categories (and higher taxa), as distinguished from the species group categories (species and subspecies). Taxonomic ranks may have super-, and sub, and infracategories as well, e g., superorder, suborder, infraorder

The common Pacific sea star *Pisaster giganteus* is classified as follows:

Category	Taxon
Phylum	Echinodermata
Subphylum	Asterozoa
Class	Asteroidea
Order	Forcipulatida
Family	Asteriidae
Genus	*Pisaster*
Species	*Pisaster giganteus* (Stimpson, 1857)

Notice that a person's name follows the species name in this classification. This is the name of the author of that species the person who first described the spe cies and gave it its name. In this particular case the author's name is in parentheses, which indicates that this species is now placed in a different genus than originally assigned by Professor Stimpson. Authors' names usually follow the first usage of a species name in the primary literature (i.e , articles published in profession al scientific journals). In the secondary literature, such as textbooks and popular science magazines, authors' names are rarely used.

The names given to animals and plants are usually descriptive in some way, or perhaps indicative of the geographic area in which the species occurs. Others are named in honor of persons for one reason or another Occasionally one runs across purely whimsical names, or even names that seem to have been formulated for seemingly diabolical reasons.[3]

The biological species definition (or genetical species concept), as codified by Ernst Mayr, defines species as groups of interbreeding (or potentially interbreeding) natural populations that are reproductively isolated from other such groups. Obviously, this definition fails to accommodate nonsexual species. George Gaylord Simpson and Edward O. Wiley developed the evolutionary species concept, which states that a species is a single lineage of ancestor-descendant populations that maintains its identity separate from other such lineages and that has its own evolutionary tendencies and histor ical fate. In reality, of course, biologists rely heavily on morphological aspects of organisms (and increasingly on gene sequence data) as surrogates in gauging these conceptual views of species. That is, we conceive of species as genetic or evolutionary ent.ties, but we recognize them primarily by their phenotypic (or gene sequence) characters. Hence, an understanding of such characters is of great importance; read on.

Higher taxa (categories and taxa above the species level) are natural groups of species (or lineages) chosen by biologists for naming in order to reflect our state of knowledge regarding their evolutionary relationships.

---

[2]When a biologist first names and describes a new species, he or she takes a "typical" or representative individual, declares it a type specimen, and deposits it in a safe repository such as a large natural history museum. If later workers are ever uncertain about whether they are working with the same species described by the original author, they can compare their material to the type specimen Although of substantially less value, the designation of a "typical" or type species for a genus, or a type genus for a family, serves a somewhat similar purpose in establishing, a "typical" species or genus upon which a genus or family is based.

Higher taxa, if correctly constructed, represent ancestor–descendant lineages (or clades) that, like species, have an origin, a common ancestry and descent, and eventually a death (extinction of the lineage); thus they too are evolutionary units with definable boundaries. There are no rules for how many species should make up a genus—only that it be a natural group. Nor are there rules about how many genera constitute a family, or whether any group of genera should be recognized as a family, or a subfamily, or an order, or any other categorical rank. What matters is simply that the named group (the taxon) be a natural group. Hence, it is incorrect to assume that families of insects are in some way evolutionarily comparable to families of molluscs, or orders of worms comparable to orders of crustaceans. Nor are there any rules about categorical rank and geological or evolutionary age. These aspects of higher taxa are often misunderstood. Interestingly, this being said, family level taxa often tend to be the most stable taxonomic groupings, usually recognizable even to laypersons—think, for example, of cats (Felidae), dogs (Canidae), abalone (Haliotidae), ladybird beetles (Coccinellidae), mosquitoes (Culicidae), octopuses (Octopodidae), or weevils (Curculionidae). This stability seems to be an artifact of the history of taxonomy, but it nonetheless makes families convenient higher taxa to study and discuss. However, biologists err when they compare equally ranked higher in ways that presuppose them to be somehow equivalent.

Systematics

The science of systematics is the oldest and most encompassing of all fields of biology. To paraphrase the eminent biologist G. G. Simpson, systematics is the study of the diversity of life on Earth, and of any and all relationships among species. The modern systematist is a natural historian of the first order. His or her training is broad, cutting across the fields of zoology and botany, genetics, paleontology, biogeography, geology, historical biology, ecology, and even ethology, chemistry, philosophy, and cellular and molecular biology. Ernst Mayr said that the field of systematics can be thought of as a continuum, from the routine naming and describing of species (a process known

---

[3]Among the many clever names given to animals are *Agra vation* (a tropical beetle that was extremely difficult for Dr Terry Erwin to collect) and *Lightiella serendipida* (a small crustacean; the generic name honors the famous Pacific naturalist S F Light, 1886–1947, while the species epithet is taken from "serendipity," a word coined by Walpole in allusion to the tale of "The Three Princes of Serendip," who in their travels were always discovering, by chance or sagacity, things they did not seek—the term is said to aptly describe the circumstances of the initial discovery of this species). There are actually over 500 described species of *Agra* (those carabid beetles known as "elegant canopy beetles"), including *Agra eponine*, named after the street urchin in *Les Miserables* who, in the Broadway version of the story, personified tragic beauty ("such is the state of the tropical forests where these beetles live," according to Dr. Erwin, who also named this species). Another of Erwin's names is *Agra ichabod*, referring to the fact that the holotype is missing its head, the allusion referring to the frightened schoolteacher Ichabod Crane's phantom nemesis, the Headless Horseman, in "The Legend of Sleepy Hollow." The nineteenth-century British naturalist W E Leach erected numerous genera of isopod crustaceans whose spellings were anagrams of the name Caroline. Exactly who Caroline was (and the nature of her relationship with Professor Leach) is still being debated, but the prevailing theory implicates Caroline of Brunswick, who was in the public eye at this time in history. It is said that Caroline was badly treated by her husband (the Prince Regent, later George IV), and that she was herself a lady of questionable fidelity. Leach, from Devon, may have taken the side of support for Caroline by honoring her with a long series of generic names, including *Cirolana*, *Innocira*, *Rocinela*, *Neracila*, *Anilocra*, *Conilera*, *Olincera*, and others.

A light-hearted attitude toward naming organisms has not always been without Freudian overtones, as there also exist *Thetys vagina* (a large, hollow, tubular pelagic salp), *Succinea vaginacontorta* (a hermaphroditic snail whose vagina twists in corkscrew fashion), *Phallus impudicus* (a slime-covered mushroom), and *Amanita phalloides* and *Amanita vaginata* (two species of highly toxic mushrooms around which numerous aboriginal ceremonies and legends exist). *Humbert humberti* is a wasp named after Vladimir Nabokov's Humbert Humbert, the narrator in the great novel *Lolita* who was obsessed with his 12 year old, soon to be stepdaughter. *Crepidula fornicata* is a hermaphroditic slipper shell (gastropod) that forms stacks of alternating male functioning/female-functioning individuals (males on top turn into females as they grow). Injecting a lyrical dose of sexual innuendo into taxonomy is not new. Linnaeus himself incorporated a few good zingers into his writings and, in fact, drew parallels between plant sexuality and human love. In 1729 he wrote of flower petals, "[These] serve as bridal beds which the Creator has so gloriously arranged, adorned with such noble bed curtains, and perfumed with so many soft scents, that the bridegroom with his bride might there celebrate their nuptials with so much the greater solemnity." Such sexually explicit writing (in the early eighteenth century) did not go uncriticized, and Linnaeus had his detractors. The German botanist Johann Siegesbeck (a Demonstrator at the Botanical Garden at St. Petersburg) called it "loathsome harlotry" and commented, "Who would have thought that bluebells, lilies, and onions could be up to such immorality?" Linnaeus had his revenge, however, when he named a small, ugly, foul smelling, mud inhabiting European weed (St. Paul's wort) *Siegesbeckia*.

Other fun names include the hoopoe (a bird), *Upupa epops*, euphoniously named for its call, and the fish *Zappa confluentus*, which was named by a fan of Frank Zappa's The Grateful Dead have a fly named in their honor (*Dicrotendipes thmatogratus*). And there is the vampire squid *Vampyroteuthis infernalis* (the "vampire squid from hell"), a bivalve named *Abra cadabra*, a blood sucking spider *Draculoides bramstokeri*, and a wasp *Alia lia*. Even Linnaeus created a curious name for a common ameba, *Chaos chaos*. And, in a stroke of whimsy, the entomologist G. W. Kirkaldy created the bug genera *Polychisme* ("Polly kiss me"), *Peggichisme*, *Marichisme*, *Dolychisme*, and *Florichisme*. There are fish genera named *Zeus*, *Satan*, *Zen*, *Batman*, and *Sayonara*. There are insect genera named *Cinderella*, *Aloha*, *Oops*, and *Euphoria*. Some other clever binomens include *Leonardo davincii* (a moth), *Phthiria relativitae* (a fly), and *Ba humbugi* (a snail). A few biologists have gone overboard in erecting names for new animals, and many binomens exceed 30 letters in length, including those of the chaetognath *Sagitta pseudoserratadentatoides* (31 letters) and the common North Pacific sea urchin *Strongylocentrotus droebachiensis* (31 letters). *Lageniwaginopsendobenedenia* is a 27-letter genus name for a group of monogenean flukes. Amphipod crustaceans probably win the grand prize in the longest overall name category, with *Siemienkiewicziechinogammarus siemienkiewitschi* (47 letters) and *Cancelloidokytodermogammarus* (*Loveninsuskytodermogammarus*) *loveni* (61 letters, including the subgenus name); these are cases in which the journal editor simply was not doing his or her job properly!

as taxonomy) through the compilation of large faunal compendia and monographs, to more synthetic studies such as the fitting of these species into classifications that depict evolutionary relationships, generating phylogenetic hypotheses based on morphological or molecular genetic data, biogeographic analyses, studies of population biology and genetics, and evolutionary and speciation studies. Mayr designated three stages of study within this continuum, which he called alpha, beta, and gamma, corresponding to the three general levels of complexity he perceived in systematics. When a group of organisms is first discovered or is in a poorly known state, work on that group is necessarily at the alpha level (e g , the describing of new species, or taxonomy). It is only when most, or at least many, species in a taxon become known that the systematist is able to work at the beta or gamma levels within that group (e.g , to perform evolutionary studies). These stages in systematic research overlap and cycle back on themselves in a highly iterative fashion. In sum, the role of systematics is to document and understand Earth's biological diversity, to reconstruct the history of that biodiversity, and to develop natural (evolutionary) classifications of living organisms.

Systematists use a great variety of tools to study the relationships among taxa. These tools include not only the traditional and highly informative techniques of comparative and functional anatomy, but also the methods of embryology, serology, physiology, immunology, biochemistry, population and molecular genetics, and molecular gene sequencing (which now works at the genomic level). A sound classification lies at the root of any study of evolutionary significance. Without systematics, the science of biology would grind to a halt, or worse yet, would drift off into pockets of isolated reductionist or deterministic schools with no conceptual framework or continuity.

Monophyly, Paraphyly, and Polyphyly

One of the concepts most crucial to our understanding of biological systematics and evolution in general is monophyly. A **monophyletic group** (or monophyletic taxon) is a group of species that includes all of the descendants of a common ancestor—that is, a natural group (Figure 2.1). Species belonging to a monophyletic group are related to one another through a unique history of descent (with modification) from a common ancestor—a single evolutionary lineage. Another name for a monophyletic group is a clade.

A group whose member species are all descendants of a common ancestor, but that does *not* contain all the species descended from that ancestor, is called a **paraphyletic group**. Paraphyly implies that for some reason (e g , lack of knowledge, purposeful manipulation of a classification) one or more members of a natural group have been separated out and placed in a different group. As we will see below, a great many paraphyletic taxa exist within animal classifications today Some biologists consider paraphyly a subset of monophyly, using the term holophyly to denote the strictly monophyletic groups. However, this alternative use of these terms is not common and we do not use it in this book.

A third possible kind of taxon is a **polyphyletic group** a group comprising species that arose from two or more, different immediate ancestors. Such

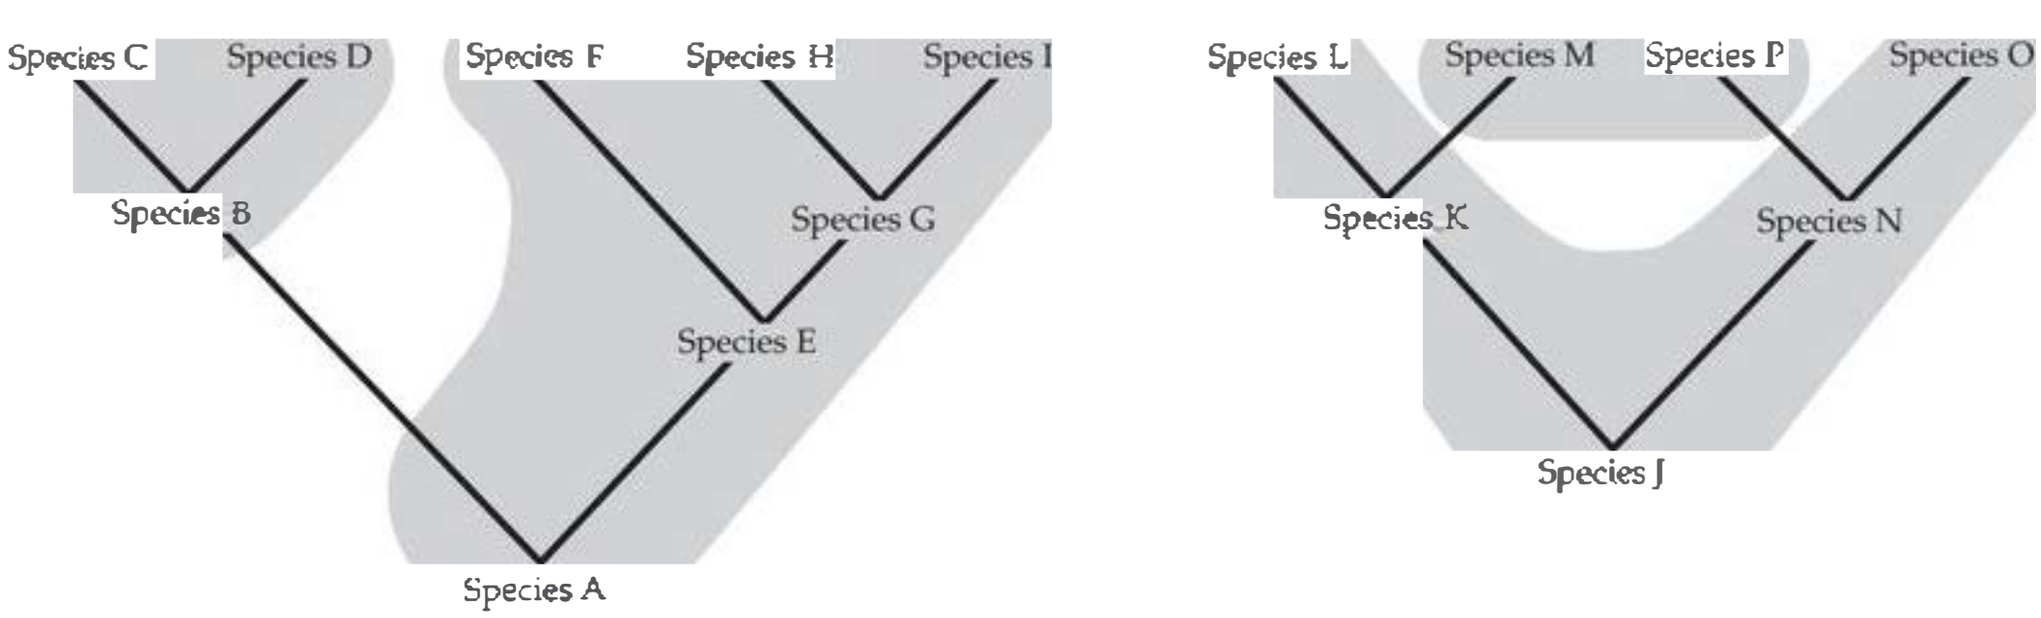

Figure 2.1 Two trees (dendrograms), illustrating three kinds of taxa. Taxon W, compris ng three spec es, is monophyletic because it conta ns an ancestor (species B) and al its descendants (species C and D). Taxon X is paraphyletic because it includes an ancestor (spec es A), but only some of its descendants (species E through I, leaving out species B, C, and D). Taxon Y is polyphyletic because it contains taxa that are not derived from an immediate common ancestor spec es M and P may look very much alike as a result of evolutionary convergence or parallelism, and therefore may have been mistakenly placed together n a single taxon. Taxon Z is paraphy etic. In this case, further systematic research should eventually reveal the correct relationships among these taxa, resulting n species M being classified w th species K and L, and species P w th species N and O.

composite taxa would have been established because of insufficient knowledge concerning the species in question. One of the principal goals of systematists is to discover such polyphyletic or "artificial" taxa and, through careful study, reclassify their members into appropriate monophyletic taxa. These three kinds of taxa or species groups are illustrated diagrammatically in Figure 2.1.

There are many examples of known or suspected polyphyletic taxa in the zoological literature. For example, the old phylum Gephyrea contained species that we now classify into three distinct taxa that are only distantly related to one another—Sipuncula, Echiura, and Priapula. Another example is the old group Radiata, which included all animals possessing radial symmetry (e g , cnidarians, ctenophores, and echinoderms). Most recently, the group called Articulata, containing the annelids and the arthropods (and their kin), has been shown by molecular phylogenetics to be polyphyletic. Polyphyletic taxa usually are established because the features or characters used to recognize and diagnose them are the result of evolutionary convergence in different lineages, as discussed below. Convergent evolution can often be understood only by careful comparative embryological or anatomical studies, sometimes requiring the efforts of several generations of specialists. The complex nature of the probable convergence between annelid and arthropod segmental development, for example, is yet to be fully worked out.

Characters and the Concept of Homology

Characters are the attributes, or features, of organisms or groups of organisms (clades, taxa) that biologists rely on to indicate their relatedness to other similar organisms and to distinguish them from other groups. Characters are the observable features and expressions of the genotype, and they can be anything from the actual amino acid sequences of the genes themselves to the phenotypic expressions of the genotype A character can be any genetically based trait that taxonomists can examine and measure, it can be a morphological, anatomical, developmental, or molecular feature of an organism, its chromosomal makeup (karyotype) or biochemical "fingerprint," or even a physiological, or ethological (behavioral) attribute. A large number of biochemical and molecular techniques for measuring similarity and inferring relationships among organisms have been developed over the past few decades Thus, a variety of kinds of data are available that provide systematists with the characters needed to define and compare species and infer phylogenies.

The fundamental basis for comparative biology is the concept of **homology**. Characters that share descent from a common ancestor are called homologues. In other words, **homologues** are characters that are present in two or more taxa, but are traceable phylogenetically and ontogenetically (i e., they share genetic and developmental ancestry) to the same character in the common ancestor of those taxa. In order to compare characters among different organisms or groups of organisms, it must be established that the characters being compared are homologous. Our ability to recognize anatomical homologues often depends on developmental or embryological evidence and on the relative position of the anatomical structure in adults (Chapter 5).

Homology is an absolute relationship: characters either are or are not homologous. Homology is also completely independent of function. The functions of homologous structures may be similar or different, but this has no bearing on the underlying homology of the structures involved. Genes, like anatomical structures, may be homologous if they are derived from a common ancestral gene either by duplication (which generates paralogous genes) or as simple copies passed on via reproduction and descent, including through speciation events (orthologous genes). The process of evolutionary descent with modification has produced a hierarchical pattern of homologies that can be traced through lineages of living organisms. It is this pattern that we use to reconstruct the history of life.

Homology is a concept that is applicable to anatomical structures, to genes, and to developmental processes. However, homology at one of these levels does not necessarily indicate homology at another. Biologists should always be clear regarding the level at which they are inferring homology: genes, their expression patterns, their developmental roles, or the structures to which they give rise. Researchers sometimes assume similar patterns of regulatory gene expression are also evidence of homology among structures. This is a mistake because it ignores the evolutionary histories of the genes and of the structures in which they are expressed. The functions of homologous genes (orthologues or paralogues), just like those of homologous structures, can diverge from one another over evolutionary time Similarly, the functions of nonhomologous genes can converge over time Therefore, similarity of function is not a valid criterion for the determination of homology of either genes or structures. For example, the phenomenon of gene recruitment (co-option) can lead to situations in which truly orthologous genes are expressed in nonhomologous structures during development. Most regulatory genes play several distinct roles during development, and homologous genes can be independently recruited to superficially similar roles. A classic example is the regulatory gene *Distal-less*, which is expressed in the distal portion of appendages of many animals during their embryogeny (e.g , arthropods, echinoderms, chordates). Although the domains of *Distalless* gene expression might reflect a homologous role in specifying proximodistal axes of appendages, the appendages themselves are clearly not homologous.

Attempts to relate two taxa by comparing nonhomologous characters will result in errors. For example, the hands of chimpanzees and humans are homologous characters (i.e , homologues) because they have the same evolutionary and developmental origin; the wings of bats and butterflies, although similar in some ways, are not homologous characters because they have completely different origins. In a strict sense, the concept of homology has nothing to do with similarity or degree of resemblance Some homologous features look very different in different taxa (e g., the pectoral fins of whales and the arms of humans; the forewings of beetles and of flies). Again, the concept of homology is related to the level of analysis being considered. The wings of bats and birds are homologous as tetrapod forelimbs, but they are not homologous as "wings," because wings evolved independently in these two groups (i.e., the wings of bats and birds do not share a common ancestral wing). Homology is a powerful concept, but it is important to remember that homologies are really hypotheses, open to testing and possible refutation.

Through the phenomenon of **convergent evolution**, similar appearing (but nonhomologous) structures may evolve in distantly related groups of organisms in quite different ways; that is, they have separate genetic and developmental origins. For example, early biologists were misled by the superficial similarities between the vertebrate eye and the cephalopod eye, the bivalve shells of molluscs and of brachiopods, and the sucking mouthparts of true bugs (Hemiptera) and of mosquitoes (Diptera). Structures such as these, which appear superficially similar but that have arisen independently and have separate genetic and phylogenetic origins, are called convergent characters. There are both ecological and genomic explanations for the evolution of morphological similarity. Through the phenomenon of convergent evolution, similarappearing structures have arisen independently, with separate genetic and developmental origins, in response to the same ecological factors. Convergent traits in animals and plants have been recognized at nearly all levels of biological organization, ranging from molecules to morphology to behaviors

One of the most interesting cases of convergent evolution is the recently discovered analogies between voice and vocal learning in some mammals and birds (vocal learning is the ability to imitate sounds). Not only have the vocal areas of certain bird and mammal brains converged in their anatomy, but more than 50 genes have contributed to their convergent specialization—convergent behavior and neural circuits for vocal learning are accompanied by convergent molecular changes of multiple genes in species separated by millions of years from a common ancestor.

Convergence is often confused with parallelism. Parallel characters are similar features that have arisen more than once in different species, but that share a common genetic and developmental basis. Parallel evolution is the result of "distant" or underlying homology; for parallel evolution to occur, the genetic potential for certain features must persist within a group, thus allowing the feature to appear and reappear in various related species or groups of species. Parallelism might be thought of as a kind of "evolutionary redundancy."[4] Failure to recognize convergences (and parallelisms) among different groups of organisms has led to the creation of "unnatural," or polyphyletic, taxa in the past. For example, the intracellular parasites known as Myxozoa were long thought to be protists, but have recently been shown to be highly specialized parasitic cnidarians. These and some other groups (e g , yeasts) mistakenly classified among the Protista made protists a polyphyletic group; removal of those nonprotistan taxa has left the Protista a paraphyletic group (a natural group, with a single origin, but from which animals, plants and fungi are excluded). Parallelism is commonly encountered in characters of morphological "reduction," such as reduction in the number of segments, spines, fin rays, and so on in many different kinds of animals.

A third phenomenon in this general category is evolutionary reversal, wherein a feature reverts back to a previous, ancestral condition. Together, these three evolutionary processes (convergence, parallelism, reversal) constitute the phenomenon known as **homoplasy**—the recurrence of similarity in evolution (Figure 2.2). As you might guess, for systematists, homoplasy can be both fascinating and frustrating!

When comparing homologues among species, one quickly sees that variation in the expression of a character is the rule, rather than the exception. The various conditions of a homologous character are often referred to as its **character states**. A character may have only two contrasting states, or it may have several different states within a taxon. Polymorphic species are those that show a range of phenotypic or genetic variation as a result of the presence of numerous character states for the features being examined. A simple example is hair color in humans; black, brown, red, and blond are all states of the character "hair color." Not only can characters vary within a species, they also typically have several states among groups of species within higher taxa, such as patterns of body hair among various primates or the spine patterns on the legs of crustaceans[5]

---

[4]Parallelism in this context is not to be confused with the evolution of species (or characters within species) "in parallel," that is, when two species (or characters) change more or less together over time. Host–parasite coevolution is an example of "evolution in parallel."

[5]In practical usage the terms "character" and "character state" are often used interchangeably. This practice can be a bit confusing When the term "character" is used in a discussion of two or more homologues, it is typically being used in the same sense as "character state"

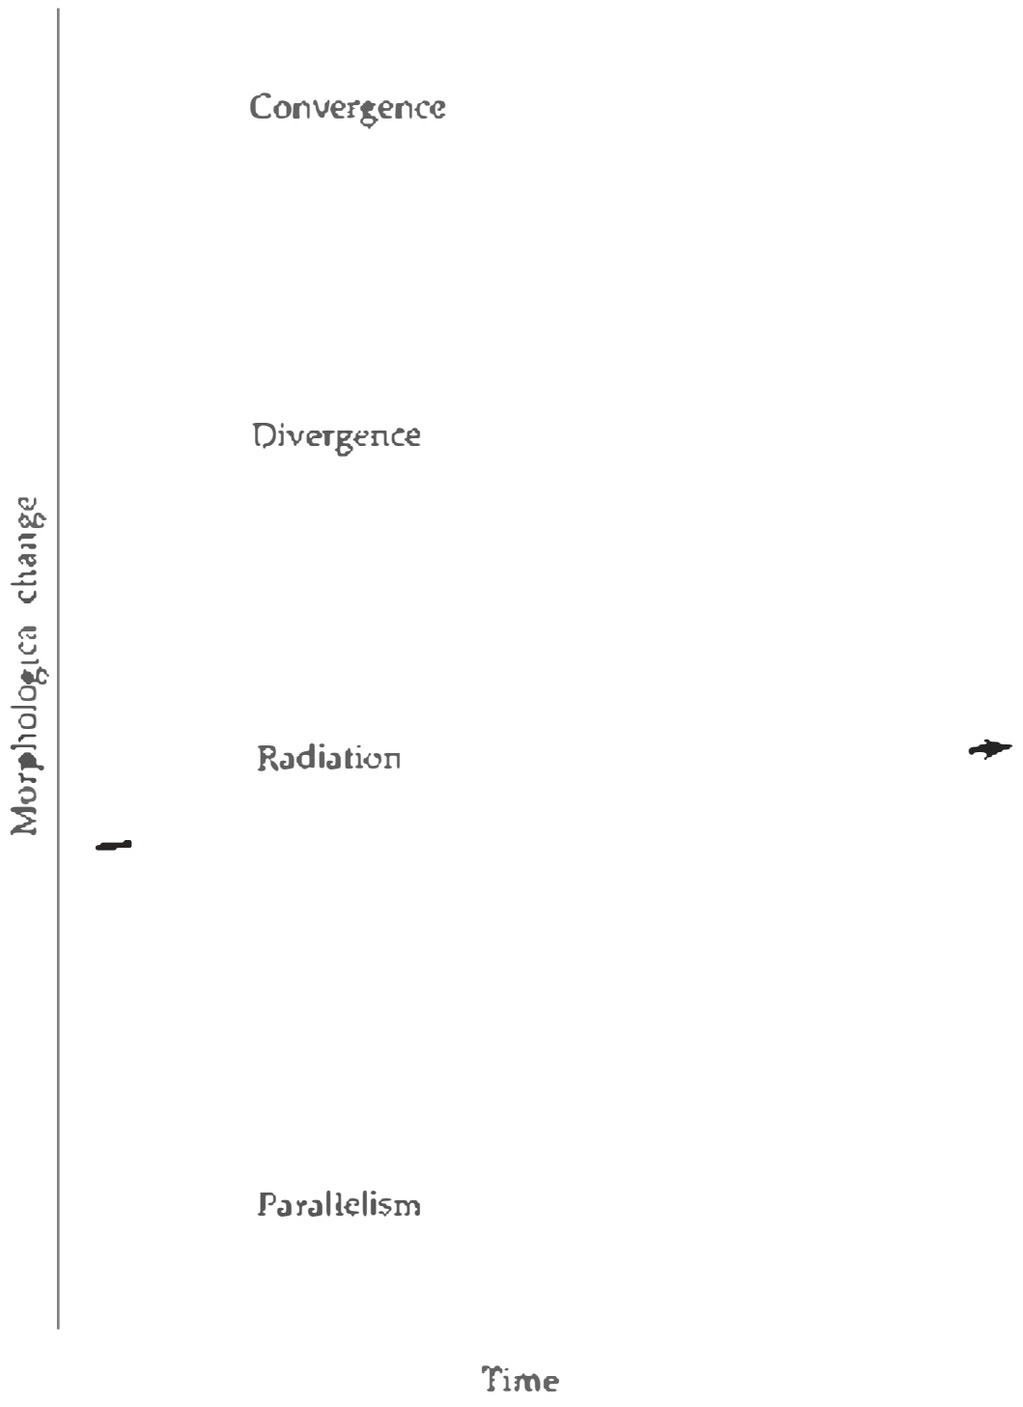

Figure 2.2 Common patterns of evolution displayed by independent lineages. Convergence occurs when two or more lineages (or characters) evolve independently toward a similar state. Convergence generally refers to very distantly related taxa and to characters sharing no common genetic (phylogenetic or ontogenetic) basis. Divergence occurs when two or more lineages (or characters) evolve independently to become less similar. Radiations are multiple divergences from a common ancestor that result in more than two descendant lineages. Parallel evolution occurs when two or more species (or lineages) change similarly so that, despite evolutionary activity, they remain similar in some ways. Parallelism generally refers to closely related taxa, usually species, within which the characters or structures in question share a common genetic basis

It is important to understand that what we designate a "character" is really a hypothesis—that two attributes that appear different in different organisms are simply alternative states of the same feature (i.e., they are homologues). Note that convergences are not homologies, whereas parallelisms and reversals do represent an underlying genetic homology. In other words, some kinds of homoplastic characters are homologues, and others are not. The recognition and selection of proper characters is clearly of primary importance in systematics and phylogenetics, and a great deal has been written on this subject. Systematics is, to a great extent, a search for the homologues that define natural evolutionary lineages. Most recently, great efforts have been made to define homologous gene sequences that can serve as reliable characters to infer relationships among species.

Phylogenetic Trees

Another important concept in systematics and comparative biology is the **phylogenetic tree**. A phylogenetic tree is a branching diagram depicting the relationships among groups of organisms. It is a graphical means of expressing relationships among species or other taxa. Most trees are intended to depict genealogical or evolutionary relationships, with the base representing the oldest (earliest) ancestors and the higher branches indicating successively more recent divisions of evolutionary lineages. Most modern phylogenetic trees, whether based on morphology or gene sequence data, also have an implied (or explicit) time axis, although not all do.

When examining trees and classifications derived from them, it is important to understand the concept of grades and clades. As depicted in Figure 2.3, a clade is a monophyletic group or branch of a tree, which may undergo very little or a great deal of diversification. A clade, in other words, is a group of species related by direct descent a natural group. A grade, on the other

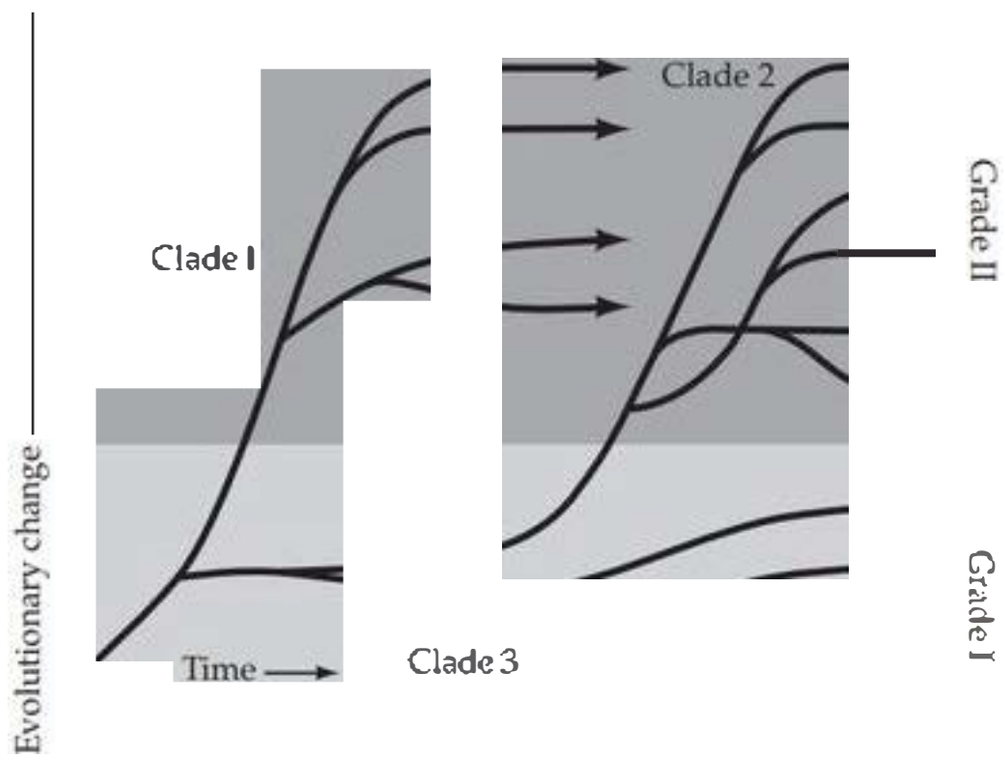

Figure 2.3 Clades and grades Clades are monophyletic branches in a tree. Grades are groups of organisms classified together on the basis of levels of functional or morphological complexity. Grades may be monophyletic, paraphyletic, or polyphyletic. In this figure, grade I is monophyletic, encompassing only a single clade (clade 3); grade II is polyphyletic, because the associated level of complexity has been achieved independently by two separate lineages, clades 1 and 2. An example of a polyphyletic animal clade is "slugs," which comprise a cluster of groups of gastropods that have all lost their shells independently.

hand, is a group of species (or higher taxa) defined by somewhat more abstract measures In fact, it is a group defined by a particular level of functional or morphological complexity. Thus, a grade can be polyphyletic, paraphyletic, or monophyletic (in the latter case, it is also a clade). A good example of a grade is the large group of gastropod taxa that have achieved shelllessness. These "slugs," however, do not constitute a clade, because shell loss has occurred independently in several different lineages of gastropods; thus the grade of shellessness we recognize as "slugs" is a polyphyletic grouping. An example of a monophyletic grade is the subphylum Vertebrata (animals with backbones).

Pleisiomorphy and Apomorphy

One last concept important to our understanding of systematics is that of primitive versus advanced character states. In the most general sense, **primitive character** states are attributes of species that are relatively "old" and have been retained from some remote ancestor; in other words, they have been around for a long time, geologically or genealogically speaking. Character states of this kind are sometimes referred to as ancestral character states. Advanced character states, on the other hand, are attributes of species that are of relatively recent origin—often called derived character states. Within the phylum Chordata, for example, the possession of hair, milk glands, and three middle ear bones are derived character states whose evolutionary appearance marked the origin of the mammals (thus distinguishing them from all other chordates). Within a subset of the Mammalia, however, such as the primates, these same features represent retained ancestral features, whereas possession of an opposable thumb is a defining, derived trait.

It should be apparent from the preceding paragraph that the designations "primitive" and "advanced" are relative, and that any given character state or attribute can be viewed as either ancestral or derived, depending on the level of the phylogenetic tree or classification being examined. Opposable thumbs may be a derived trait defining primates within the mammal lineage, but it is not a derived character state within the primate line itself (all primates have opposable thumbs). Thus, in the primate genus *Homo*, "opposable thumbs" is a primitive (ancestral) feature, and certain features of the nervous system that distinguish humans from the "lower apes" would be considered derived (such as Broca's center in the human brain). Thus it behooves us to more precisely define the concepts of primitive and advanced. The most unambiguous way to describe and use these important concepts is to define the exact place in the phylogenetic history of a group of organisms at which a character actually undergoes an evolutionary transformation from one state to another At the specific point on a phylogenetic tree where such a transformation takes place, the new (derived) character state is called an **apomorphy** and the former (ancestral) state a **plesiomorphy**. Thus the appearance of an apomorphy denotes the specific place in the tree of life where a "primitive" or "ancestral" character state changes to become an "advanced" or "derived" character state. Use of these terms thus implies a precise phylogenetic placement of the character in question, and this placement constitutes a testable phylogenetic hypothesis in and of itself. Apomorphies shared by two or more taxa are termed **synapomorphies**; plesiomorphies shared by two or more taxa are called **symplesiomorphies**.

Constructing Phylogenies and Classifications

Our classifications will come to be, as far as they can be so made, genealogies

Charles Darwin, *The Origin of Species*, 1859

From what you have read so far in this chapter, it should be evident that comparative biologists, particularly systematists, spend a great deal of their time seeking to identify and unambiguously define two natural entities, homologues and monophyletic groups (i.e., clades). In fact, modern phylogenetic trees are composed primarily of these two entities: homologues and clades. Biologists may present their ideas on such matters of relationship in the form of trees, classifications, or narrative discussions (evolutionary scenarios). In all three contexts, these presentations represent sets of evolutionary hypotheses—hypotheses of common ancestry (or ancestor–descendant relationships).

The least ambiguous (most testable) way to present evolutionary hypotheses is in the form of a dendrogram, or branching tree. Although classification schemes are ultimately derived from such dendrograms, they do not always reflect precisely the arrangement of natural groups in the tree. Discrepancies between phylogenetic trees and classifications derived from them most commonly occur when biologists purposely choose to establish or recognize paraphyletic taxa. Thus, to recognize the protists as a distinct taxon (the kingdom Protista) would be to recognize a paraphyletic group (because it excludes three large lineages that descended from it—animals, plants, and fungi). Whereas most systematists advocate that only monophyletic taxa be recognized in a formal classification, many paraphyletic taxa persist in animal classification, for convenience or tradition, or because they are simply not yet known to be paraphyletic (there are probably thousands of taxa for which we do not know whether they are monophyletic or paraphyletic). For example, the long-recognized group Reptilia is paraphyletic because it excludes one of that group's most distinct

lineages, the birds. The subphylum Crustacea is paraphyletic because it omits the insects, which evolved out of the crustaceans long ago. And as we will see in Chapter 14, the class Polychaeta is also paraphyletic. And of course, the group "invertebrata" is a paraphyletic group it is Metazoa excluding the vertebrates Even the Prokaryota is a paraphyletic group (the Eukaryota evolved out of it). In fact, taxonomic groups at all levels are likely to have been derived from *within* other taxonomic groups, leaving the latter paraphyletic, and we are beginning to discover that paraphyly abounds in the Linnean hierarchy of life that has been built over the past century. The issue of how to deal with such long-standing, well-known paraphyletic taxa in classification schemes is still being debated. One way of doing this might be to indicate their paraphyletic status by a code in the classification scheme (e g , some type of notation beside the name). This code would inform readers that to view the precise phylogenetic relationships of such taxa, they must look to the phylogenetic tree.

Biologists today use a method known as **phylogenetic systematics**, or cladistics, when construing biological dendrograms. Phylogenetic systematics had its origin in 1950 in a book by the German biologist Willi Hennig; the English translation (with revisions) appeared in 1966 Its popularity has grown steadily since that time. Through the years, cladistics has evolved well beyond the framework Hennig originally proposed. Its detailed methodology has been formalized and expanded and will certainly continue to be elaborated for some time to come. (For good discussions of the philosophical underpinnings of phylogenetic systematics see Eldredge and Cracraft 1980, Nelson and Platnick 1981, and Wiley and Lieberman 2011.) The goal of phylogenetic systematics is to produce explicit and testable hypotheses of genealogical relationships among monophyletic groups of organisms. As a systematic methodology, cladistics is based entirely on recency of common descent (i.e , genealogy). The dendrograms used by phylogenetic systematists are called cladograms, or phylogenetic trees, and they are constructed to depict only genealogy, or ancestor-descendant relationships. The term **cladogenesis** refers to splitting; in the case of biology, this means the splitting of one species (or lineage) into two or more species (or lineages). It is this splitting process that produces genealogical (ancestor-descendant) relationships.

Phylogenetic systematists rely heavily on the concept of ancestral versus derived character states discussed earlier. They identify these homologies in the strict sense, as plesiomorphies and apomorphies. An apomorphy restricted to a single species is referred to as an autapomorphy, whereas an apomorphic character state that is shared between two or more species (or other taxa) is called a synapomorphy. Identifying synapomorphies (also known as shared derived characters, or evolutionary novelties) is the systematist's most powerful means of recognizing close evolutionary (genealogical) relationships. Because synapomorphies are shared homologues inherited from an immediate common ancestor, all homologues may be considered synapomorphies at one (but only one) level of phylogenetic relationship, and they therefore constitute symplesiomorphies at all lower levels. As noted earlier, hair, milk glands, and so forth are synapomorphies uniquely defining the appearance of the mammals within the vertebrates, but these are symplesiomorphies *within* the group Mammalia. Jointed legs are a synapomorphy of the Arthropoda, but *within* the arthropods jointed legs are a symplesiomorphy. The keystone of phylogenetic systematics is the recognition that all homologues define monophyletic groups at some level. The challenge is, of course, recognizing the level at which each character state is a unique synapomorphy. Generally speaking, synapomorphies are either structural or genetic features. However, in the broadest sense, and in the context of the biological species definition, reproductive isolation can be thought of as a synapomorphy for any given species. And thus, incomplete reproductive isolation (successful hybridization) could be viewed as a symplesiomorphy shared among the species involved.

Numerous methods and criteria have been used to determine which is the apomorphic and which is the plesiomorphic form of two character states—a process sometimes referred to as character state polarity analysis. No method is foolproof, but some may be better than others under specific circumstances. Only three methods appear to have a strong evolutionary basis and provide a reasonably powerful means for recognizing the relative place of origin of a synapomorphy on a tree: out-group analysis (seeking clues to ancestral character states in groups thought to be earlier derived than the study group), developmental studies (ontogenetic analysis, or seeking clues to ancestral character states in the embryogeny of the study group), and study of the fossil record. Out-group analysis helps identify the states of the characters in question in taxa that are closely related to the study group, but are not part of it. Ontogenetic analysis identifies character changes that occur during the development of a species (see the discussion of ontogeny and phylogeny in Chapter 5). And the use of fossils and associated dating and stratigraphic techniques provides direct historical information (e.g , providing critical calibration points for molecular-based evolutionary studies). These techniques of polarity analysis are not discussed in detail here; we refer those with a serious interest in systematics, evolution, and comparative biology to the readings listed at the end of this chapter.

A cladistic analysis often comprises four steps: (1) identifying homologous characters among the organisms being studied (whether they be based on anatomy, gene sequences, gene expression, etc.), (2) assessing the direction of character change or

character evolution (character state polarity analysis), (3) constructing a phylogenetic tree of the taxa possessing the characters analyzed, and (4) testing the tree with new data (new taxa, new characters, new character interpretations, new statistical tests, etc.). Phylogenetic trees depict only one kind of event the origin or sequence of appearances of unique derived character states (synapomorphies). Hence, phylogenetic trees may be thought of in the most fundamental sense as nested synapomorphy patterns. However, biologists define and categorize taxa by the character states they possess. Thus, in a larger sense, the sequential branching of nested sets of synapomorphies in a cladogram creates a "family tree" an evolutionary pattern of hypothesized monophyletic lineages.

Phylogenetic systematists generally adhere to the principle of logical parsimony[6] and thus generally prefer the tree containing the smallest number of evolutionary transformations (character state changes). Typically this will also be the tree with the least evolutionary redundancy (= homoplasy). Although parsimony is the only inference method currently used for analyses of non molecular data, the use of gene sequence data has spawned a new family of model based methods that incorporate hypotheses of nucleotide evolution. In these methods (i.e, maximum likelihood and distance methods, Bayesian analyses), DNA nucleotide sequences from organisms in the study group are analyzed within a framework of assumptions based on how we believe nucleotides operate and change over time.

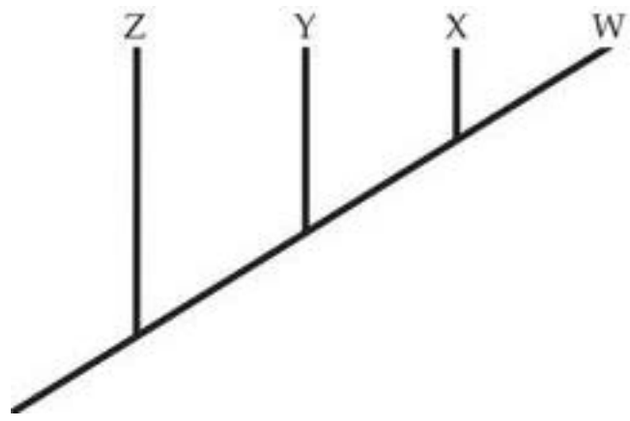

Figure 2.4 A cladogram of four taxa, illustrating the concept of sister groups. Taxon W is the sister of taxon X; taxon W + X is the sister group of taxon Y; taxon W + X + Y is the sister group of taxon Z.

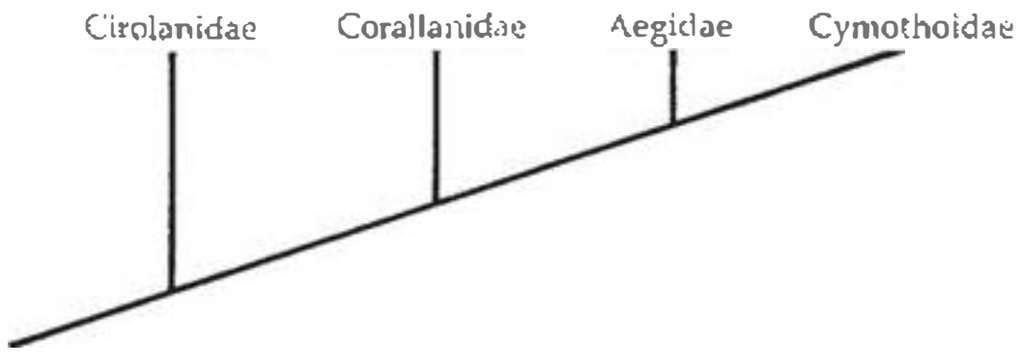
Construction of a cladogram can be a time-consuming process. The number of mathematically possible trees (of all branching patterns) for more than a few species is enormous for three taxa there are only four possible trees, but for ten taxa there are about 280 million possible trees, 34 million of which are fully dichotomous. Needless to say, such analyses are not possible without the aid of a computer. Algorithms for computerassisted tree construction began appearing in the late 1970s, and today the development of such programs comprises an entire field of research. But, all of these programs generate trees by clustering taxa into clades on the basis of nested sets of synapomorphies.



By identifying the precise points at which synapomorphies occur, phylogenetic trees unambiguously define monophyletic lineages. Hence, these trees are called explicit phylogenetic hypotheses. Being explicit, they can be tested (and potentially falsified) by anyone. The synapomorphies are markers that identify specific places in the tree where new monophyletic taxa arise. For phylogenetic systematists, a phylogeny consists of a genealogical branching pattern expressed as a phylogenetic tree. Each split or dichotomy within the tree produces a pair of newly derived taxa called sister taxa, or sister groups (for example, sister species). Sister groups always share an immediate common ancestor. In Figure 2.4, set W is the sister of set X; set W + X is the sister group of set Y; and set W + X + Y is the sister group of set Z. This nested set pattern of hierarchical relationships results from the fact that cladogenesis is a historical process. As depicted on a phylogenetic tree, the product of cladogenesis (or the splitting of a taxon) is two (or more) new lineages that constitute sister groups. Another way of stating this is to say that the two (or more) subsets of any set defined by a synapomorphy constitute sister groups.

Like all scientific hypotheses, phylogenetic analyses and their resulting trees are tested by the discovery of new data. As new characters or new species are identified and their character states elucidated, new data matrices are developed, and new analyses are undertaken.

---

[6]Parsimony is a method of logic in which economy in reasoning is sought. The principle of parsimony, also known as Ockham's razor, has strong support in science William of Ockham (Occam), the fourteenth-century English philosopher, stated the principle as "Plurality must not be posited without necessity." Modern renderings would read, "An explanation of the facts should be no more complicated than necessary," or, "Among competing hypotheses, favor the simplest one." Scientists in all disciplines follow this rule daily, and it can be viewed as a consequence of deeper principles that are supported by statistical inferences Thus, parsimonious solutions or hypotheses are those that explain the data in the simplest way. Evolutionary biologists rely on the principle of logical parsimony for the same reason other scientific disciplines rely on it doing so presumes the fewest ad hoc assumptions and produces the most testable (i.e, the most easily falsified) hypotheses If evidential support favored only one hypothesis, we would have little need for parsimony as a method. The reason we must rely on parsimony in science is that there is virtually always more than one hypothesis that can explain our data. Parsimony considerations come into play most strongly when a choice must be made among equally supported hypotheses

In phylogenetic reconstruction, any given data set can be explained by a great number of possible trees A three-taxon data set has 3 possible dichotomous (all lines divide into just two branches) trees that explain it. A four-taxon data set has 15 possible dichotomous trees, a five-taxon data set has 105 possible dichotomous trees, and so on. Thus, the evidence alone does not sufficiently narrow the class of admissible hypotheses, and some extra evidential criterion (parsimony) is required. The virtue of choosing the shortest (i.e, most parsimonious) tree among a universe of possible trees lies in its testability. William of Ockham, by the way, also denied the existence of universals except in the minds of humans and in language. This notion resulted in a charge of heresy from the Church, after which he fled to Rome and, alas, died of the plague

Classification scheme A

Family Aegidae
Family Cirolanidae
Family Corallanidae
Family Cymothoidae

Classification scheme B

Family Cirolanidae
Family Corallanidae
Subfamily Corallaninae
Subfamily Aeginae
Tribe Aegini
Tribe Cymothoini

Classification scheme C

Family Cirolanidae
Family Corallanidae
Family Aegidae
Family Cymothoidae

Figure 2.5 A phylogenetic tree of four closely related families of isopod crustaceans (marine pillbugs; see Chapter 21). In this example, the four families constitute an interesting "evolutionary series," from the free-living carnivorous Cirolanidae through micropredators and temporary fish parasites (Corallanidae and Aegidae) to obligatory fish parasites (Cymothoidae). Classification scheme A simply lists the families in alphabetical order, and there is no way to recover their phylogenetic history from this classification. Scheme B arranges the taxa in a subordinated (hierarchical) classification and precisely reflects the structure of the tree (but requires assigning the taxa to new nomenclatural ranks). Scheme C utilizes the phylogenetic sequencing convention to arrange the taxa in the exact sequential order in which they appear on the tree, but without subordination; it also precisely reflects the structure of the phylogenetic tree.

The first molecular phylogenetic trees were based on a single gene. But as techniques improved, these trees were tested with multiple gene sets, and eventually with entire genomic data sets. Hypotheses (branches of the tree) that consistently resist refutation are said to be highly corroborated. For example, the clade called Arthropoda has been examined in thousands of analyses using a great variety of data, and it has consistently been shown to constitute a monophyletic group (i.e., it is a highly corroborated phylogenetic hypothesis).

The final step in a phylogenetic analysis is often the conversion of the tree into a classification scheme. There is more than one way to make this conversion. Figure 2.5 shows a phylogenetic tree of four families of marine isopods, with three possible ways to classify the taxa. In this tree, these four families show an evolutionary trend from free living (the Cirolanidae) to parasitic lifestyles (the Cymothoidae). The Cymothoidae (a family of isopods that are obligatory parasites on fishes) is the sister group of Aegidae (a family of temporary fish parasites); together they constitute a sister group of the Corallanidae (micropredators on fishes); and all three constitute a sister group of the Cirolanidae (carnivorous predators and scavengers). Each of these nested sister-group pairs shares one or more unique synapomorphies that defines them. In Figure 2.5, the synapomorphies that define the sister group Cirolanidae + Corallanidae + Aegidae + Cymothoidae become symplesiomorphies higher in the cladogram (i.e., for each of the separate families). Sister groups are monophyletic by definition.

As illustrated in Figure 2.5 (classification scheme B), some phylogenetic systematists early on suggested that every lineage depicted in a tree should be designated by a formal name and categorical rank, and that each member of a sister group pair must be of the same categorical rank. A moment's thought reveals that giving names to every branching point in a cladogram would result in an impossible proliferation of names and ranks. Other systematists have proposed a method of avoiding such name proliferation, called the phylogenetic sequencing convention. When this convention is used, linear sequences of taxa can all be given equal categorical designations (e.g., they can all be classified as genera, or all as families, and so on), so long as they are listed in the classification scheme in the precise sequence in which the branches appear on the cladogram (classification scheme C). Either method of creating a classification scheme allows one to convert the classification scheme directly back into a cladogram—that is, to visualize the phylogenetic branching pattern it depicts. Classification scheme A does not reflect the phylogeny of these four families at all (it is simply alphabetical), so the only information it provides is that these families are "somehow" related to one another within a monophyletic clade.

The adoption of cladistic methodologies (the empirical construction of phylogenetic trees with precise branching patterns based on synapomorphies) in the 1980s led to an explosion of new phylogenetic work. This resulted in a proliferation of new phylogenetic trees, which in turn led to new classifications. A similar explosion of the field of molecular phylogenetics (using cladistic principals) shortly thereafter gave evolutionary biology another big boost, and has further changed some of our views on animal relationships and classifications. And just since the turn of the century another revolution in phylogenetics has begun as we have learned to sequence not just one gene at a time, but thousands of genes or even entire genomes. This latest development has begun to shine a very bright light on our understanding of animal evolution. It is also generating large and highly detailed phylogenetic trees, with long branching patterns depicting the history of life on earth (Figure 2.6, for example). Such detail creates challenges for biologists who like to produce classifications that accurately reflect phylogeny, because the traditional Linnean hierarchical ranks are too few in number to capture the great depth and detail

HEXAPODA

Figure 2.6 This phylogenetic tree of hexapod relationships (Misof et al. 2014) illustrates the challenges of converting large molecular-based phylogenies into classifications. The tree includes over 130 hexapod species and nearly as many branches. In order to erect a classification based on this tree, decisions must be made as to which nodes (clades) to name, whether or not to limit the named clades to the 30 or so traditional Linnean ranks or use unranked names, and whether to make the classification perfectly match the phylogeny. To see one way of dealing with these classification issues, see Chapter 22 (Hexapoda). Note that the seven Crustacea included in the analysis are shown to be a paraphyletic cluster at the base of hexapod clade (i.e., "Crustacea" is a paraphyletic grouping; Chapter 21), and that the sister group of Hexapoda is Remipedia. Note also that this is a dated phylogeny (the time scale, in millions of years, is shown at the top and bottom of the figure).

of these trees. Many of the new multigene or genomic trees have scores of branching points, or even hundreds of branches that appear as long comblike topologies. But the standard Linnean ranks number only nine or ten, or about four times that at best, when the prefixes super-, sub-, and infra- are also used.

There are a few solutions to this dilemma, but none of them is perfect (Figure 2.7). The most straightforward solution is to not use ranks at all in the classification, instead just indenting the subordinated groups in ways that reflect the phylogeny—an unranked classification. Another solution is the phylogenetic sequencing convention, described above. A third solution (and probably still the most frequently seen) is to create classifications that *do not* precisely mirror the phylogeny, referring readers to the tree if they want to understand the precise relationships of the taxa in a classification. Unranked classifications are useful when the phylogeny of a group is still quite poorly known (e.g., Chapter 14, Annelida). Fully ranked classifications

Classification scheme A

Phylum Chordata
- Subphylum Vertebrata
  - Class Pisces (fishes)
  - Class Amphibia (amphibians)
  - Class Reptilia (turtles, crocodilians, snakes, lizards)
  - Class Aves (birds)
  - Class Mammalia (mammals)

Classification scheme B

Phylum Chordata
- Vertebrata
  - Tetrapoda
    - Lissamphibia (amphibians)
    - Amniota
      - Mammalia (mammals)
      - Sauropsida (Reptilomorpha)
        - Anapsida (turtles)
        - Diapsida
          - Lepidosaura (snakes, lizards)
          - Archosauria
            - Crocodilia (crocodilians)
            - Aves (birds)

Classification scheme C

Phylum Chordata
- Subphylum Vertebrata
  - Class Pisces
  - Class Amphibia
  - Class Mammalia
  - Class Anapsida (turtles)
  - Class Lepidosaura (snakes, lizards)
  - Class Crocodilia (crocodilians)
  - Class Aves (birds)

Figure 2.7 Sometimes genealogy and overall morphological similarity/dissimilarity can lead to conflicting approaches to a classification. This is exemplified by the birds and reptiles. The cladogram in this figure depicts the generally accepted view of the relationships among the major groups of living vertebrates. Classification scheme A depicts a traditional classification of the vertebrates, in which crocodilians are classified with lizards, snakes, and turtles in the taxon Reptilia, while birds are retained as a separate taxon, Aves. In this classification, class Reptilia is paraphyletic (because it excludes the birds). Classification schemes B and C strictly reflect the phylogenetic tree. Scheme B reflects the branching pattern of the cladogram with subordinated taxa (unranked in this case); thus, the reptiles are broken into separate taxa in recognition of their genealogical relationships—the snakes and lizards (Lepidosaura) are classified together as a separate sister group to the birds and crocodilians. Scheme C also strictly mirrors the tree, but uses the phylogenetic sequencing convention rather than subordinated sets of sister-groups. But in both B and C, all taxa are monophyletic. Notice that scheme C, using the sequencing convention, requires four fewer taxonomic names than scheme B.

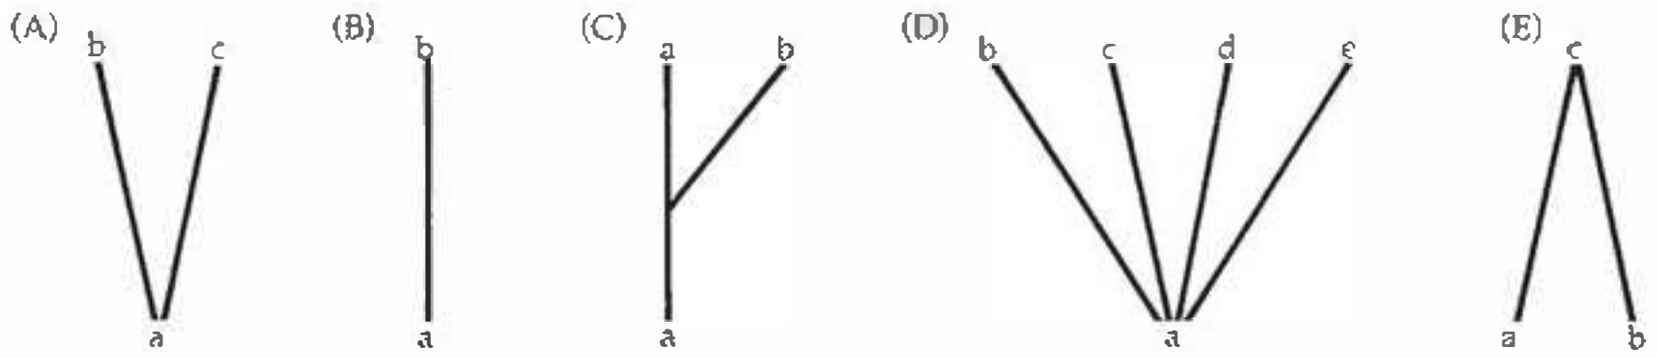

Figure 2.8 Common models of speciation. (A) One species splits into two new species. (B) One species is transformed into another over time. This type of speciation may be viewed as either gradual or rapid. (C) One species remains unchanged, while an isolated peripheral population evolves into a distinct new species. (D) "Explosive adaptive radiation," in which one species suddenly splits into many new species. Speciation events represented by this model are predicted to occur when a species is suddenly confronted with a vast new array of habitats or "unfilled niches" to exploit, resulting in rapid specialization and reproductive isolation as the new niches are filled. Explosive radiation might also occur when the range of a widespread species is fragmented into numerous smaller, isolated populations. Classic examples of explosive radiation include cichlid fishes in Africa's Rift Lakes and ant nest beetles in Madagascar (and elsewhere). (E) A new species is "created" by hybridization of two other species; this type of speciation appears to be rare and may occur primarily in plants and protists, although examples are also known from the Metazoa (e.g., whiptail lizards).

can get cumbersome when "pushed to the limit" of available taxonomic categories (e.g., Chapter 10, Platyhelminthes). The upshot is, things are changing and the "traditional" classification schemes many students are used to seeing are beginning to look rather different these days. In this book, we mostly use ranked classifications that mirror, or at least do not conflict with the phylogeny of the groups in question. In a few instances, we have had to use fully or partly unranked classifications (e.g., annelids and molluscs).

Further confusion is added when names that have been used for many decades are difficult to discard. Some of these legacy names have been redefined to represent monophyletic groups, or clades, such as Protostomia and Deuterostomia. Others, however, are now known to represent nonmonophyletic groups, yet the names have not yet disappeared from either textbooks or the scientific literature, for example, the gastropod group "heteropods" (which is a polyphyletic group of pelagic gastropods with laterally-compressed translucent bodies and reduced or lost shells). In this book, if we use a name that is not indicative of a natural (i.e., monophyletic) group, we point this out.

One criticism of phylogenetic systematics occasionally heard is that it always depicts the speciation process as the splitting of an ancestral species into two sister species, despite the probability that numerous other speciation modes exist (Figure 2.8). In a phylogenetic tree, once a new species appears, a "split" must be placed on the tree, and the two branches represent sister groups, whether or not the original species has in fact changed at all. Some biologists have claimed that this practice is misleading. This criticism is unfounded, and it derives from simple lack of understanding. First of all, trees need not always be completely dichotomous; they can (theoretically) have branching points that are trichotomous or even polytomous (Figure 2.8D). Second, a terminal taxon on a cladogram may lack any defining synapomorphies, thus indicating that it is not only the sister group of its adjacent lineage, but also the actual ancestor of that lineage. A phylogenetic tree can express any kind of speciation event; it simply does so in a restricted way—by way of branches depicting a pattern of nested synapomorphies.

The methods of phylogenetic systematics force the systematist to be explicit about groups and characters. The method is also largely independent of the biases of the discipline in which it is applied. In its fundamental principles, it is not restricted to biology, but is applicable to a variety of fields in which the relations that characterize groups are comparable to the homology concept and possess a hierarchical nature. Thus, cladistic analyses have been applied to other historical systems, such as linguistics and textual criticism (in which the "homologues" are shared tongues or texts), and even to the classification of musical instruments. Cladistic analysis has also used in biogeographic analyses, wherein taxa are replaced by their appropriate areas of endemism, and the "homologues" are thus sister groups shared by geographic regions. Although the information stored in a phylogenetic tree is restricted to genealogy, such trees are often used to test other kinds of hypotheses, such as modes of speciation, historical relationships among geographic areas, and coevolution in host–parasite lineages.

As stressed earlier, the concept of similarity plays a central role in phylogenetic systematics. There are really only three kinds of evolutionary similarity expressed among organisms: (1) shared evolutionary novelties inherited from an immediate common ancestor (i.e., apomorphies); (2) similarity inherited from some more remote ancestor (any number of descendant taxa may retain such similarity); and (3) similarity due to evolutionary convergent evolution. Phylogenetic

systematists accept only the first kind of similarity (synapomorphies) as valid evidence of close affinity (common ancestry) between two taxa. The second kind of similarity reflects plesiomorphies, attributes that originated before the appearance of the study group and thus, while being informative, do not provide specific evidence relevant to branching points in phylogenetic trees. The third kind of similarity (convergence) holds no value at all in phylogenetic analyses, although it can lead to interesting questions about evolutionary biology.

It is worth noting that the concept of shared derived characters has been around for many decades, and a careful review of the work produced by the most critical systematists through time will reveal that most were striving to delimit monophyletic taxa and construct phylogenetic trees based on nested sets of synapomorphies. However, many existing older classifications are still based in part on symplesiomorphies rather than solely on synapomorphies, and these classifications are destined to be revised as modern studies are accomplished.

Molecular Phylogenetics

On February 12, 1988 (by appropriate coincidence, Charles Darwin's birthday), a paper published by Katherine Field, Rudy Raff, and others presented the first credible molecular analysis of metazoan phylogeny based on sequences from the small subunit ribosomal RNA gene (SSU). This work initiated a paradigm shift in phylogenetic analysis, and today the field of molecular phylogenetics is rooted in the methods pioneered in that important paper. In 1997, Anna Marie Aguinaldo and colleagues also published a revolutionary paper, proposing a radical new view of animal phylogeny—one that hypothesized the Protostomia to comprise two distinct clades, a "molting clade" (called Ecdysozoa) and a nonmolting clade (called Spiralia in this book). With the advent of technology for rapid amplification of DNA fragments and sequencing of the nucleic acids, the field of systematics has undergone dramatic change. Questions of evolutionary relationship, which had traditionally been addressed only by comparative morphology, can now be tested by a new and independent source of data. Since the 1990s, **molecular phylogenetics** has swept the literature with evolutionary trees built by analyses of gene sequences. Molecular matrices are DNA sequence data, constructed of the four nucleotides of the genetic code: adenine (A), thymine (T), cytosine (C), and guanine (G). Molecular trees have corroborated some relationships previously inferred by analyses of morphological traits, but they also provided support for novel relationships never predicted.

The first molecular phylogenies were constructed from analyses of ribosomal genes, which code for RNA that forms the 3D structure of ribosomes (the large subunit 28S, and small subunit 18S).[7] However, not long after the first molecular based trees were published, it was recognized that analyses of molecular sequence data are prone to predicting erroneous relationships under certain circumstances. Rapidly evolving lineages were inferred to be closely related, regardless of their true evolutionary relationships, due to a phenomenon known as **long branch attraction** (LBA). Since there are only four possible character states in molecular sequence data (the four nucleotides), when DNA substitution rates are high, there is a high probability that two lineages will *independently* evolve the same nucleotide at the same site by chance alone. In these circumstances, phylogenetic algorithms (especially parsimony methods) erroneously interpret these convergences to be signs of shared ancestry (synapomorphies) and therefore misinterpret taxa on long branches to be close relatives

Using phylogenetic algorithms that incorporate **models of evolution** can minimize the LBA problem. These models include three components: (1) models of DNA substitution, which describe the rates at which one nucleotide replaces another over evolutionary time, (2) the relative nucleotide base frequency in a dataset, and (3) the relative rates at which sites in an alignment evolve in a dataset. Popular evolutionary-model-based algorithms include **maximum likelihood** and **Bayesian methods** of phylogenetic estimation.

The number of genes used to infer phylogenies increased quickly to include both nuclear and mitochondrial protein coding genes. Inferring phylogeny from protein coding genes offers several advantages. Protein sequences from distant relatives are easier to align to one another than ribosomal genes. And since a three-nucleotide codon in a nucleic acid sequence specifies an amino acid according to the genetic code, protein-coding genes can be analyzed at either the nucleotide or the amino acid level.[8] Whereas analyses of single genes were the standard only a few years ago, most molecular phylogenetic analyses today use multiple, preferably unlinked, genes concatenated together in one **supermatrix** of 5 to 10 or more genes. In fact, new and relatively inexpensive DNA sequencing technology, known as **next generation sequencing**, is allowing for molecular phylogenies to be constructed from larger portions of the genome, up to tens of thousands of genes. Specific regions of the genome can be targeted a priori through methods such as anchored hybrid enrichment, or novel genes of phylogenetic significance can be discovered after shotgun sequencing of all DNA molecules (genomes) or RNA molecules

[7] The genetic information in the nucleic acid DNA (deoxyribonucleic acid) is transcribed to the nucleic acid RNA (ribonucleic acid), and this information is then translated from RNA to protein

[8] The human genome contains about 21,000 genes, and protein coding regions account for only around 1.5% of the genome. Many other complex species get by with far fewer genes.

(transcriptomes). No mater what type of genetic data is selected or how it is sequenced, these methods result in rich multigene datasets for phylogenetic inference. Resulting trees are therefore inferred from a larger portion of the genome than previous methods that relied on only a handful of genes, whose history may or may not precisely reflect the history of the taxa being analyzed.

Equally exciting are techniques being developed to extract DNA from fossilized bone, tissue, or dung. In 2003, scientists managed to extract DNA from Siberian permafrost sediments and soils of caves in New Zealand. The Siberian sediments yielded the oldest reliable ancient DNA up to that time, from plants as much as 400,000 years old (angiosperms, gymnosperms, and mosses) as well as from numerous animals, including both living and extinct species up to 30,000 years old. In 2008, the entire genome of the extinct woolly mammoth (*Mammuthus primigenius*) from Siberia was sequenced, showing a sequence identity of over 98 percent with modern African elephants (the two diverged from one another about 6 million years ago). Also in 2008, DNA was sequenced from lice (Insecta: Phthiraptera: *Pediculus humanus*) preserved in the scalps of 1000-year old Peruvian mummies. The lice belonged to a subtype of head and body lice found all over the world, thus proving that human lice were in the New World well before Columbus. Since then, scientists have begun sequencing DNA from even older animals—the oldest so far is a 700,000-year-old horse, perhaps pushing the limits of how long DNA can actually survive. By extracting fragments of DNA from ancient soils and sediments (known as "environmental DNA") in North America, scientists have begun to reconstruct Pleistocene and early Holocene ecosystems. The extraction of DNA from 2000- to 4000-year-old cores from the Arctic region has yielded a variety of plants, bison, horses, bears, mammoths, and lemmings. Environmental DNA comes from urine, feces, hair, skin, eggshells, fathers, and even the saliva of animals, as well as from the decaying leaves and fine rootlets of plants. Ancient DNA has led to the discovery of new types of ancient humans and revealed interbreeding between our ancestors and our archaic cousins, which left a genetic legacy that shapes who we are today. Much of the genome of Neanderthal has now been sequenced. As a result, we now know that modern *Homo sapiens* carry a remnant of Neanderthal DNA from interbreeding events that have been postulated to have occurred as humans migrated out of Africa and into Eurasia, at least 80,000 years ago.

Research suggests that in closely-related species (e.g., sister species) that have recently diverged from one another there are key genes that diverge rapidly and produce reproductive incompatibility, thus reducing the likelihood of viable or fertile hybrid offspring. Other key genes that evolve quickly during the origin of a new species appear to be those that confer a special advantage to the new population. For example, the genomes of humans and chimpanzees (*Pan troglodytes*) are about 99 percent identical. But among the genes that comprise that one percent are two small stretches of bases known as the HAR1 (the human accelerated region 1) and the *FOXP2*. Before humans appeared, HAR1 appears to have evolved extremely slowly, but in *Homo sapiens* it underwent abrupt evolution. It turns out that HAR1 is active during embryogenesis in a type of neuron that plays a key role in the pattern and layout of the developing cerebral cortex of the brain. *FOXP2* is involved in speech. Thus, it appears that the rapid burst of substitutions in these genetic regions may have altered our brains significantly from those of chimpanzees. A small amount of rapid gene change can have a major impact in species divergence and evolution. Interestingly, the *FOXP2* sequence of Neanderthals is very similar to that of modern humans, suggesting that they may have had speech similar to ours.

CHAPTER 3

The Protists

Kingdom Protista

It has long been a tradition in invertebrate zoology courses to cover the protists, at least the most common groups, and today well over half of the invertebrate courses taught in North America still do so. And in today's world of diminishing "-ology" courses many students will find this to be their only detailed exposure to this very important assemblage of organisms. For this reason we have chosen to retain the protist chapter in this edition of *Invertebrates*, despite the challenges of presenting this highly diverse collection of phyla in a succinct fashion. The formal taxon "Protozoa" was established by Richard Owen in 1858, the same year Charles Darwin and Alfred Russel Wallace published their theory of natural selection. In its most common use it has always been a paraphyletic taxon, although before the Myxozoa, yeasts, and a few others were removed it was a polyphyletic grouping. However, the name "Protozoa" has been used for a plethora of different groupings of eukaryotes over the past 150 years, and it is probably best laid to rest as a formal taxonomic name today.

Because the protists are a paraphyletic group, they are not easy to define. Like other paraphyletic groups, they are defined primarily by what they lack. One definition is, "eukaryotic, largely unicellular organisms that do not undergo tissue formation through the process of embryological layering." The assemblage we call protists is paraphyletic because it excludes numerous multicellular descendant lineages (Metazoa, Fungi, Plantae), as well as the Glaucophyta, and the red and green algae. Thus protists are the "soup" out of which the three great multicellular kingdoms evolved. Some protists (such as the choanoflagellates) are more closely related to animals than to other protists; and four phyla once regarded as protists are now usually classified in the kingdom Plantae (=Archaeplastida): Glaucophyta (glaucophyte algae), Rhodophyta (red algae), Chlorophyta (green algae), and Charophyta (stoneworts).[1] Recently, some workers have subdivided the protists into

---

[1]Plants form a monophyletic group, comprising unicellular and multicellular, photosynthetic, chlorophyll-bearing eukaryotes with chloroplasts directly descended from an initially enslaved cyanobacterium (i.e., the "primary plastid"). These chloroplasts are surrounded by two membranes, and they may contain chlorophyll *a* and/or *b*. Plantae contains two subkingdoms: Biliphyta (phyla Glaucophyta and Rhodophyta) and Viridiplantae (the phyla Chlorophyta, Charophyta, Anthocerotophyta, Bryophyta, Marchantiophyta, and Tracheophyta). The two-layered chloroplast membrane, structure of plastid genomes, and derived chloroplast protein-import machinery all suggest a single origin for the Plantae

two groups Protozoa and Chromista. This arrangement, championed by Thomas CavalierSmith, separates out the Chromista as those chromophtye algae (those with chlorophyll *a* and *c*, but not *b*) thought to have evolved by symbiogenetic enslavement of a red alga, as well as all heterotrophic protists descended from them by loss of photosynthesis or entire plastids. In this scheme, the "kingdom Chromista" would include such phyla as Haptophyta, Ciliophora, and Cercozoa; and the "kingdom Protozoa" would contain phyla such as Euglenozoa, Amoebozoa, and Choanozoa (see Ruggiero et al. 2015 for a version of this classification). However, multigene analyses of protists are still ambiguous on the precise nature of this dichotomy and whether Chromista is monophyletic, and we feel the redefined use of the now highly ambiguous term "Protozoa" is confusing. Thus we have not adopted this classification for this edition of *Invertebrates* In fact, classification of the protists is still in a significant state of flux as new multigene phylogenies continue to discover, sort out, and rearrange the many clades Because the protists are no more than a paraphyletic assemblage, and because brown algae (Phaeophyta), like red and green algae, arose from a separate protistan ancestor, some workers would exclude the Phaeophyta from the protists.

About 200,000 species of protists have so far been described, but taxonomists have only scratched the surface and it is almost certain that species diversity in this assemblage of phyla exceeds that of Metazoa. For example, recent large-scale molecular screening techniques have revealed an unimagined diversity of minute (picoplankton, 0.2 2 µm) protists in the world's oceans, most of which have not even begun to be classified. Most protists are unicellular, but there are also colonial and multicellular species, although the multicellular forms do not undergo embryonic tissue formation as seen in the plants and animals (thus distinguishing them from the kingdoms Plantae and Metazoa). Some protists are exclusively asexual; others can also reproduce sexually, or at least employ the sexual processes of meiosis and syngamy Some protists are photoautotrophs containing plastids, organelles with light capturing pigments for photosynthesis. Some are heterotrophs, absorbing organic molecules or ingesting larger food particles (phagotrophy). Still others are mixotrophs, combining photosynthesis and heterotrophic nutrition. In years past, protists were divided into three large groupings on the basis of these nutritional modes: protozoans (the ingestive heterotrophs, or animal-like protists); algae (the photosynthetic, or plantlike protists); and the funguslike (absorptive) protists. However, we now know that these represented no more than loose ecological groupings

The prokaryotic and eukaryotic phytoplankton, mainly Cyanobacteria ("blue green algae") and photosynthetic protists such as the diatoms, dinoflagellates, and coccolithophores, are critically important to oceanic food chains, the global carbon cycle, and marine ecosystem functioning Even though they account for less than 1% of Earth's standing photosynthetic biomass, they are responsible for about half of Earth's annual production of atmospheric oxygen (the rest coming from terrestrial plants, that, unlike marine primary producers, are much longer-lived and channel more of their energy to standing biomass). And, of course, much of the petroleum we consume at an ever-increasing pace came from phytoplankton that settled on the ocean floor and was buried and "cooked" over past millennia. This took place on a warmer Earth that had less dissolved oxygen in the sea, and less decay of organic matter as it sank to the seafloor. However, it has been estimated that only about 2% of all oceanic plankton makes it to the ocean floor in modern seas, the rest being recycled before it reaches the benthic realm. The smallest oceanic protists (below 1 mm body size), such as diatoms, are, like bacteria, completely at the mercy of the currents and tend to disperse far and wide. For this reason, species of small protists tend to disperse everywhere, and the local environment selects where they can survive.

The "big three" eukaryotic primary producers that are conspicuous in the world's oceans today (diatoms, dinoflagellates, coccolithophores) came to prominence during the Mesozoic era, although they first arose much earlier than that. Chemical evidence of lipid biosignatures from dinoflagellates has been found in Neoproterozoic and Paleozoic strata. Evidence of coccolithophores has been found in Late Triassic strata. The siliceous remains of diatoms have left a somewhat substantial fossil record, the earliest clear evidence (fossil frustules) being Jurassic (remnants of their silica shells make up the porous rock called diatomite). However, molecular clock analyses suggest an origin for the diatoms around the Permian-Triassic boundary. Interestingly, all three groups contain plastids derived from an ancestral red alga by secondary (or even higher-level) symbioses, and all three groups began their major radiations subsequent to the End Permian mass extinction event.[2]

Photosynthetic protists contain a variety of types of chlorophyll and have differently constructed chloroplasts, reflecting their many separate lineages. Like mitochondria, plastids have an intricate internal structure of folded membranes. But the plastid's membranes are not continuous with the inner membrane of the chloroplast envelope. Instead, the internal membranes lie in flattened disclike sacs called thylakoids. Each thylakoid consists of an outer thylakoid membrane surrounding an inner space. Thylakoids are piled up like plates. Most protists have thylakoids that form stacks two or

[2]Some dinoflagellates and other groups, obtained their plastids through tertiary or higher-order symbioses (i e , acquisition of a eukaryotic algal cell and retention of the plastid as well as other pieces of cell machinery).

three units thick. Green algae and land plants have many thylakoidsstacked into piles called grana (sing granum), and a chloroplast may contain many grana. Red algae (Rhodophyta) have unstacked thylakoids.

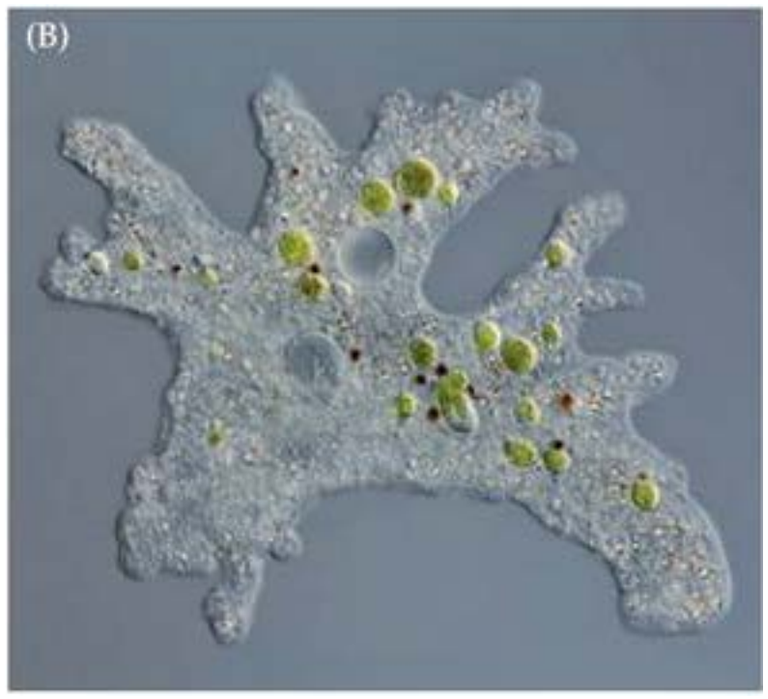
The body plans of protists demonstrate a remarkable diversity of nonmetazoan form, function, and survival strategies. Most, but not all, are unicellular. In any case, they carry out all of life's functions using only the organelles found in a "typical" eukaryotic cell. Many of the fundamentally unicellular protist phyla also contain species that form colonies. Others are multicellular, though lacking the embryonic tissue-layering processes and differentiated organs and tissues seen in animals, plants, and fungi. Multicellularity in a number of protist groups (e.g., the formation of cellular slime molds in dictyostelids; the formation of multicellular thalli in different groups of brown algae) is but one example of rampant convergent evolution seen among these creatures. Different lineages of free-living protists have, for instance, independently evolved a wide variety of cytoskeletal extensions (e.g., flagella, axopods, haptonemes), feeding apparatuses (e.g., rods and gullets), secreted cell coverings (e.g., scales, loricas, frustules, spines), and intracellular armor (e.g., thecae, pellicles).

Protists include an awesome array of shapes and functional types. Figure 3.1 illustrates some of this variety. Most unicellular protists are microscopic, although a few, such as the foraminiferans, are commonly visible to the naked eye. Many protists are actually larger than the smallest metazoans (e.g., some gastrotrichs, kinorhynchs, nematodes, loriciferans, and others). Protists include marine, freshwater, terrestrial, and symbiotic species, and the last category includes many serious pathogens. Humans are hosts to over 30 species of protistan symbionts, many of which are pathogenic.

Protist diversity, indeed the diversity of the entire superkingdom Eukaryota, had its origin in a remarkable and critically important evolutionary event that occurred 2–2.7 billion years ago, when a free-living proteobacterium took up residence in an anaerobic prokaryote, first becoming an endosymbiont, and then being fully assimilated into the cytoplasm and cellular machinery of its host to become the first mitochondrion. This **primary endosymbiosis** origin of mitochondria is believed to have occurred only once (Figure 3.2), and it represents the origin of the monophyletic lineage called Eukaryota.

Some time later, a cyanobacterium became endosymbiotic in a protist and, as with the proteobacterium, became enslaved and incorporated into its host. As the cyanobacterium became a permanent fixture in this host, the photosynthetic apparatus of its plastid (or chloroplast) continued to function and thus serve its new master. From this singular endosymbiotic event, arose the kingdom Plantae, or Archaeplastida. The plastids in these phyla are called **primary plastids**. The bulk of the genes present in the genome of the cyanobacterial progenitor of plastids were either lost or transferred to the nuclear genome of the eukaryotic host, where they are now expressed and their protein products targeted back to the organelle in which they were originally encoded by a dedicated plastid protein import system.[3]

Subsequent to the ancient primary endosymbiotic event, many other protist clades adopted chloroplasts secondarily by entering into a symbiosis with a green or red alga, and then gradually reducing the symbionts until all that remained was the chloroplast — a process known as **secondary endosymbiosis**. At least three independent secondary endosymbioses between unrelated host cells and red and green algal endosymbionts probably occurred, one involving a red alga and two involving green algae. From the red algal secondary endosymbiotic event arose the cryptomonads, haptophytes, heterokonts, dinoflagellates, and probably apicomplexans (the apicomplexans having lost their chloroplasts as they took up their parasitic lifestyle). From the green algal line, euglenids and chlorarachniophytes each evolved independently. And we now know of tertiary, and perhaps even quaternary endosymbiotic events that transferred photosynthetic capabilities to newly evolving protist clades. Indeed, one of the most stunning achievements of protists has been their ability to engage in endosymbiotic relationships with one another — a trait seen in nearly every major lineage. Some fundamentally heterotrophic groups have become specialists at developing symbioses with a variety of autotrophic protists, such as the forams, which may harbor endosymbiotic diatoms, dinoflagellates, or red or green algae. Diatoms themselves are a highly chimeric group, with about 10% of their nuclear genes being of foreign algal origin (from ancient, secondary endosymbiotic events with red and green algae).



---

[3]Photosynthetic plastids (those with chlorophyll) are called chloroplasts, and they contain their own DNA (cpDNA). Plastids without chlorophyll are usually called leucoplasts (and generally contain lpDNA). Both cpDNA and lpDNA are transcribed and translated just like nuclear DNA, except these organelle genes are effectively haploid. Chloroplasts are the solar-powered, energy-generating, oxygen-producing organelles of plants and algae (photosynthetic protists). All are descendants of once-free-living cyanobacteria. Chlorophyll (a green pigment) is found in most plants, algae, and Cyanobacteria. Chlorophyll absorbs light most strongly in the blue and red wavelengths, and only poorly in the green wavelengths (hence the reflected green color). Chlorophyll molecules are arranged in and around pigment protein complexes called photosystems, which are embedded in the thylakoid membranes of chloroplasts. Besides the very common chlorophyll *a* (which may be universal in photosynthetic eukaryotes), there are other pigments, called accessory pigments, which occur in the photosystems. These include other forms of chlorophyll, such as chlorophyll *b* in green algae and higher plants, and chlorophyll *c* or *d* in other algae. There are also nonchlorophyll accessory pigments, such as carotenoids and phycobilins (phycobiliproteins), which also absorb light and transfer that energy to the photosystem's chlorophyll. The different chlorophyll and nonchlorophyll pigments all have different absorptive spectra (e.g., the phycobilins in red algae, and typically in Cyanobacteria, and some cryptomonads, can absorb green light relatively well).

Cryptomonads and chlorarachniophytes have been the subject of intense research in recent years, because they each possess four genomes—two nuclear genomes, an endosymbiont-derived plastid genome, and a mitochondrial genome derived from the host cell. Like mitochondrial and plastid genomes, the persistent genome of the endosymbiont nucleus, called a nucleomorph, has been retained in these two groups. Much of the nucleomorph genome has been lost in cryptomonads and chlorarachniophytes, reduced through the combined effects of gene loss and intracellular gene transfer to the "host" nucleus. In fact, nucleomorph genomes are the smallest genomes known in the Eukaryota. It was an ultrastructural understanding of nucleomorphs, largely led by the work of A. D. Greenwood in the 1970s, that showed them to be degenerate nuclei and provided the "smoking gun" of the secondary endosymbiotic theory. The still unanswered question is, why have the ancestral endosymbiont genomes been retained in cryptomonads and chlorarachniophytes, when they have been lost in all other secondary plastid-containing organisms? One answer is, they are still gradually disappearing as their genes are lost or transferred to the "host" nucleus.

Taxonomic History and Classification

Antony van Leeuwenhoek is generally credited with being the first person to report seeing protists, in about 1675. In fact, Leeuwenhoek was the first to describe a number of microscopic aquatic life forms (e.g., rotifers), referring to them as "animalcules" (little animals). For nearly 200 years, protists were classified along with a great variety of other microscopic life forms under various names (e.g., Infusoria). The name protozoon (Greek, *proto*, "first"; *zoon*, "animal") was coined by Goldfuss in 1818 as a subgrouping of a huge assemblage of animals known at that time as the Zoophyta (protists, sponges, cnidarians, rotifers, and others). Ernst Haeckel's Protista (in 1866) did not include the green algae or ciliates (placed among the animals) but did include the sponges. Following the discovery of cells in 1839, the distinctive nature of protists became apparent. On the basis of this distinction, Karl von Siebold, in 1845, restricted the name protozoa to apply

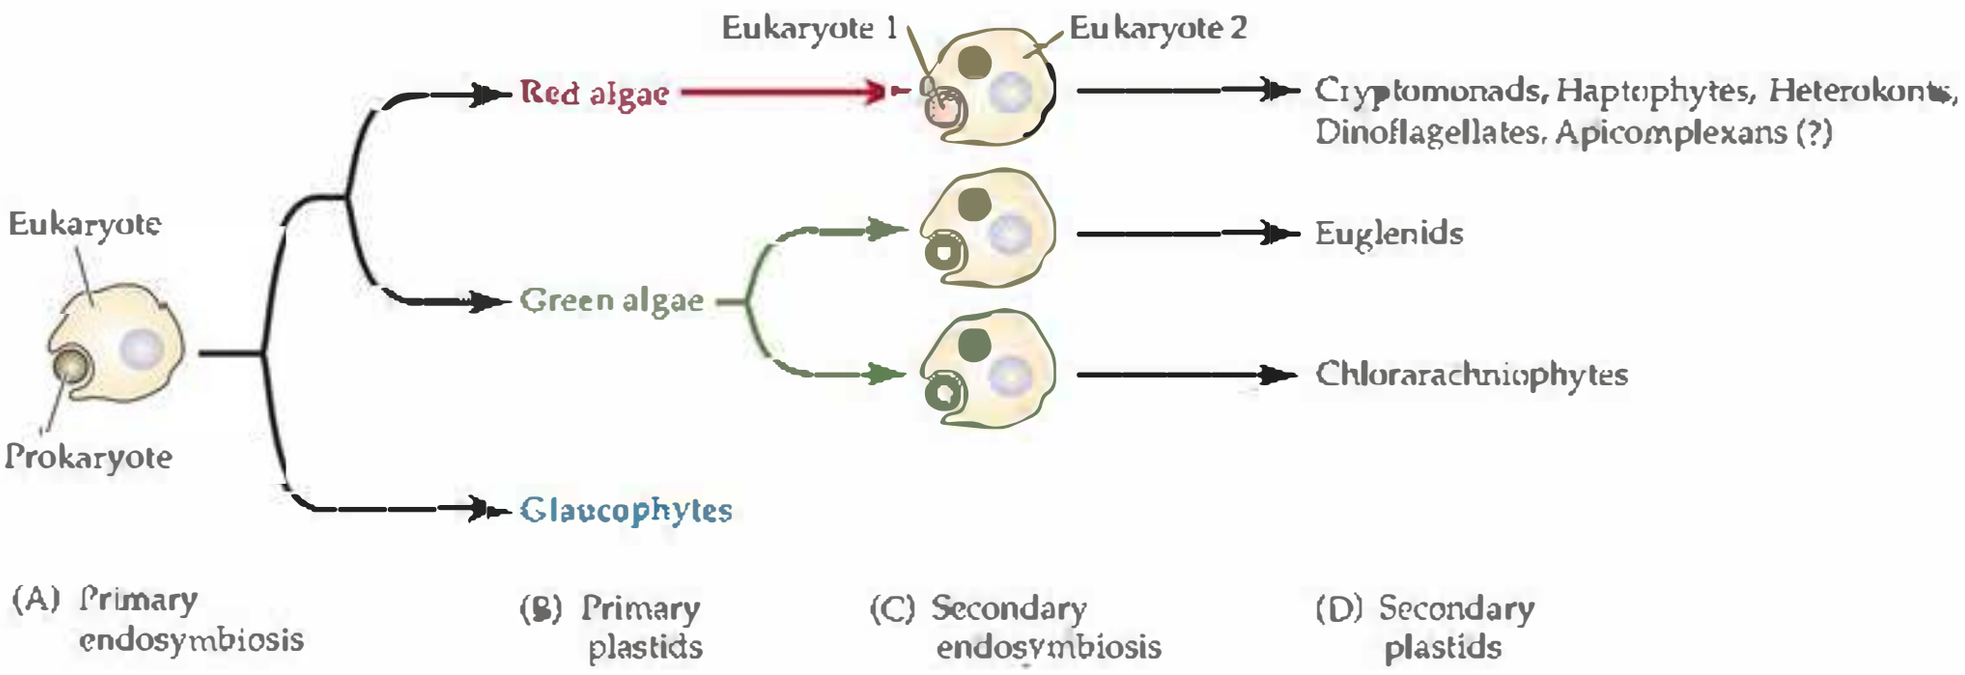

Figure 3.2 The origin and spread of plastids in eukaryotic cells. (A) Primary endosymbiosis between a heterotrophic eukaryote and a photosynthetic prokaryote. (B) Three modern-day eukaryotic lineages (red and green algae, glaucophytes) possess primary plastids whose ancestry traces directly back to the primary endosymbiosis; the green algae spawned multicellular lineages such as land plants. (C) At least three independent secondary (i.e., eukaryote-eukaryote) endosymbiosis events between unrelated host cells and red and green algal endosymbionts have probably occurred. (D) Diversity of eukaryotes harboring secondary plastids; cryptomonads, haptophytes, heterokonts, many dinoflagellates, and (probably) apicomplexans harbor plastids derived from a red algal endosymbiont, while euglenids and chlorarachniopytes acquired their plastids from green algae, probably in separate events. The cryptomonads and chlorarachniopytes are the only known secondary plastid-containing algae to still possess the nucleus and nuclear genome of their algal endosymbionts. Some dinoflagellate lineages have replaced their ancestral red algal secondary plastid with a tertiary plastid through the uptake of cryptomonad, heterokonts, or haptophytes algae. The apicomplexans are an entirely nonphotosynthetic lineage of parasites, some of which have completely lost their plastid.

to all unicellular forms of animal life. It was the great naturalist Ernst Haeckel who united the algae and Protozoa into a single group, the Protista.

Throughout most of the twentieth century, a relatively standard classification scheme was used for the protists, or "Protozoa." This scheme, which has its roots in the work of the great nineteenth century German zoologist Otto Bütschli, was based on the idea that the different groups could be classified primarily by their modes of locomotion and nutrition. Thus the protozoans were divided into the Mastigophora (locomotion with flagella), Ciliata (locomotion with cilia), Sarcodina (locomotion with pseudopodia), and Sporozoa (parasites, with no obvious locomotory structures, but forming resistant spores for transmission between hosts). Flagellated protists were further divided into the zooflagellates (heterotrophs) and phytoflagellates (photosynthetic autotrophs). While these divisions might accurately describe protists' roles in ecosystems, we now know that they do not accurately reflect evolutionary relatedness. Pseudopodia and flagella are present in many different kinds of cells (including plant and animal cells) and their presence does not necessarily indicate unique relatedness. Flagella (and cilia) are clearly shared primitive features, or symplesiomorphies, whereas pseudopodia come in many different forms that represent cases of independent evolution. Modern molecular phylogenetics and comparative ultrastructural studies have completely reorganized the classification of protists, and will continue to make adjustments for some time come.

Although there continues to be much debate over how these enigmatic organisms are related to each other, there are now dozens of well-defined clades of protists, many of which cluster into larger hypothesized clades. However, readers are cautioned that the field of protist systematics is highly dynamic, and major changes continue to appear at a rapid pace. In fact, protistan classification is probably the most unstable of any classification seen in eukaryote systematics today, and nearly every book that treats the subject uses a somewhat different classification scheme. This instability simply reflects the exciting, rapid state of ongoing discovery among the protists. Certainly, by the time this book is printed protistan classification will have already undergone numerous revisions, and it will continue to do so for the foreseeable future.

One of the more surprising recent discoveries is that the former protist phylum Myxozoa comprises a group of highly modified cnidarians, parasitic in certain invertebrates and vertebrates (see Chapter 7). This revelation was made possible through DNA analyses, and by the discovery of certain metazoan and cnidarian features (e.g., collagen, nematocysts) in myxozoans. Also, the Microsporidia, once thought to be basal protists, are now thought to be highly atypical fungi that dramatically reduced the mitochondria during their evolution. Microsporidia are an enigmatic group of parasites, and some workers retain them among the Protista because they are phagotrophic and lack the chitinous wall around vegetative cells that characterize Fungi. And we now know that the amebas do not constitute a monophyletic group, but are spread through many distantly related protist taxa (i.e., pseudopodia are very different in structure and function in different protist groups, and the basic ameba cell form has evolved many times independently). The kingdom Fungi is now known to have been polyphyletic as once defined, and many of its former members are now spread through several protistan phyla, with the remaining "true fungi" sometimes given the name Eumycota (all true fungi, or Eumycota, have chitin in their cell walls, except the Microsporidia). There are many protist groups that remain quite enigmatic, and we still are not certain about their phylogenetic relationships.

Depending on which specialists you follow, protists can be divided into as few as a half-dozen, or as many as 50+ phyla, and phylogenetic research is clustering these into a half dozen or so larger clades (Box 3A). The deep relationships among protists are now beginning to emerge, and the completion of genome sequencing projects on various species is shedding critical new light on protist relationships. In fact, new data are appearing so rapidly, and so fluid are many of the new hypotheses, that many workers are now opting not to use formal taxonomic names at all, and instead refer to hypothesized "higher clades" simply as "groups" (a practice we follow, in part, in this book). Other workers consider these major clades worthy of "kingdom" or some other status, and still others prefer to simply use vernacular or formal names that have no categorical taxonomic standing at all ("rankless taxa"). The protist phyla we treat in this chapter are the most commonly encountered ones. Although we have organized them by current phylogenetic thinking, this classification scheme will surely be modified as new studies emerge. At the time this book went to press, a conservative view based on molecular phylogenetics (with support from ultrastructural studies) groups the eukaryotes largely into six groups, or putative clades: (1) Amoebozoa, (2) Chromalveolata, (3) Rhizaria, (4) Excavata, (5) Opisthokonta (Choanoflagellata, Metazoa, and Fungi), and (6) Plantae (= Archaeplastida).

CLASSIFICATION OF THE PROTIST PHYLA TREATED IN THIS CHAPTER

GROUP 1 AMOEBOZOA

PHYLUM AMOEBOZOA Examples include: *Acanthamoeba, Amoeba Arcella Chaos, Centropyxis, Difflugia, Endolimax, Entamoeba, Euhyperamoeba, Flabellula, Hartmanella,*

BOX 3A Classification of Eukaryota, Including the 17 Protist Phyla Covered in this Book

(nonprotist taxa are shown in blue)

Kingdom Protista*

GROUP 1 AMOEBOZOA

Phylum Amoebozoa Lobate pseudopod amebas, myxomycetes, dictyostelids, myxogastrids (plasmodial slime molds), and dictyostelids (cellular slime molds or "social amoebae") (200+ described species)

GROUP 2 CHROMALVEOLATA

Phylum Dinoflagellata Dinoflagellates (2,000 described species)

Phylum Apicomplexa Gregarines, coccidians, haemosporidians, and their kin (5,000+ described species)

Phylum Ciliata (= Ciliophora) Ciliates (10,000–12,000 described species)

Phylum Stramenopila Bacillariophytes (photosynthetic diatoms), Phaeophyta (brown algae), Chrysophytes (golden algae), the fungus-like nonphotosynthetic Oomycetes (water molds or Oomycota downy mildews, etc.), and certain parasitic (opalines and blastocystids) and free-living (some heliozoans and flagellates) groups (9,000 described species)

Phylum Haptophyta (= Prymnesiophyta) Coccolithophores and their relatives

Phylum Cryptomonada Cryptomonads

GROUP 3 RHIZARIA

Phylum Chlorarachniophyta Chlorarachniophytes

Phylum Granuloreticulosa Foraminiferans and their kin (4,000+ described species)

Phylum Radiolaria Radiolarians (2,500 described species)

Phylum Haplosporidia Haplosporidans

*Paraphyletic group

GROUP 4 EXCAVATA

Phylum Parabasalida Trichomonads, hypermastigotes, etc (300 described species)

Phylum Diplomonadida Diplomonads (100 described species)

Phylum Euglenida Euglenids (1,000 described species)

Phylum Kinetoplastida Trypanosomes, bodonids, and their kin (600 described species)

Phylum Heterolobosea (Naegleria, Stephanopogon, etc.)

GROUP 5 OPISTHOKONTA

Phylum Choanoflagellata Choanoflagellates (150 described species)

Kingdom Metazoa

Kingdom Fungi

Kingdom Plantae (= Archaeplastida)

Subkingdom Biliphyta

Phylum Glaucophyta Glaucophytes

Phylum Rhodophyta Red algae

Subkingdom Viridiplantae

Phylum Chlorophyta Green algae

Phylum Charophyta Freshwater green algae; includes the stoneworts

Subgroup Embryophyta

Phylum Anthocerotophyta Hornworts

Phylum Bryophyta Other nonvascular plants

Phylum Marchantiophyta Liverworts

Phylum Tracheophyta Vascular plants. Includes clubmosses, horsetails, ferns, gymnosperms, and angiosperms (flowering plants)

Iodamoeba, Mayorella, Pamphagus, Pelomyxa, Thecamoeba, Vannella, Dictyostelium (cellular slime mold), *Fuligo* (plasmodial slime mold), *Physarum* (plasmodial slime mold)

GROUP 2 CHROMALVEOLATA

PHYLUM DINOFLAGELLATA (OR DINOZOA) Examples include: *Amphidinium, Ceratium, Haplozoon, Kofoidinium Gonyaulax, Nematodinium Nematopsides Noctiluca, Peridinium, Perkinsus Pfiesteria Polykrikos Protoperidinium Symbiodinium, Syndinium, Zooxanthella*

PHYLUM APICOMPLEXA Gregarines, coccidians, haemosporidians, and their kin (e.g., *Cryptosporidium, Diaplauxis, Didymophyes, Eimeria, Gregarina, Haemoproteus Lankesterella, Lecudina Leucocytozoon, Plasmodium, Pterospora, Selenidium Strombidium Stylocephalus Toxoplasma*)

PHYLUM CILIATA (OR "CILIOPHORA") The ciliates (e.g., *Balantidium, Coleps, Colpidium Colpoda Didinium Euplotes, Halteria, Laboea, Oxytricha, Paramecium, Podophrya, Stentor Tetrahymena, Tintinnidium, Vorticella*)

PHYLUM STRAMENOPILA Brown algae (= Phaeophyta), Chrysophytes ("golden algae"), the fungus-like nonphotosynthetic Oomycetes (water molds or Oomycota, downy mildews), and certain parasitic (opalines and blastocystids) and free-living (some heliozoans and flagellates) groups (e.g., *Actinophrys, Actinosphaerium, Dinobryon, Fucus, Macrocystis, Opalina, Poteriochromas, Protopalina, Saprolegnia, Synura*); and the photosynthetic diatoms [Bacillariophyta] (e.g., *Actinoptychus, Chaetoceros, Coscinodiscus, Didymosphenia, Melosira, Navicula, Nitzschia, Pseudonitzschia, Thalassiosira*)

PHYLUM HAPTOPHYTA (= PRYMNESIOPHYTA) Coccolithophores and their relatives; placement of Haptophyta within the Chromalveolata is only weakly supported (e.g., *Emiliania Pavlova*)

PHYLUM CRYPTOMONADA Placement of Cryptomonada within the Chromalveolata is only weakly supported (e.g., *Cryptomonas* [= *Chilomonas*], *Goniomonas Guillardia*)

GROUP 3 RHIZARIA

PHYLUM CHLORARACHNIOPHYTA Examples include: *Bigelowiella, Bigelowiella, Chlorarachnion Gymnochlora, Lotharella*

PHYLUM GRANULORETICULOSA Foraminiferans and their kin (e.g., *Allogromia, Ammonia, Astrorhiza, Arachnula, Biomyxa, Chitinosiphon Elphidium, Glabratella, Globigerina, Globigerinella, Gromia Iridia, Lenticula, Microgromia, Nummulites, Rhizoplasma, Rotaliella, Technitella, Tretomphalus*)

PHYLUM RADIOLARIA Examples include: *Acanthodesmia Acanthosphaera, Arachnosphaera, Artopilium Challengeron, Dendrospyris Heliodiscus, Helotholus, Lamprocyclas, Peridium Phormospyris, Sphaerostylus*

PHYLUM HAPLOSPORIDIA Examples include: *Bonamia Haplosporidium, Marticella Minchinia, Urosporidium*

GROUP 4 EXCAVATA

PHYLUM PARABASALIDA Trichomonads, hypermastigotes (e.g., *Dientamoeba, Histomonas, Monocercomonas, Pentatrichomonas, Trichomonas, Trichonympha, Tritrichomonas*)

PHYLUM DIPLOMONADIDA Examples include: *Enteromonas, Giardia, Hexamita, Octomitis, Spironucleus, Trimitus*

PHYLUM HETEROLOBOSEA Examples include: *Naegleria* and *Stephanopogon*

PHYLUM EUGLENIDA (= EUGLENOZOA) Examples include: *Ascoglena, Calkinsia, Colacium, Entosiphon, Euglena Lepocinclis Menoidium, Peranema Phacus Rapaza, Strombomonas, Trachelomonas*

PHYLUM KINETOPLASTIDA Trypanosomes, bodonids, and their kin (e.g., *Bodo, Cryptobia, Dimastigella, Leishmania, Leptomonas, Procryptobia, Rhynchomonas Trypanosoma*)

GROUP 5 OPISTHOKONTA

PHYLUM CHOANOFLAGELLATA Examples include: *Codosiga, Monosiga, Proterospongia*

The Opisthokonta also includes the taxa Nucleariida, chthyosporea (= Mesomycetozoea), and the kingdoms Metazoa and Fungi

Overviews of the Major Clades, or Groups

GROUP 1: AMOEBOZOA

The Amoebozoa include most of the well known amebas with lobate (rather than threadlike) pseudopodia, as well as the bizarre slime molds. Although lacking clear cut morphological synapomorphies, most are unicellular and most produce lobate pseudopodia. Amoebozoa is well supported by molecular phylogenetic studies. The group contains only a single nominate phylum (Amoebozoa), and includes such familiar groups as the gymnamoebas, entamoebas, and plasmodial and cellular slime molds. Most amoebozoans are free living heterotrophs that feed by engulfing other cells with their pseudopodia. Also included are some mitochondria lacking organisms (pelobionts and entamoebas) and several facultative or obligate parasites. Current evidence suggests both the plasmodial slime molds and cellular slime molds (the social amebas) belong to this clade. Cellular slime molds (e.g., *Dictyostelium*) are amebas that periodically congregate to form an asexual, spore producing phase called a fruiting body. Plasmodial slime molds (e.g., *Fuligo*) don't have congregating cells, but do have sexual fruiting bodies that produce aggregated cell masses.

GROUP 2: CHROMALVEOLATA

This chapter treats six of the phyla included in this large and diverse assemblage: Dinoflagellata, Apicomplexa, Ciliata, Stramenopila, Haptophyta, and Cryptomonada. Photosynthetic species in these groups have plastids that contain chlorophyll *c*, in addition to chlorophyll *a*. Chromalveolates are predominately unicellular, and they may be photosynthetic or nonphotosynthetic. They are united by the "chromalveolate hypothesis," which states that a single secondary endosymbiosis with a red alga gave rise to a plastid ancestor of all chromalveolates. This plastid was secondarily lost or reduced in some lines, and there was a tertiary reacquisition of a plastid in others. Support for this group is largely based on plastid-related characters, and no single character- or molecular phylogeny has been able to unite all of its hypothesized members.

The phyla Dinoflagellata, Apicomplexa, and Ciliata form a monophyletic clade, the Alveolata, uniquely characterized by a system of flattened, membrane-bounded sacs or cavities, called **alveoli**, that lie just beneath the outer cell membrane. The function of the alveoli is unknown; researchers hypothesize that they may help stabilize the cell surface or regulate the cell's water and ion content. The alveolate clade is also strongly supported by gene sequence phylogenetics.

All three alveolate phyla contain predatory and parasitic species, but only dinoflagellates (and an unusual lineage called *Chromera*) are known to contain fully integrated and photosynthetic plastids.

Closely related to the alveolates is a large and diverse cluster of protists called the Stramenopila, now usually given phylum status. The Stramenopila were first identified through molecular phylogenetic studies and later received confirmation from comparative anatomical work. "Stramenopila" (Latin *stramen*, straw; *pilos*, hair) refers to a flagellum lined with numerous, fine, tubular hairs—a distinctive feature of these protists. In most stramenopiles, this "hairy" flagellum is paired with a smooth (nonhairy) flagellum. In some stramenopile groups, the only flagellated cells are motile reproductive cells. The Stramenopila include: photosynthetic diatoms; brown algae (formerly placed in their own phylum, Phaeophyta); Chrysophytes (the "golden algae"); the funguslike, nonphotosynthetic Oomycetes (water molds or Oomycota, downy mildews, etc.); and certain parasitic (opalines and blastocystids) and free-living (some heliozoans and flagellates) groups. The opalines and diatoms are thought to have secondarily lost the unique hollow hairs (although in centric diatoms the male gametes have hairy flagella). The largest known eukaryotes are stramenopiles—brown algae known as kelp (e.g., *Macrocystis*, *Nereocystis*, *Egregia*). Recent work suggests that many stramenopiles also contain nuclear genes from an ancient secondary endosymbiotic event with a green alga, perhaps even predating the red algal gene acquisition that now dominates the photosynthetic machinery in this phylum.

Two other chromalveolate groups, Haptophyta (or Prymnesiophyta; coccolithophores and their relatives) and Cryptomonada (e.g., *Cryptomonas*, = *Chilomonas*) have plastids that contain chlorophyll *a* and *c*, suggesting they also might belong to the alveolate assemblage. However, the precise nature of their affinity with stramenopiles and alveolates has yet to be established. Recent molecular analyses suggest the Stramenopiles, Alveolata, and Rhizaria (the "SAR group") might share a common ancestry to the exclusion of the haptophytes and cryptomonads, which would leave these three taxa with an uncertain classification. There is also reasonable support for Haptophyta being sister to the SAR group.

GROUP 3: RHIZARIA

The clade called Rhizaria contains the mixotrophic, green chloroplast-containing phylum Chlorarachniophyta, the parasitic Haplosporidia, and the phyla Granuloreticulosa and Radiolaria, as well as some fungilike plant parasites such as the plasmodiophorids. Most amebas (including radiolarians) that have threadlike pseudopodia are part of Rhizaria, although these filopodia may vary from simple, to branching or anastomosing. The relationships of the major rhizarian clades remain unresolved, and even the number and placement of the "phyla" is highly unstable. Some recent molecular evidence suggests that Radiolaria and Granuloreticulosa are basal groups, the remaining groups forming the subgroup, or clade, sometimes called Cercozoa (e.g., chlorarachniophytes, plasmodiophorids, haplosporids). There are numerous flagellated cercozoans, many of which use pseudopodia for feeding, if not movement. Although poorly studied, it is known that many small-to-medium sized, heterotrophic cercozoans (e.g., *Cercomonas*, *Heteromita*, *Euglypha*), both flagellates and amebas, are important members of benthic and soil microbial communities. Chlorarachniophytes (e.g., *Chlorarachnion*, *Cryptochlora*, *Gymnochlora*, *Lotharella*) are unusual within the cercozoan clade in having chloroplasts. Most studies suggest that Radiolaria is the deepest branch, and that Granuloreticulosa and Haplosporidia branch next to, or even within Cercozoa, but it has also been proposed that Granuloreticulosa and Radiolaria are a clade, or that Granuloreticulosa and Cercozoa are sister groups. The group Rhizaria is united only by molecular phylogenetics; other kinds of synapomorphies are as yet unknown. Recent molecular analyses link the rhizarians closely to the chromalveolates.

GROUP 4: EXCAVATA

The excavates comprise a somewhat loose amalgamation of protists whose relationships to one another are just beginning to be understood. These are unicellular eukaryotes that share an array of cytoskeletal features as well as a distinctive ventral excavation that functions as a feeding groove (a suspension feeding cytostome capturing small particles from a feeding current generated by a posteriorly directed flagellum), plus forms that have apparently lost some of these features. Overall, the clade Excavata is only weakly supported by molecular data. Most excavates are heterotrophic flagellates, and many have greatly modified mitochondria.

Currently included within the Excavata are the following protist groups: the phyla Parabasalida (trichomonads and hypermastigotes; e.g., *Dientamoeba*, *Histomonas*, *Monocercomonas*, *Pentatrichomonas*, *Trichomonas*, *Trichonympha*, *Tritrichomonas*), Diplomonada (e.g., *Enteromonas*, *Giardia*, *Hexamita*, *Octomitis*, *Spironucleus*, *Trimitus*), and Heterolobosea (e.g., *Naegleria*, *Stephanopogon*), as well as the groups Jakobida (e.g., *Reclinomonas*), Oxymonada, Retortamonada, Euglenozoa, and a few others. Recent multigene analyses of excavate taxa identify three clades. One clade

comprises diplomonads, parabasalids, and the free living amitochondriate protist *Carpediemonas*. The second clade consists of two other amitochondriate groups, oxymonads and *Trimastix*. The third clade is composed of Euglenozoa, Heterolobosea, and Jakobida. Several of the excavate taxa were long thought to lack mitochondria, but recent evidence suggests these groups have highly reduced or modified mitochondria (e.g., Parabasalida, Diplomonada). The jakobids have the most primitive (bacterialike) mitochondrial genomes known.

The phylum Heterolobosea is more closely related to euglenids and kinetoplastids than to other amebas. *Naegleria fowleri* (= *N. aerobia*) is the major agent of a disease called primary amebic meningoencephalitis (PAM), or simply "amebic meningitis." PAM is an acute, fulminant, rapidly fatal illness usually affecting young people who have been exposed to water harboring the free-living trophozoites, most commonly in lakes and swimming pools (but this ameba has even been isolated from bottled mineral water in Mexico). It is thought that the amebas are forced into the nasal passages when the victim dives into the water. Once in the nasal passages, they migrate along the olfactory nerves, through the cribiform plate, and into the cranium. Death from brain destruction is rapid. They do not form cysts in the host. *Naegleria* infections are rare, but usually fatal. Only a few hundred cases have been documented since its discovery in Australia in 1960s, including a few dozen in the United States. As environments warm, *Naegleria* is expected to spread to higher latitudes.

The excavate subclade Euglenozoa contains the "plantlike" phylum Euglenida, the phylum Kinetoplastida (trypanosomes, bodonids, and their kin), and a few other odds and ends (e.g., diplonemids). Euglenozoans comprise a diverse group of flagellate predatory heterotrophs, photosynthetic autotrophs, and pathogenic parasites. Two principal anatomical features distinguish euglenozoans: (1) a spiral, or crystalline rod inside each of their two flagella, which insert into an anterior pocket; and (2) disk-shaped mitochondrial cristae. Parasitic and commensal euglenozoans have evolved independently several times among the kinetoplastids. The Euglenozoa clade is also supported by molecular phylogenetic studies. Both the Euglenida and the Kinetoplastida were formerly classified in the old "protozoan" phylum Sarcomastigophora.

The excavates are mostly heterotrophic flagellates, and even within the parasitic groups there are heterotrophic members. Many excavates have highly modified mitochondria not used for oxidative phosphorylation, and these are common in low-oxygen habitats (including animal guts). Broad-pseudopod forming amebas have evolved in one group (Heterolobosea), independently of the Amoebozoa, and even include their own group of slime molds (the acrasids). The euglenids appear to have originated via secondary endosymbiosis between a predatory euglenid and a green alga prey.

GROUP 5: OPISTHOKONTA

The clade known as Opisthokonta includes the kingdoms Metazoa and Fungi (and its likely sister group, Nucleariida), the Choanoflagellata, and a few other small protist groups. Two spore-forming groups once allied with protists in this group are now known to be animals (Myxozoa) and fungi (Microsporidia). In this chapter, we treat the choanoflagellates, which comprise the sister group, and probable direct ancestors, of the Metazoa. Together, Choanoflagellata and Metazoa (along with a few enigmatic unicellular eukaryotes that predated choanoflagellates) comprise a clade called Holozoa. The clades Opisthokonta and Holozoa are both strongly supported by molecular phylogenetics.

The General Protistan Body Plan

While realizing that the protists do not represent a monophyletic group, it is still advantageous to examine them together from the standpoint of the strategies and constraints of a unicellular, or at least a nontissue-level, eukaryotic body plan. Protists represent the "most primitive," or more accurately, the most ancient, living eukaryotes, yet, within the limitations imposed by their unicellularity, these creatures still must accomplish all of the basic life functions common to the Metazoa. Recall that the Eukaryota is distinguished from the other two major clades of life (prokaryotic Bacteria and Archaea) by the structural complexity of the cells—characterized by internal membranes and by having many functions segregated into semiautonomous regions (organelles) and by the cytoskeleton. Fundamentally unique to the Eukaryota, and evidence of their singular origin, is the double membrane-bound nucleus with its linear chromosomes (*eukaryote*, "true nuclei").

Body Structure, Excretion, Gas Exchange, and Single Celledness

Most life processes are dependent upon activities associated with surfaces, notably with cell membranes. Even in the largest multicellular organisms, the regulation of exchanges across cell membranes and the metabolic reactions along the surfaces of various cell organelles are the phenomena on which all life ultimately depends. Consequently, the total area of these important surfaces must be great enough relative to the volume of the organism to provide adequate exchange and reaction sites. Nowhere is the "lesson" of the surface area-to-volume ratio more clearly demonstrated than among the protists, where it reveals the impossibility of massive, 100 kg amebas (1950s horror

movies notwithstanding). Lacking both an efficient mechanism for circulation within the body and the presence of membrane partitions (multicellularity) to enhance and regulate exchanges of materials, protists must remain relatively small (with a few notably unique groups, such as the brown algae). The diffusion distances between protists' cell membranes (their "body surface") and the innermost parts of their bodies can never be so great that it prevents adequate movement of materials from one place to another within the cell. Certainly there are structural elements (e.g., microtubules, endoplasmic reticula) and various processes (e.g., protoplasmic streaming, active transport) that supplement passive phenomena. But the fact is, unicellularity mandates that a high surface area-to-volume ratio be maintained by restricting shape and size. This is the principle behind the fact that the largest protists (other than certain colonies, or colonylike species) assume shapes that are elongate, thin, flattened, or hollow--shapes that maintain small diffusion distances.

The formation of membrane-bounded pockets, or vesicles, is common in protists, and these structures help maintain a high surface area for internal reactions and exchanges. The elimination of metabolic wastes and excess water, especially in freshwater forms living in hypotonic environments, is facilitated by water expulsion vesicles (Chapter 4, Figure 4.22). As explained in Chapter 4, these vesicles (frequently called contractile vacuoles) release their contents to the outside in a more or less controlled fashion, often counteracting the normal diffusion gradients between the cell and the environment.

Support and Locomotion

The cell surface is critical not only in providing a means of exchange of materials with the environment but also in providing protection and structural integrity to the cell. The plasma membrane itself serves as a mechanical and chemical boundary to the protist "body," and when present alone (as in the "naked amebas"), it allows great flexibility and plasticity of shape. However, many protists maintain a more or less constant shape (spherical, radial, or even bilaterally symmetrical) by thickening the cell membrane to form a rigid or semirigid pellicle, by secreting scales or a shelllike covering called a test (usually of cellulose, $CaCO_3$ or SiO_2), by accumulating particles from the environment, or by other skeletal arrangements described below.[4]

The cytoskeleton is a complex array of proteins that provides the structural framework for protist (indeed, for all eukaryote) cells and its components and organelles. Locomotory capabilities are also ultimately provided by interactions between the cell surface and the surrounding medium. Pseudopodia, cilia, and flagella provide the means by which many protists push or pull themselves along.

Pseudopodia come in a variety of forms. **Lobopods** (lobopodia) are broad and blunt tipped. **Filopods** (filopodia) are thin and tapering; they can be simple, branching or anastomosing. **Axopods** (axopodia) are also thin and tapering, but supported by microtubules. **Reticulopods** are thin and anastomosing and supported by microtubules.

Nutrition

Various types of nutrition occur among protists, but fundamentally they may be either autotrophic or heterotrophic, and many are both. Photosynthetic protists have plastids and are capable of photosynthesis, although not all use the same pigments, and they may differ in plastid structure (Figure 3.3). All heterotrophic protists acquire food through some interaction between the cell surface and the environment. Heterotrophic forms may be saprobic, taking in dissolved organics by diffusion, active transport, or pinocytosis. Or they may be holozoic, taking in solid foods--such as organic detritus or whole prey (e.g., bacteria, smaller protists)—by phagocytosis. Many heterotrophic protists are symbiotic on or within other organisms. Those protists that engage in pinocytosis or phagocytosis rely on the formation of membrane-bounded vesicles called food vacuoles (Figure 3.4). These structures may form at nearly any site on the cell surface, as they do in the amebas, or at particular sites associated with some sort of "cell mouth," or cytostome, as they do in most protists with more or less fixed shapes. The cytostome may be associated with further elaborations of the cell surface that form permanent invaginations or feeding structures (discussed in more detail below, under specific taxa).

Once a food vacuole has formed and moved into the cytoplasm, it begins to swell as various enzymes and other chemicals are secreted into it. The vacuole first becomes acidic, and the vacuolar membrane develops numerous inwardly directed microvilli (Figure 3.4). As digestion proceeds, the pH of the vacuolar fluid shifts to become increasingly alkaline. The cytoplasm just inside the vacuolar membrane takes on a distinctive appearance from the products of digestion. Then the vacuolar membrane forms tiny vesicles that pinch off and carry these products into the cytoplasm. Much of this latter activity resembles cell-surface pinocytosis. The result is numerous, tiny, nutrient carrying vesicles offering a greatly increased surface area for absorption of the digested products into the cell's cytoplasm. During this period of activity, the original vacuole gradually shrinks and undigested materials eventually are expelled from the cell. In some protists (e.g., many amebas), the spent vacuole may discharge anywhere

[4] Cellulose is the most abundant organic polymer on Earth. It is a polysaccharide consisting of a linear chain of several hundred to many thousands of $\beta(1 \rightarrow 4)$ linked D glucose units.

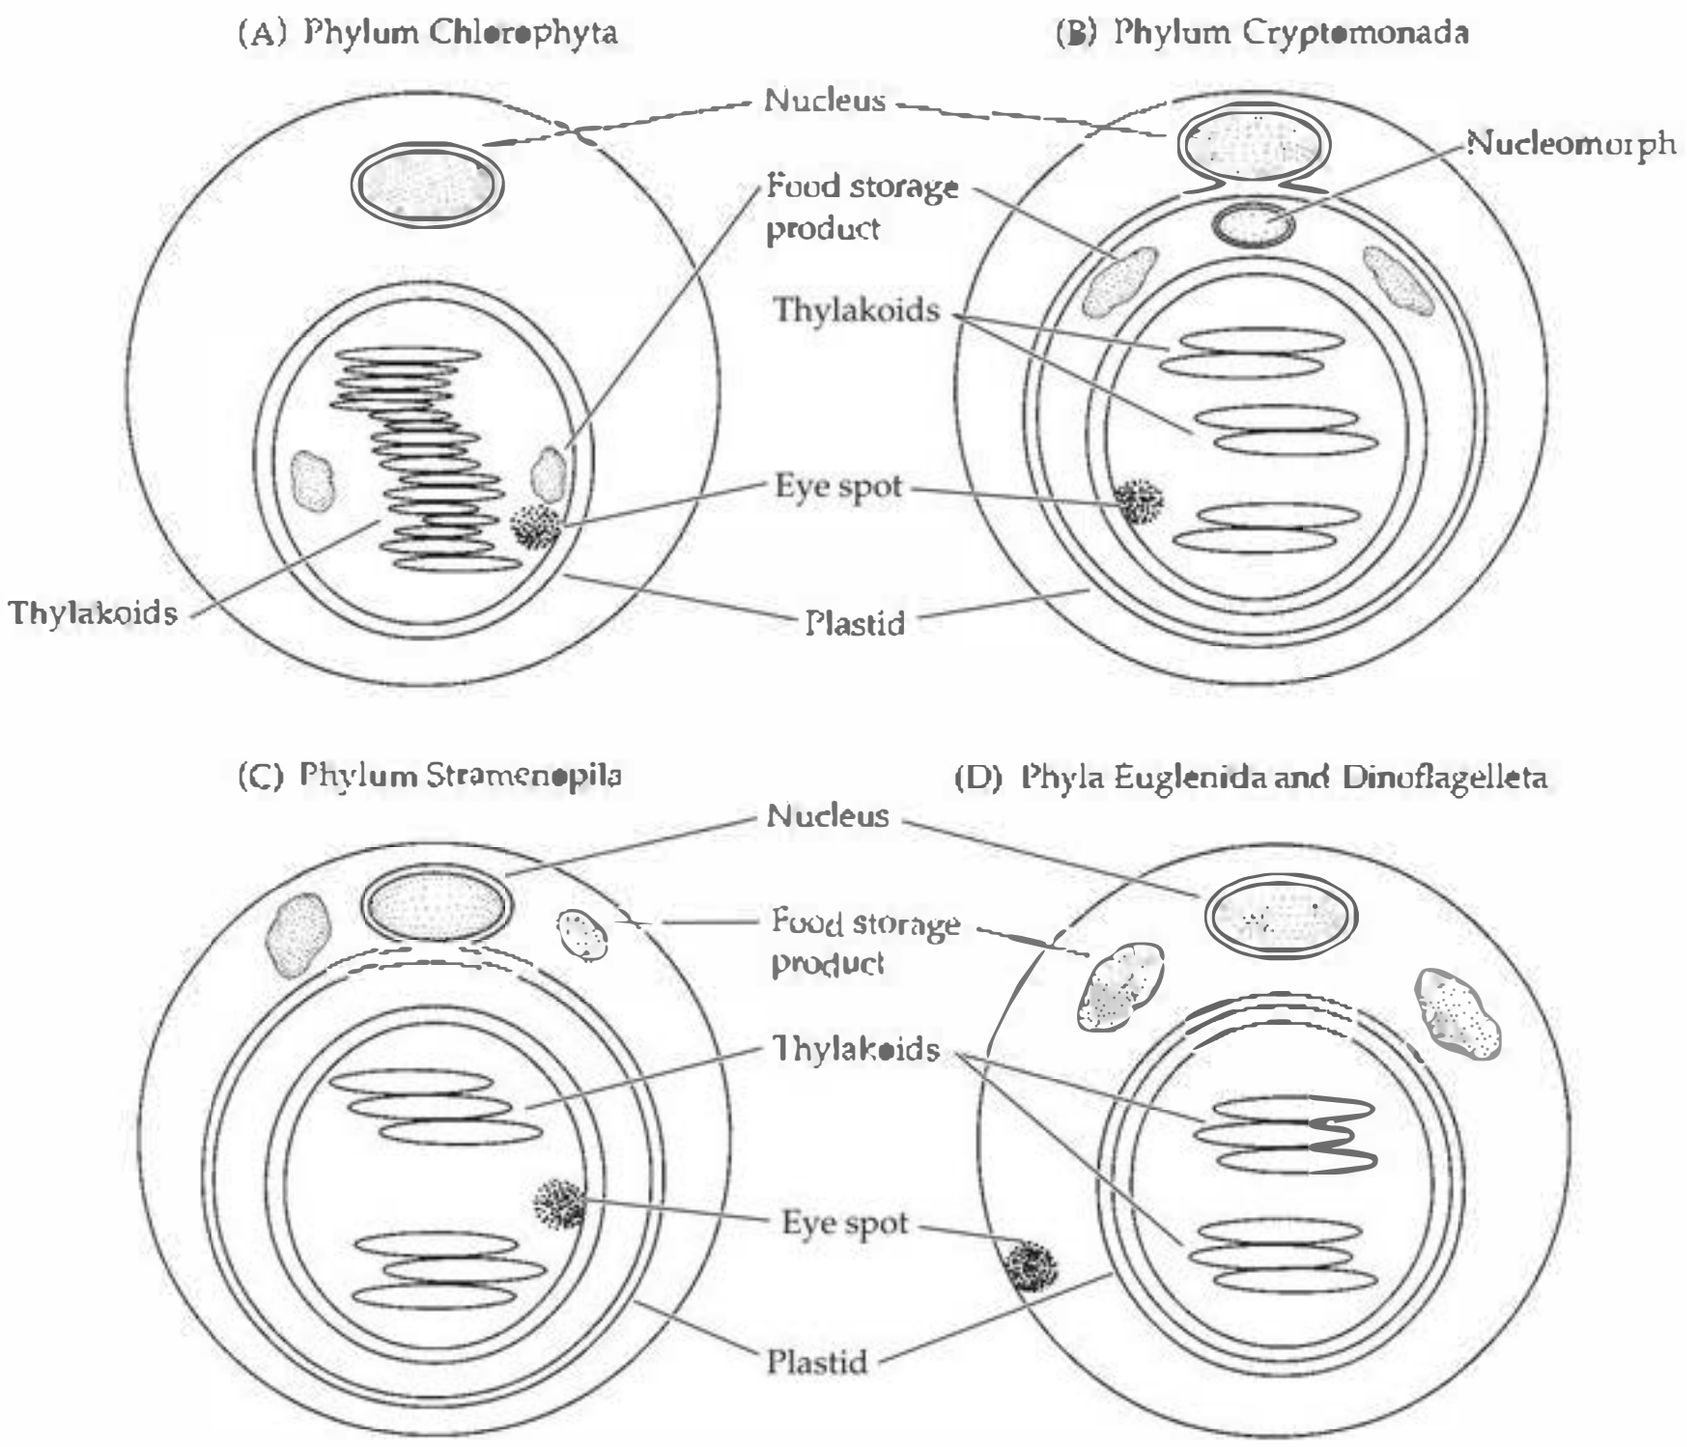

Figure 3.3 Variations in protist (and Chlorophyta) chloroplast anatomy. (A) Phylum Chlorophyta. As in land plants, the chloroplast in Chlorophyta is surrounded by two membranes and the thylakoids are arranged in irregular stacks, or grana. Also as in land plants, the primary photosynthetic pigments in chlorophytes are chlorophylls *a* and *b*, and food reserves are stored as starch inside the chloroplast. (B) Phylum Cryptomonada. In cryptomonads, the chloroplast is surrounded by four membranes and the thylakoids occur in stacks of two. The inner two membranes enclose the thylakoids and eyespot; the outer two membranes also enclose the storage product granules and nucleomorph. The outermost membrane of the four is also continuous with the nuclear envelope. The nucleomorph is thought to be the nucleus of an ancient endosymbiont that eventually became the chloroplast. Food reserves are stored as starch and oils, and the primary photosynthetic pigments are chlorophylls *a* and c_2; accessory pigments include phycobilins and alloxanthin. (C) Phylum Stramenopila. In photosynthetic stramenopiles, the chloroplast is surrounded by four membranes and the thylakoids occur in stacks of three. In many stramenopiles, the outermost membrane is continuous with the inner envelope. Food reserves are stored as liquid polysaccharide (usually laminarin) and oils, which are located in the cytoplasm. The primary photosynthetic pigments are chlorophylls a, c_1, and c_2. (D) Phyla Euglenida and Dinoflagellata. In both of these phyla, the chloroplasts are surrounded by three membranes and the thylakoids are arranged in stacks of three. Also in both phyla, the food storage products (starch and oils) and the eyespots are located outside of the chloroplast. The primary photosynthetic pigments in euglenids are chlorophylls *a* and *b*. Food reserves are stored as paramylon. In dinoflagellates, the photosynthetic pigments include chlorophylls *a* and c_2; accessory pigments include the xanthophyll peridinin, which is unique to dinoflagellates. Note that in some dinoflagellates, the eyespot is located inside the chloroplast rather than in the cytoplasm. The food storage products are starch and oils.

on the cell surface. But in ciliates and others in which a relatively impermeable covering exists around the cell, the covering bears a permanent pore (cytoproct) through which the vacuole releases material to the outside. Anything left in the food vacuole when it reaches the cytoproct is discharged.

In most protists, as in other eukaryotic organisms, the organelles responsible for most ATP production are the mitochondria. The mitochondria of protists, like all mitochondria, have two membranes, but the inner membranes, or cristae, have different forms—tubular, discoidal, and lamellar (Figure 3.5). However, in several groups of protists the mitochondria have been profoundly modified to generate ATP using alternative non-oxygen–dependent pathways, or no longer have a known energy-generating role at all.

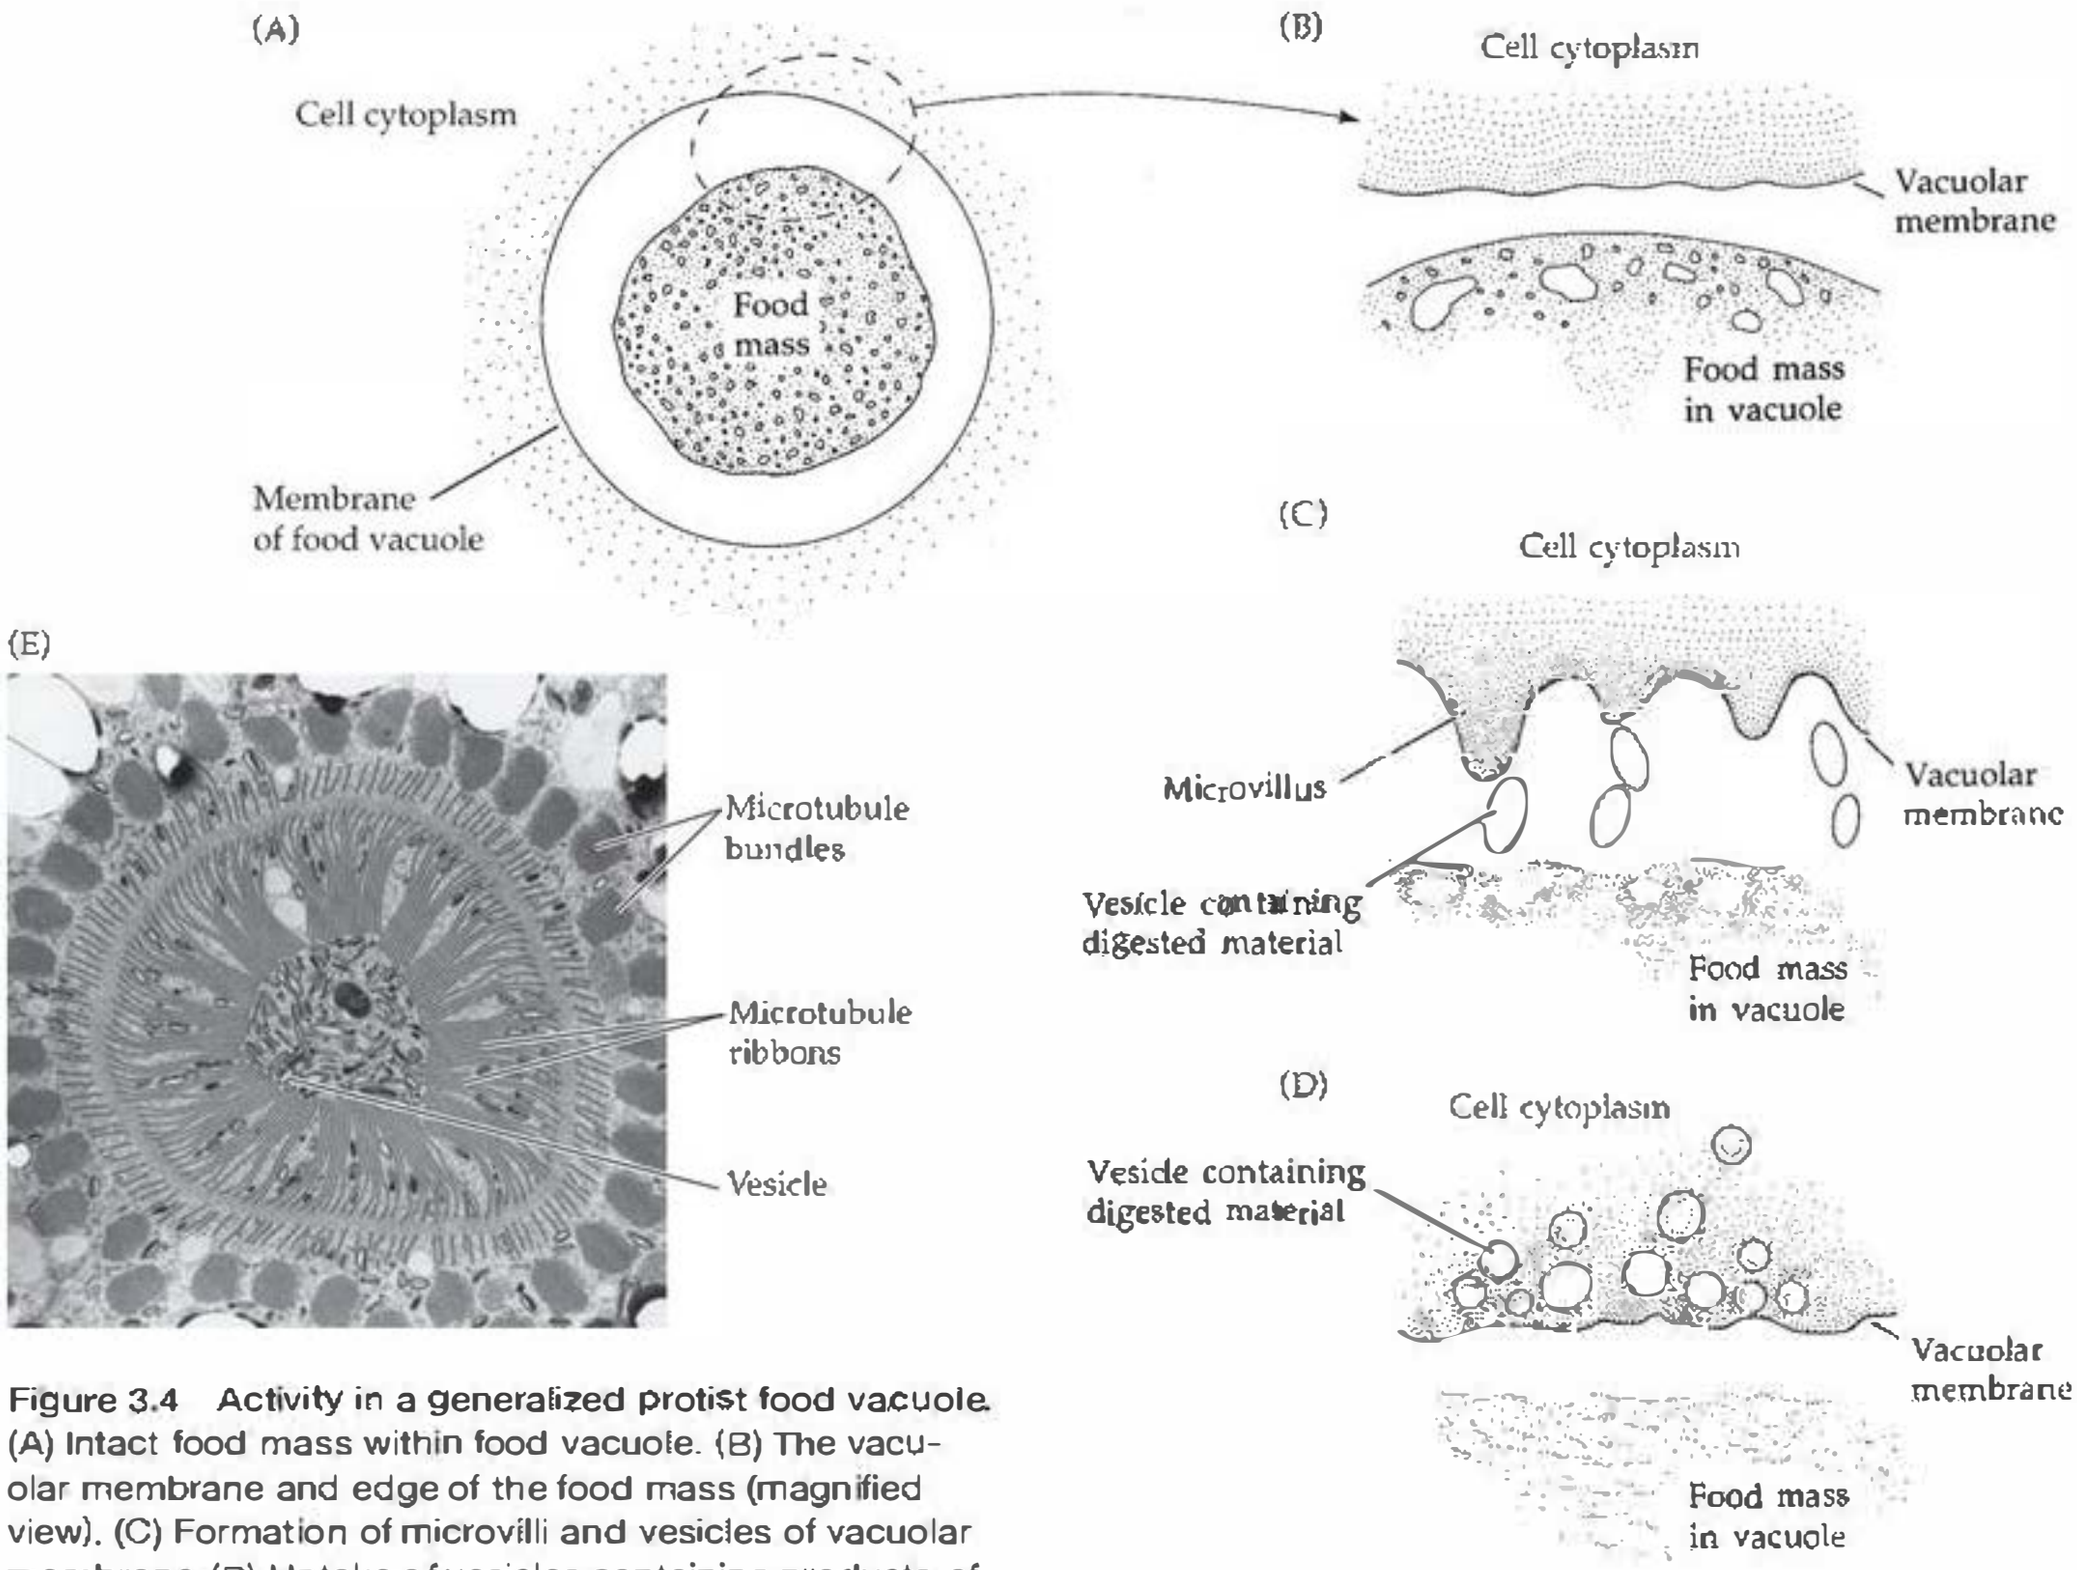

Figure 3.4 Activity in a generalized protist food vacuole. (A) Intact food mass within food vacuole. (B) The vacuolar membrane and edge of the food mass (magnified view). (C) Formation of microvilli and vesicles of vacuolar membrane. (D) Uptake of vesicles containing products of digestion into the cytoplasm. (E) Cross section through the cytostome of the ciliate *Helicoprorodon*, showing the area of food vacuole formation at center. Microtubules provide support to the mouth.

Activity and Sensitivity

Many protists display remarkable degrees of sensitivity to environmental stimuli and are capable of surprisingly complex behaviors. But, unlike that of animals, protists' entire stimulus–response circuit lies within the confines of a single cell. Response behavior may be a function of the general sensitivity and conductivity of protoplasm, or it may involve special organelles. Sensitivity to touch often involves distinctive locomotor reactions in motile protists and avoidance responses in many sessile forms. Cilia and flagella are touch-sensitive; when mechanically stimulated, they typically stop beating or beat in a pattern that moves the organism away from the point of stimulus. These responses are most dramatically expressed by sessile stalked ciliates, which display very rapid reactions when the cilia of the cell body are touched. Contractile elements within the stalk shorten, pulling the animal's body away from the source of the stimulus.

Many protists have **extrusomes**, membrane-bound (exocytotic) organelles containing various chemicals. Extrusomes have a variety of functions (e.g., protection, food capture, secretion), but they have one feature in common: they readily, and sometimes explosively, discharge their contents when subjected to stimuli. The best-known extrusome is the trichocyst of ciliates such as *Paramecium*, but about ten different types are known among protists.

Thermoreception is known to occur in many protists but is not well understood. Under experimental conditions, most motile protists will seek optimal temperatures when given a choice of environments. This behavior probably is a function of the general sensitivity of the organism and not of special receptors. Some evidence suggests that thermoreception in protists may be under electrophysiological control. Chemotactic responses are probably similarly induced. Most protists react positively or negatively to various chemicals or concentrations of chemicals. For example, amebas are able to distinguish food from nonfood items and quickly eject the latter from their vacuoles. Many ciliates, especially predators, have specialized patches of sensory cilia that aid in finding prey, and even filter feeders use

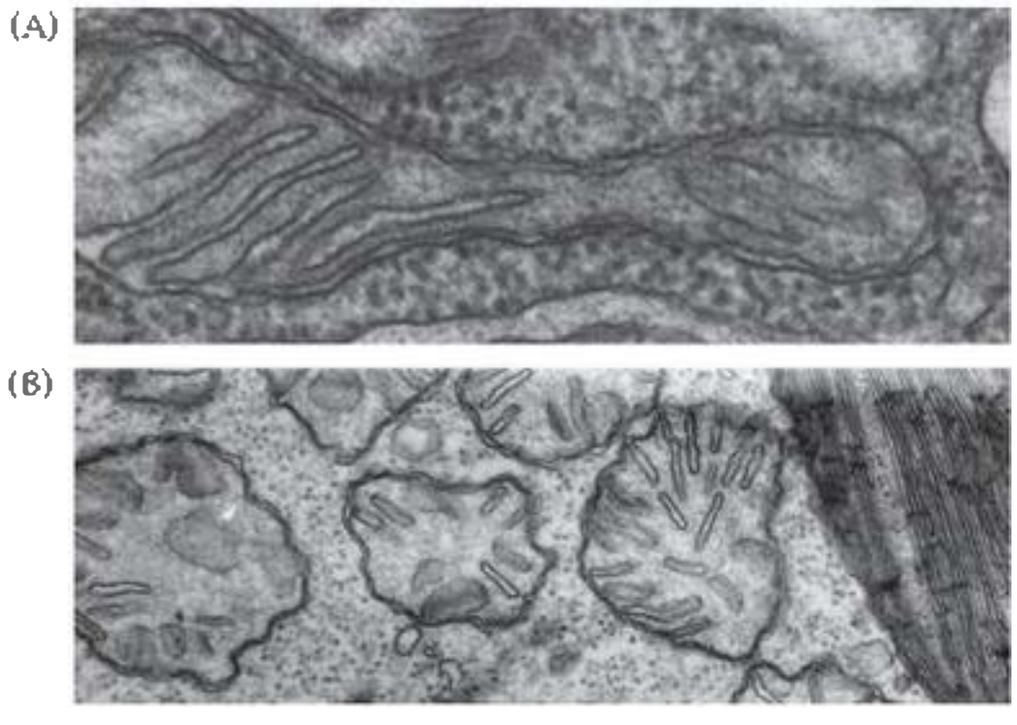

Figure 3.5 Protist mitochondria, showing variation in the inner membrane (i.e., cristae), plus the chlorophyte *Pteromonas lacerata*. (A) Lamellar cr stae from the mitochondr on of the choanoflagellate *Stephanocea* (× 80,000). (B) Discoida cristae from the mitochondrion of the euglenid *Euglena spirogyra* (× 40,000). (C) Dilated tubular cr stae from the mitochondrion of *Apusomonas proboscidea*, an enigmatic f agel ate of uncertain affinity (× 97,000). (D) Tubular cr stae from the mitochondrion of the chlorophyte *Pteromonas lacerata* (× 27,000).

cilia located around the cytostome to "taste" and then accept or reject food items

Photosynthetic protists typically show a positive taxis to low- or moderate light intensities, an obviously advantageous response for these creatures. They usually become negatively phototactic in very strong light. Specialized light sensitive organelles are known among many flagellates, especially the photosynthetic ones. These organisms often have pigmented eyespots, or stigmata (sing. stigma) that are usually associated with the flagellar apparatus. The stigmata are oriented to shade the light sen sitive region (often part of the flagellum itself) from some directions, and the flagella thus behave differently depending on whether or not the sensitive region is receiving direct light Some stig mata are actually contained inside a lobe of the chloro plast. Eyespots vary in complexity, ranging from very simple pigment spots to complex, lens-like structures.

Reproduction

A major aspect of protist success is their surprising range of reproductive strategies. Most protists have been able to capitalize on the advantages of both asexual and sexual reproduction, although some appar ently reproduce only asexually. Many of the complex life cycles seen in certain protists (especially parasitic forms) involve alternation between sexual and asexual processes, with a series of asexual divisions between brief sexual phases.

Protists undergo a variety of strictly asexual repro ductive processes including binary fission, multiple fission, and budding. **Binary fission** involves a single mitotic division, resulting in two daughter cells. During **multiple fission**, the nucleus undergoes sev eral multiple divisions prior to **cytokinesis** (partitioning of the cytoplasm), resulting in many daughter cells. Some protists engage in a process called **plasmotomy**, considered by some to be a form of budding, in which a multinucleate adult simply divides into two multi nucleate daughter cells Still others undergo a type of internal budding called **endopolygeny**, during which daughter cells actually form within the cytoplasm of the mother cell.

The advantage of sexual reproduction has long been viewed to be the generation and maintenance of genetic variation within populations and species. Protists have evolved a variety of methods that achieve this, not all of which result in the immediate produc tion of additional individuals. If we expand our traditional definition of meiosis to include any nuclear process that results in a haploid condition, then meiosis can be considered a general eukaryotic phenomenon. This disclaimer is necessary because protist "meiosis" is more variable than that seen in animals, and it is certainly less well understood. Nonetheless, reduction division does occur, and haploid cells or nuclei of one kind or another are produced, and then fuse to restore the diploid condition. The production and subsequent fusion of gametes in protists is called syngamy. However, not all protists are diploid. In the diploid forms, gametes are produced by mitosis, or simply by an existing cell starting to behave as a gamete—when two gametes from haploid individuals fuse to form a

BOX 3B Six Categories of Mitosis in Protists

Open mitosis

1. *Open orthomitosis.* The nuclear envelope breaks down competely; the spindle is symmetrical and bipolar; an equatorial plate occurs.

Semi-open mitosis

2. *Semi-open orthomitosis.* The nuclear envelope persists except for small fenestrae through which the spindle microtubules enter the nucleus; the spindle is symmetrical and bipolar; an equatorial plate occurs.
3. *Semi-open pleuromitosis.* The nuclear envelope persists except for small fenestrae through which the spindle microtubules enter the nucleus; the spindle is asymmetrical; an equatorial plate does not form.

Closed mitosis with an intranuclear spindle

4. *Intranuclear orthomitosis.* Nuclear envelope persists throughout mitosis; spindle is symmetrical, bipolar, and forms inside the nucleus; an equatorial plate usually forms.
5. *Intranuclear pleuromitosis.* Nuclear envelope persists throughout mitosis; spindle is asymmetrical and forms inside the nucleus; an equatorial plate does not form.

Closed mitosis with an extranuclear spindle

6. *Extranuclear pleuromitosis.* Nuclear envelope persists throughout mitosis; spindle is asymmetrical and forms outside of the nucleus; an equatorial plate does not form.

diploid cell, the fusion is followed by meiosis to form the next generation of nonreproductive cells (e.g., in apicomplexans). There are also taxa that will live asexually in either the diploid or haploid state for extended periods (e.g., haptophytes), and in these cases the two forms might look quite different.

Protist cells responsible for the production of gametes are often called **gamonts.** Syngamy may involve gametes that are all similar in size and shape (**isogamy**), or the more familiar condition of gametes of two distinct types (**anisogamy**). Thus, as in the Metazoa, both haploid and diploid phases can be produced in the life histories of sexual protists. As noted above, the meiotic process may immediately precede the formation and union of gametes (prezygotic reduction division), or it may occur immediately after fertilization (postzygotic reduction division), as it also does in haploid protists and in many plants. Other sexual processes that result in genetic mixing by the exchange of nuclear material between mates (conjugation) or by the re-formation of a genetically "new" nucleus within a single individual (autogamy) are best known among the ciliates and are discussed below for that phylum.

There is also considerable variability in mitosis among protists (Box 3B). Different mitotic patterns are primarily distinguished on the basis of persistence of the nuclear membrane (= envelope), and the location and symmetry of the spindle (Figure 3.6). The terms "open," "semi-open," and "closed" refer to the persistence of the nuclear envelope. If mitosis is open, the nuclear membrane breaks down completely; if it is semi-open, the nuclear envelope remains intact except for small holes

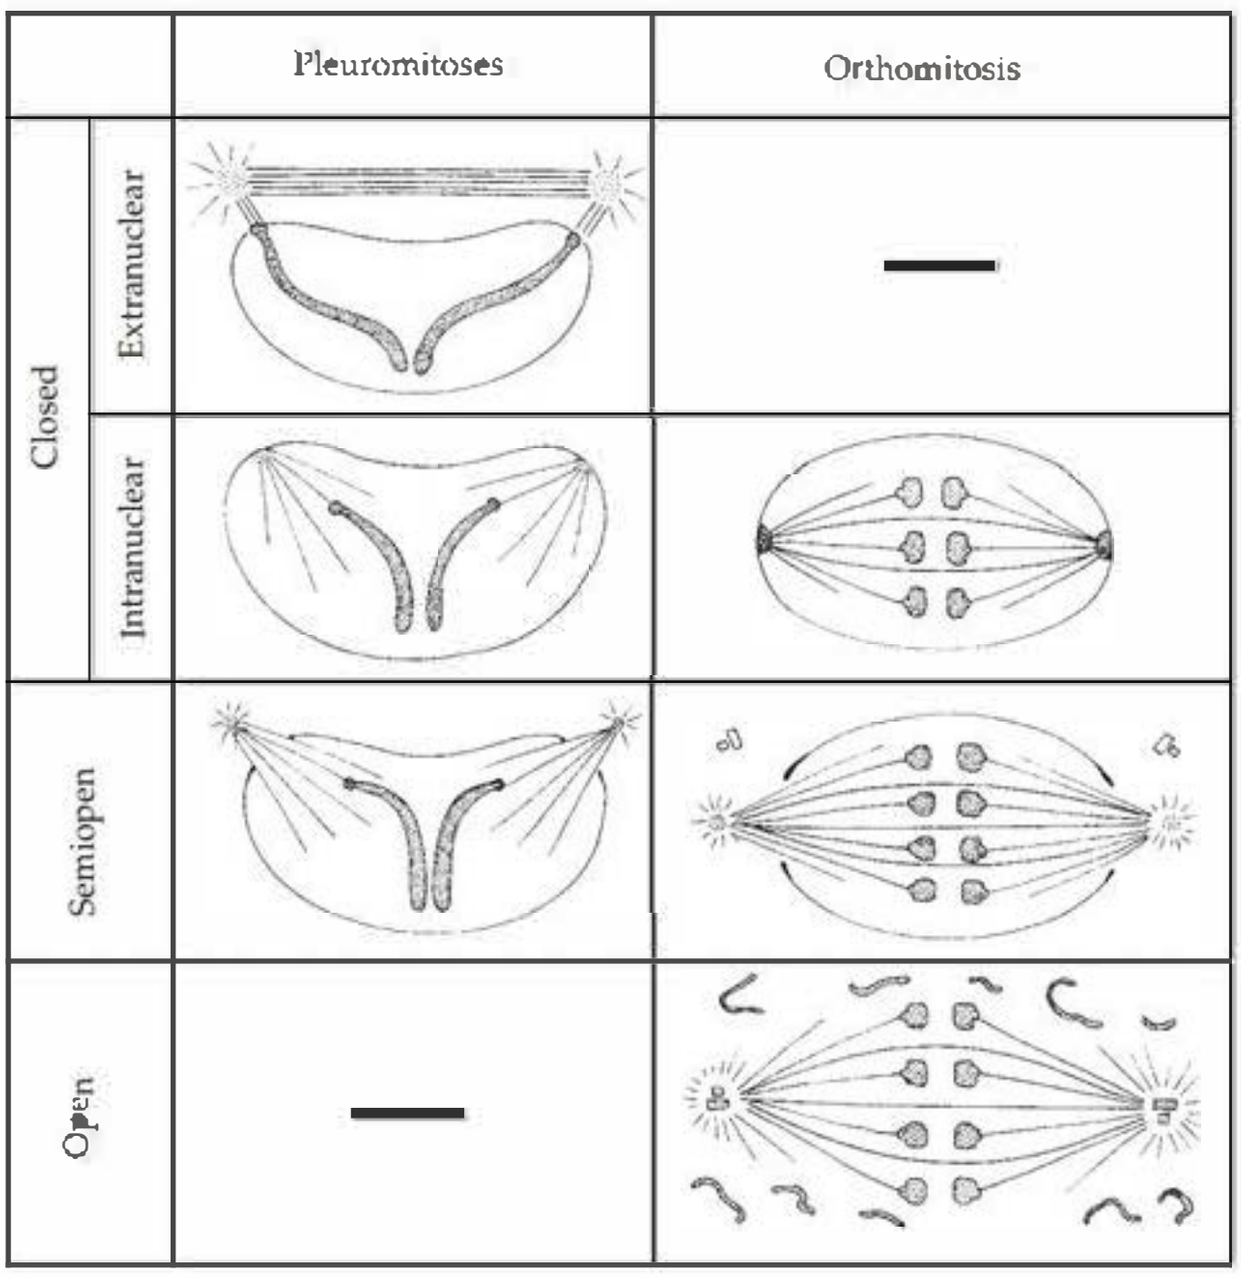

Figure 3.6 Mitosis in protists. In open mitosis the nuclear membrane breaks down completely. In semi-open mitosis the nuclear envelope remains intact except for small holes where the spindle microtubules penetrate the nuclear envelope. In closed mitosis the nuclear envelope remains completely intact throughout mitosis, and the spindle forms either inside the nucleus (intranuclear mitosis) or outside the nucleus (extranuclear mitosis). Orthomitosis refers to the spindle being bipolar and symmetrical, usually with the formation of an equatorial plate. Pleuromitosis occurs when the spindle is asymmetrical and an equatorial plate does not form.

(fenestrae) where the spindle microtubules penetrate the nuclear envelope; if it is closed, the nuclear envelope remains completely intact throughout mitosis. The terms "orthomitosis" and "pleuromitosis" refer to the symmetry of the spindle. During orthomitosis, the spindle is bipolar and symmetrical, and an equatorial plate usually forms. During pleuromitosis, the spindle is asymmetrical, and an equatorial plate does not form. The terms intranuclear and extranuclear refer to the location of the spindle. During intranuclear mitosis, the spindle forms inside of the nucleus; during extranuclear mitosis, the spindle forms outside of the nucleus.

Protist nuclei also show remarkable diversity. The most common type of nucleus is the vesicular nucleus, and is characterized as being between 1–10 μm in diameter, round (usually), with a prominent nucleolus, and uncondensed chromatin. Ovular nuclei are characterized as being large (up to 100 μm in diameter), with many peripheral nucleoli, and uncondensed chromatin. Chromosomal nuclei are characterized by the tendency of the chromosomes to remain condensed during interphase, and for there to be one nucleolus that is associated with a chromosome. Ciliates are unique in their possession of two different kinds of nuclei: small micronuclei (with no nucleoli and dispersed chromatin), and large macronuclei (with many prominent nucleoli and compact chromatin). In summary, protist diversity and success is reflected by the tremendous variation within the unicellular body plan. The following accounts of protist phyla explore this variation in some detail.

BOX 3C Characteristics of the Phylum Amoebozoa

1. Mostly free living, but some are endo- or ectosymbiotic, including some pathogens
2. Cell surrounded by plasma membrane (naked amebas), which may be coated with layer of glycoprotein (the glycocalyx); some also form external test (testate amebas)
3. With temporary extensions of cytoplasm (pseudopodia) for feeding and locomotion; pseudopodia are broad and blunt (lobopods)
4. Some species harbor intracellular symbionts (e.g., algae, bacteria).
5. Mitochondria with tubular cristae
6. Most with single vesicular nucleus
7. Mitotic patterns variable
8. Asexual reproduction by binary fission and multiple fission
9. Sexual reproduction reported for slime molds, otherwise not confirmed
10. Without plastids; strictly heterotrophic
11. Some store glycogen (e.g., *Pelomyxa*), but most do not appear to store carbohydrates

THE PROTIST PHYLA

GROUP 1: AMOEBOZOA

Phylum Amoebozoa: Amebas

The phylum Amoebozoa, although small, comprises a singular clade of protists consisting of just over 200 species. Most are freeliving, but some endosymbiotic groups are known, including some pathogenic forms. The most obvious characteristic of amoebozoans is that they form temporary extensions of the cytoplasm, or pseudopodia (described in Chapter 4, used in feeding and locomotion (Figure 3.7; see also Figures 3.1B and 3.10) (Box 3C). Amoebozoans are ubiquitous creatures that can be found in nearly any moist or aquatic habitat: in soil or sand, on aquatic vegetation, on wet rocks, in lakes, streams, glacial meltwater, tidepools, bays, estuaries, on the ocean floor, and afloat in the open ocean. Many are ectocommensals on aquatic organisms and some are parasites of diatoms, fishes, molluscs, arthropods, or mammals. Some amoebozoans harbor intracellular symbionts such as algae, bacteria, and viruses, although the nature of these relationships is not well understood. Amoebozoans have often been used in laboratories as experimental organisms for studies of cell locomotion (*Amoeba proteus*), nonmuscle contractile systems (*Acanthamoeba*), and the effects of removing and transplanting nuclei.

Although most amoebozoans are harmless free-living creatures, some are endosymbiotic, and many of these are considered to be parasites. They occur most commonly in arthropods, annelids, and vertebrates (including humans). Three cosmopolitan species are commensals in the large intestines of humans: *Endolimax nana*, *Entamoeba coli*, and *Iodamoeba buetschlii*. All three species feed on other microorganisms in the gut. *Entamoeba coli* infection levels reach 100% of the population in some areas of the world. *Entamoeba coli* often coexists with the more problematic *E. histolytica*; transmission (via cysts) is by the same method, and the trophozoites of the two species are difficult to differentiate. *Iodamoeba buetschlii* infects humans, other primates, and pigs. *Entamoeba gingivalis* was the first ameba of humans to be described. Like *E. coli*, it is a largely harmless commensal, residing only on the teeth and gums, in gingival pockets near the base of the teeth, and occasionally in the crypts of the tonsils. It also occurs in dogs, cats, and other primates. No cyst is formed and transmission is direct, from one person to another. An estimated 50% of the human population with healthy mouths harbors this ameba.

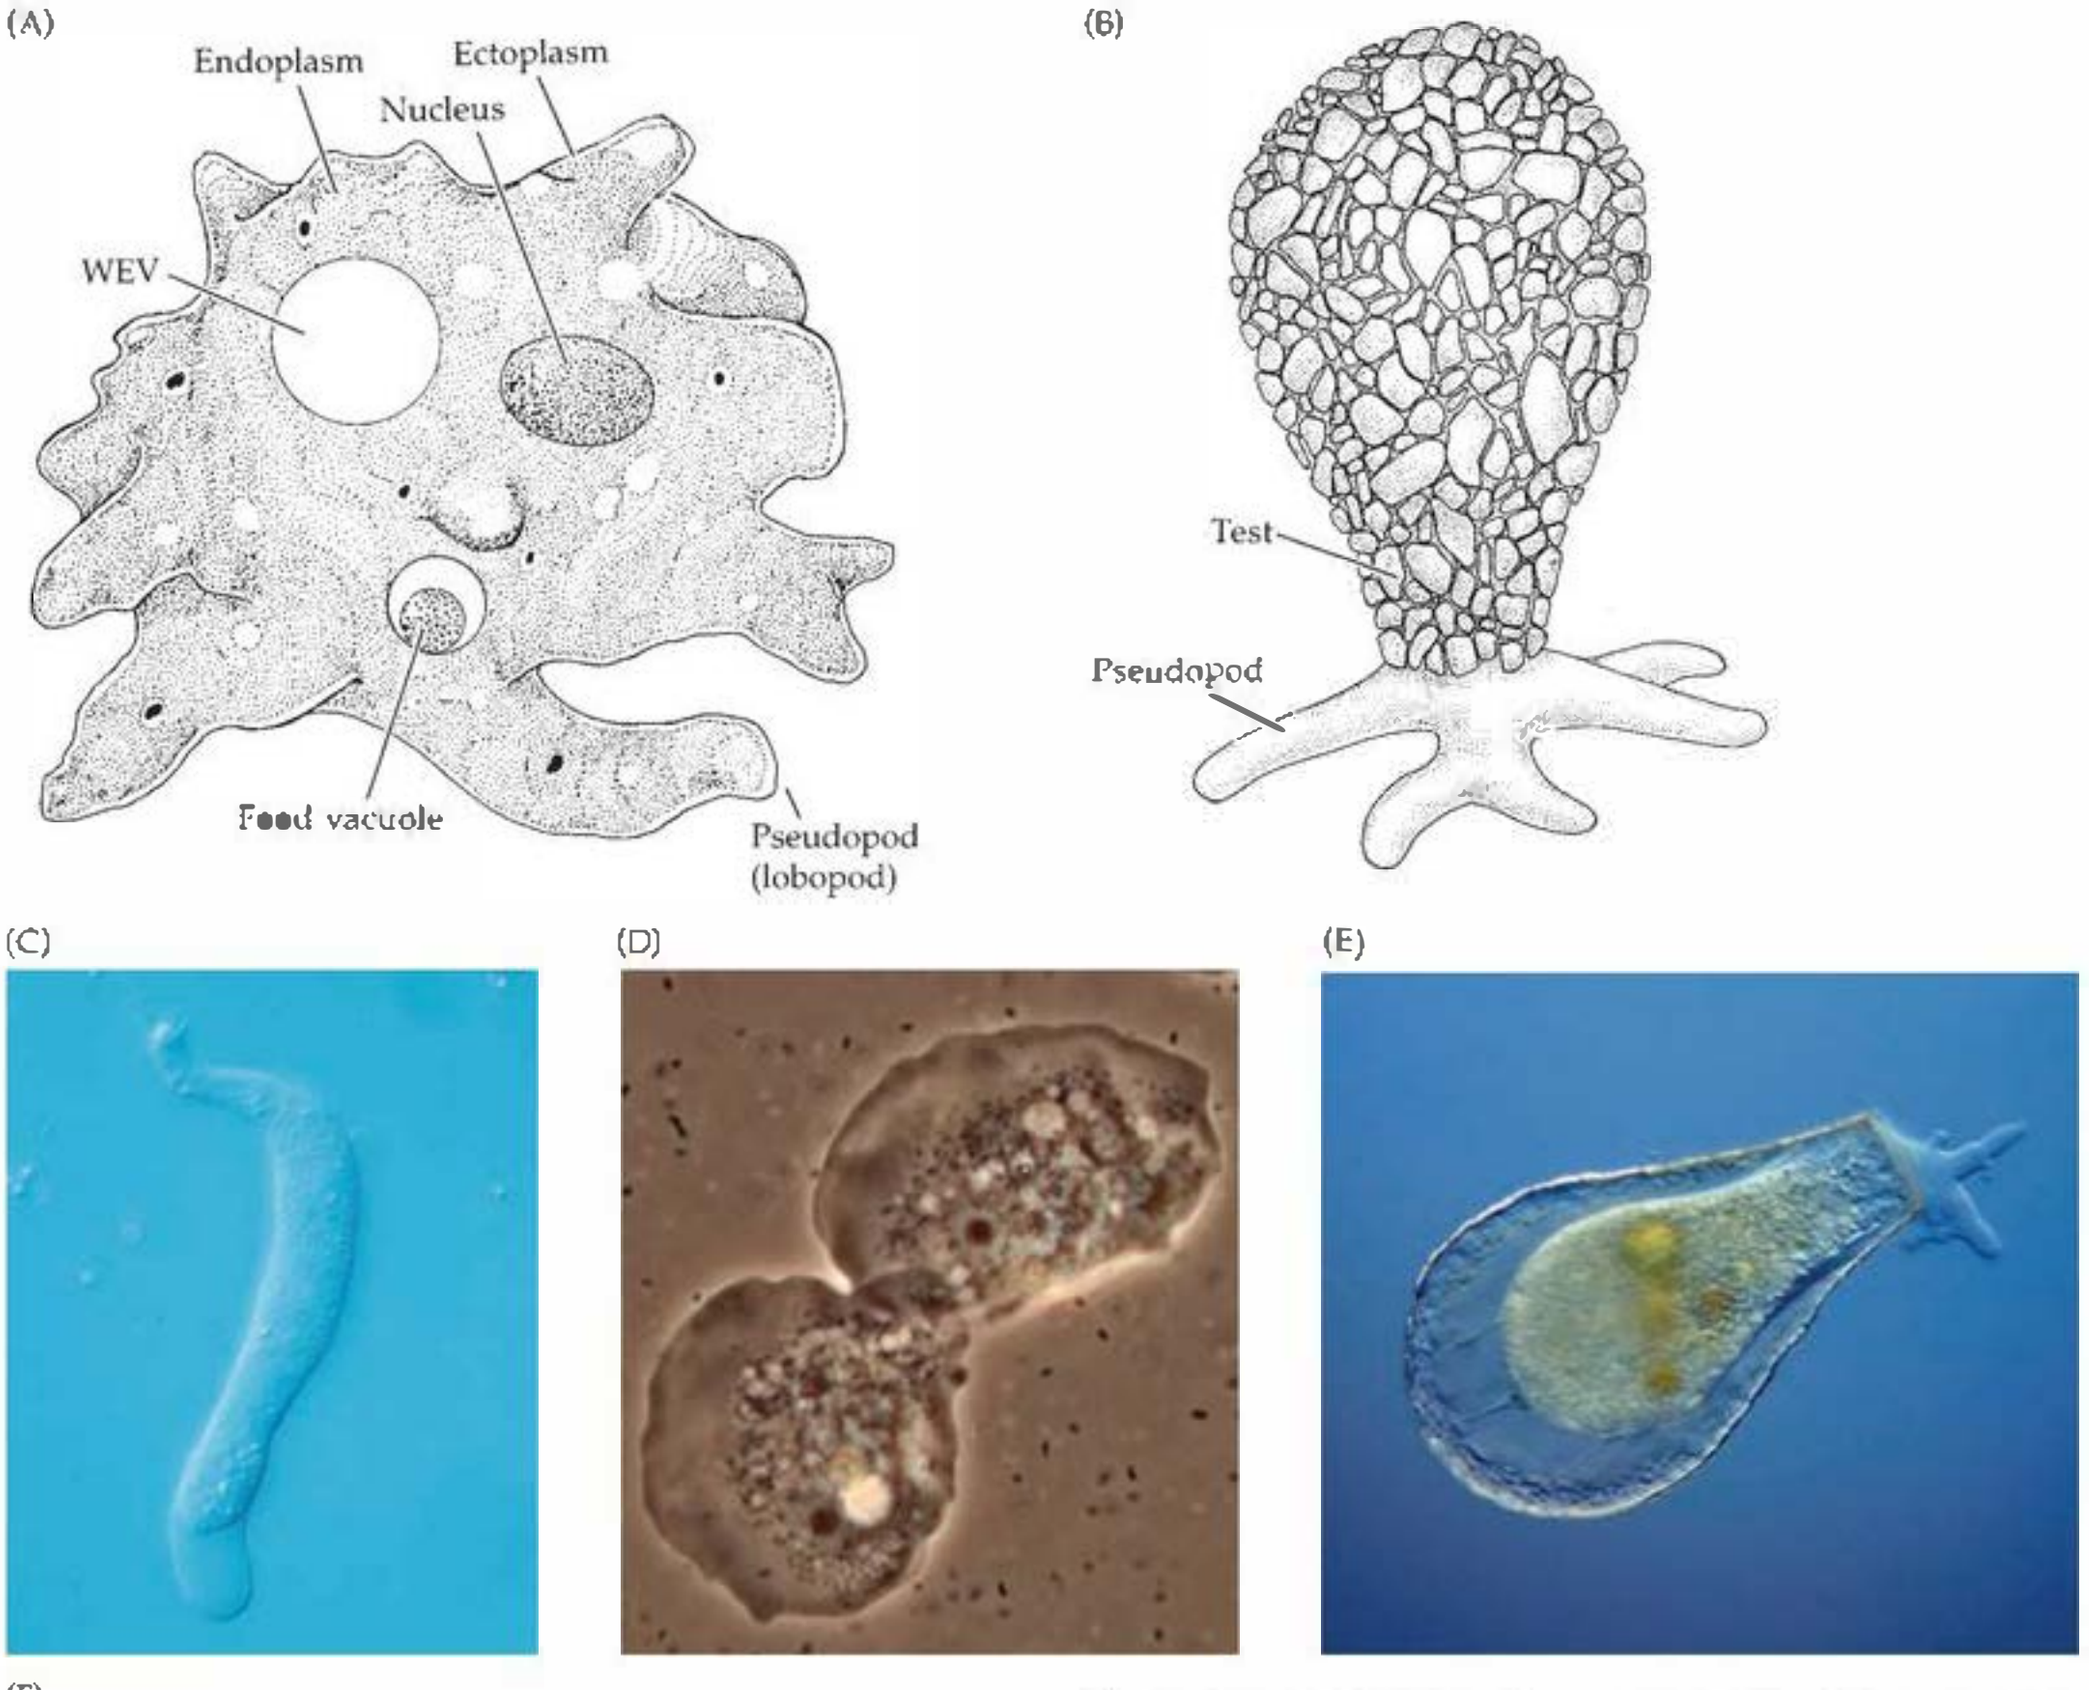

Figure 3.7 Phylum Amoebozoa. Amoebozoan diversity. (A) Anatomy of a "naked" ameba; note the multiple lobopods. (B) A testate ameba, *Difflugia* (test of microscopic mineral grains). (C) *Hartmanella*, with single fingerlike lobopod. (D) *Vannella*, with fan-shaped pseudopod. (E) *Nebela collaris*, a testate ameba. Thick pseudopods (lobopods) extend from the test aperture, and the ameba's body is attached to the interior of the shell by fine pseudopods (filopods). (F) *Mayorella*, a "naked" ameba.

Under severe stress, symbiotic gut amoebozoans (e.g., *Entamoeba coli*) that are normally harmless can increase to abnormally high numbers and cause temporary mild gastrointestinal distress in people. *Entamoeba histolytica*, however, is a serious pathogen in humans (Box 3D). This species causes amebic dysentery, an intestinal disorder resulting in destruction of cells lining the gut. The parasite is usually ingested in its cyst stage, and is acquired by way of fecal contamination. Emergence of individuals in the active (motile) stage (i.e., the trophozoites) takes place quickly once in the host's gut, and it is this stage that releases the histolytic enzymes that break down the epithelium of the large intestine and rectum.

One of the most enigmatic groups of amoebozoans is the social amebas, or cellular slime molds. These odd creatures, and their close relatives the plasmodial (acellular) slime molds (Myxogastrida), were once thought to be allied with the fungi, but are now classified as amoebozoans. So bizarre are the lives of these creatures that they inspired one of the all-time great 1950s science fiction movies, *The Blob* (with Steve McQueen).

BOX 3D Histolytic (Amebic) Dysentery

Entamoeba histolytica s the et o og cal agent of ameb c dysentery, a d sease that has p agued humans throughout al of recorded h stoıy. *E histolytica* is the third most common cause of parasitic death in the world. About 500 million peop e in the word are infected at any one time, w th up to 100,000 deaths annual y Interestingly, *E histolytica* comes in two sizes. The smaller race (trophozoites 12 15 µm in diameter cysts 5-9 µm w de) is nonpathogen c, and some workers consider it a separate species (*E hartmanni*). The larger form (trophozoites 20–30 µm n dameter, cysts 10-20 µm w de) is sometimes pathogenic and other t mes not. Another species of *Entamoeba*, *E moshkovskii*, s identical in morpho ogy to *E. histolytica*, but s not a symb ont; it l ves in sewage and is of:en mistaken for *E. histolytica*.

When swa lowed, the cysts of *E histolytica* pass through the stomach unharmed. When they reach the alkaline medum of the smal intest ne, they break open and re ease trophozo tes that are swept to the large intestine They can surv ve both anaerobical y and in the presence of oxygen. Trophozoites of *E. histolytica* may l ve and mu t p y indefi n tely w thin the crypts of the mucosa of the large intestine, apparent y feed ng on starches and mucous secret ons. In order t o absorb food in t h s sett ng, they may require the presence of certa n natural y occurring gut bacteria. However they can also invade t ssues by hydrolyzing mucosal cel s of the large ntestine, and n th s mode they need no he p from the r bacter al par:ners to feed. *E. histolytica* produces several hydro ytic enzymes, includ ng phospha tases, g ycosidases, prote nases, and an RNAse. They erode ulcers into the intest nal wal , eventua y entering the bloodstream to infect other organs such as the l ver lungs, or even the skin. Cysts form on y in the arge intest ne and pass with the host's feces. Cysts can remain v able and nfect ve for many days, or even weeks, but are kil ed by desiccat on and temperatures below 5°C and above 40°C The cysts are res stant to leve s of chlorine norma ly used for water purification.

Symptoms of amebiasis vary greatly, due to the strain of *E. histolytica* and the host's res stance and physica condit on. Commonly, the d sease develops s owly, with intermittent diarrhea, cramps, vom t ng, and genera ma a se. Some infect ons may m m c appendicitis. Broad abdominal pa n, fu m nat ng diarrhea, dehydrat on, and oss of blood are typ cal of bad cases. Acute infections can resu t in death from per ton tis, the result of gut perforat on, or from card ac fa lure and exhaustion. Hepatic amebiasis results when trophozoites enter the mesenteric veins and trave to the iver through the hepato portal system; they d gest the r way through the portal cap l aries and form abscesses n the liver Pulmonary ameb as s usual y develops when ver abscesses rupture through the d aphragm. Other sites occas ona ly nfected are the bra n, sk n, and penis (possibly acquired through sexual contact).

Although ameb as s s most common in tropica regions, where up to 40% of the population may be infected, the parasite is firmly estab shed from Alaska to Patagon a. Transm ssion s v a feca contam nation, and the best pre vent on is a sanitary l festy e. Fi th flies, particularly the common housefly (*Musca domestica*), and cockroaches are impoı tant mechan cal vectors of cysts, and houseflies hab t of vom t ng and defecating wh le feed ng s a key means of transm ssion Human carriers (cyst passers) handling food are also major sources of transm ssion. The use of human feces as fe ti zer in Asia, Europe, and South America contributes heav ly to transmiss on in those reg ons. A though humans are the primary reservo r of *E. histoly tica*, dogs, p gs, and monkeys have a so been mp icated

Among the cellular slime molds, each organism begins its life as a unicellular ameba, primarily feeding on soil bacteria. However, when food is insufficient they aggregate to form a multicellular fruiting body. The fruiting body (or "fructification") takes several forms, depending on the species. This process has been best described for the "model organism" *Dictyostelium discoideum*. In *D. discoideum*, the aggregate of up to 100,000 cells first transforms into a finger-shaped structure, the "slug." The "head" region of the slug senses environmental stimuli such as temperature and light and directs the slug toward the soil's upper surface, where spores will be dispersed. The slug then stands up to form the asexual fruiting body, or sorocarp (Figure 3 8). The cells in the head region move into a prefabricated cellulose tube and differentiate into stalk cells that ultimately die. The remaining "body" cells then crawl up the stalk and encapsulate to form spores. Recent work with *Dictyostelium* suggests the spores carry with them soil bacterial "seeds," which are used to inoculate the new ameba's new location. Thus the Dictyostelida display characteristics akin to multicellularity, such as cell-cell signaling, cellular specialization, coherent cell movement, and programmed cell death although embryonic tissue layering, diagnostic of the Metazoa, obviously does not occur The dictyostelids' ability to cultivate their own "food crop" of soil bacteria puts these creatures in a unique class of "invertebrate farmers" that also includes fungus growing ants, termites, and ambrosia beetles

Whereas the dictyostelids aggregate to from asexual fruiting bodies, the fruiting bodies of the Myxogastrida (e.g., *Physarum, Fuligo*) function in sexual reproduction. Further, myxogastrids don't form fruiting bodies by aggregation. Instead, two haploid cells fuse by syngamy. The resulting diploid ameba then grows without undergoing further cell division to form a multinucleate plasmodium. This super-cell eventually grows fruiting bodies containing uninucleate spores. The process is sexual because there is a meiotic step in the production of the spore cells in the fruiting bodies, so the spores, and the amebas that hatch from them, are haploid. Thus the life cycle of myxogastrids contains critical haploid and diploid components.

Figure 3.8 Phylum Amoebozoa. Cellular slime molds (social amebas) and plasmodial slime molds. (A) Fruiting bodies of the cellular slime mold (Dictyostelida) *Dictyostelium discoideum*. (B) The wood-rot slime mold *Stemonitis*, with its distinctive brown sporangia supported on slender stalks. (C) Large, multinucleate (but acellular) plasmodium of the plasmodial slime mold (Myxogastrida) *Fuligo septica*, the "scrambled-egg slime mold." (D–F) The highly variable slime mold *Physarum polycephalum*.

In North America, the famous scrambled-egg slime mold, or "dog-vomit slime mold" (Myxogastrida: *Fuligo septica*) is often encountered (Figure 3.8C). The gigantic (up to 40 cm across), yellow, cushiony crusts of *F. septica* grow on dead or living trees, and on wood mulches in landscaped areas. The plasmodia slowly creep over the surface, engulfing bacteria, plant and fungal spores, other protists, and organic detritus. When the large, multinucleate (but acellular) plasmodium converts into a spore-bearing structure (an aethalium) it becomes a spongy mass that is the largest spore-producing structure known among the Amebozoa. The spores of *F. septica* are dispersed by beetles of the family Lathridiidae.

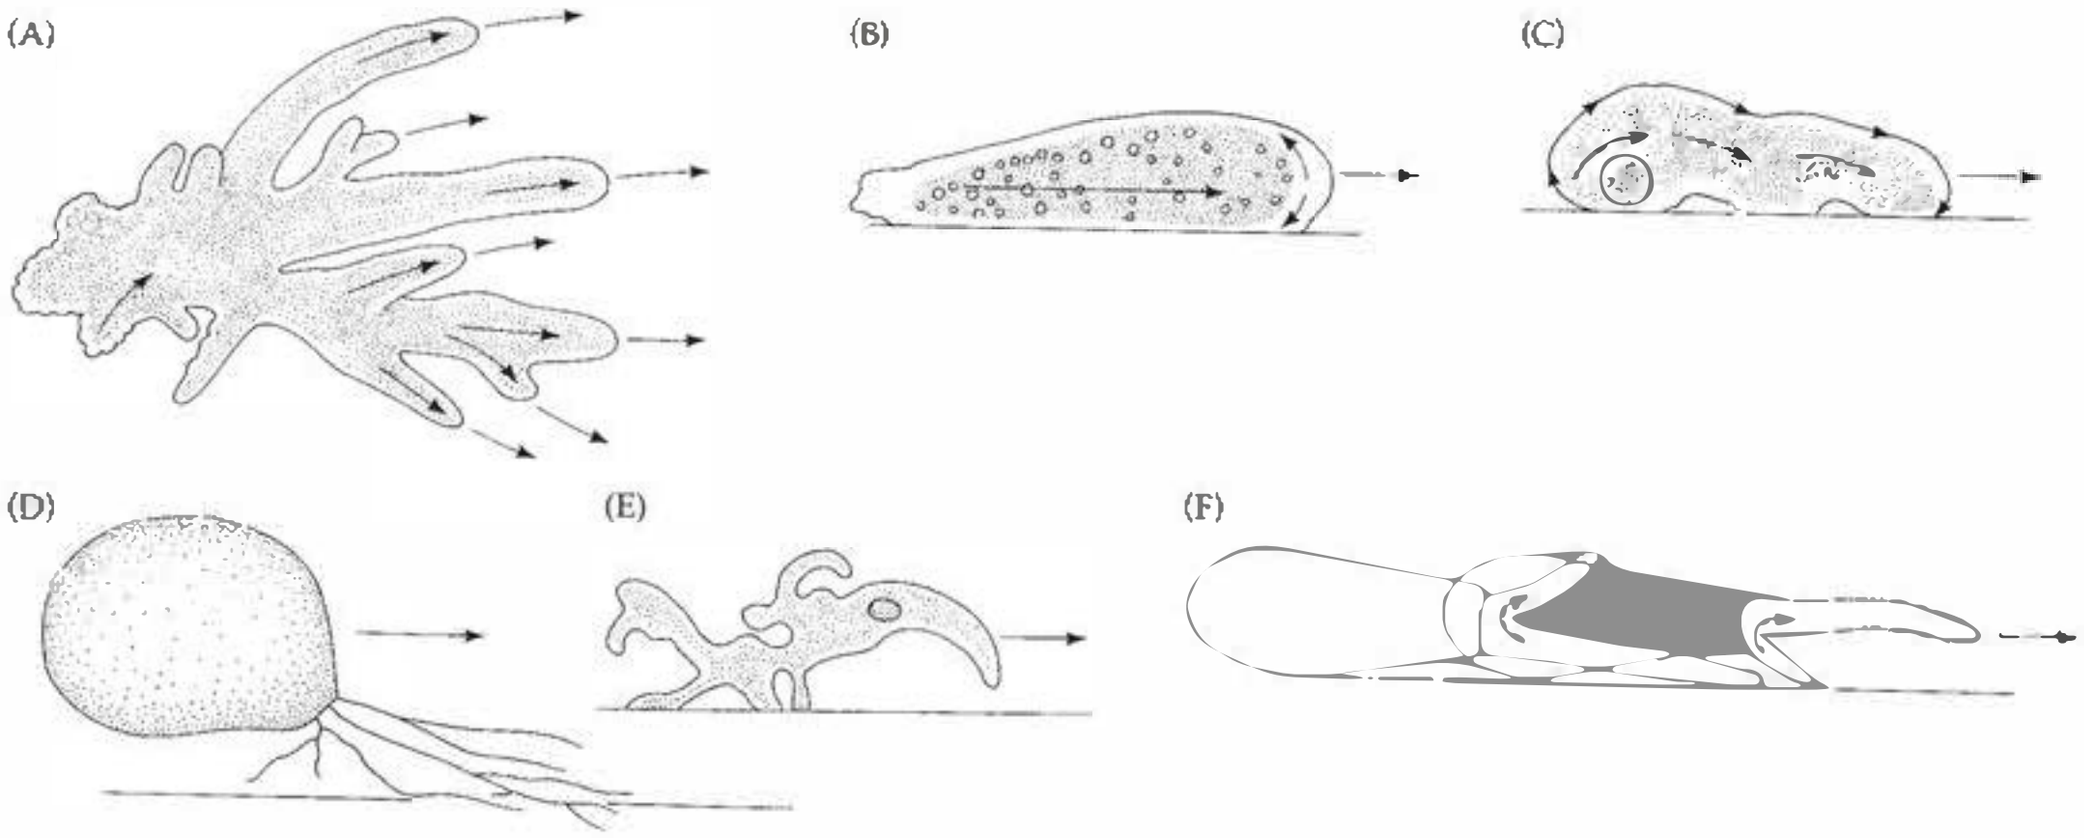

Figure 3.9 Phylum Amoebozoa. Locomotion in amebas. (A) Typical ameboid movement by lobopods in *Amoeba proteus*. (B) Creeping, "limax" form of movement. (C) Rolling, treadlike movement. (D) Filopodial creeping in *Chlamydophorus*. (E) "Walking" locomotion in certain naked amebas. (F) "Bipedal-stepping" in *Difflugia*.

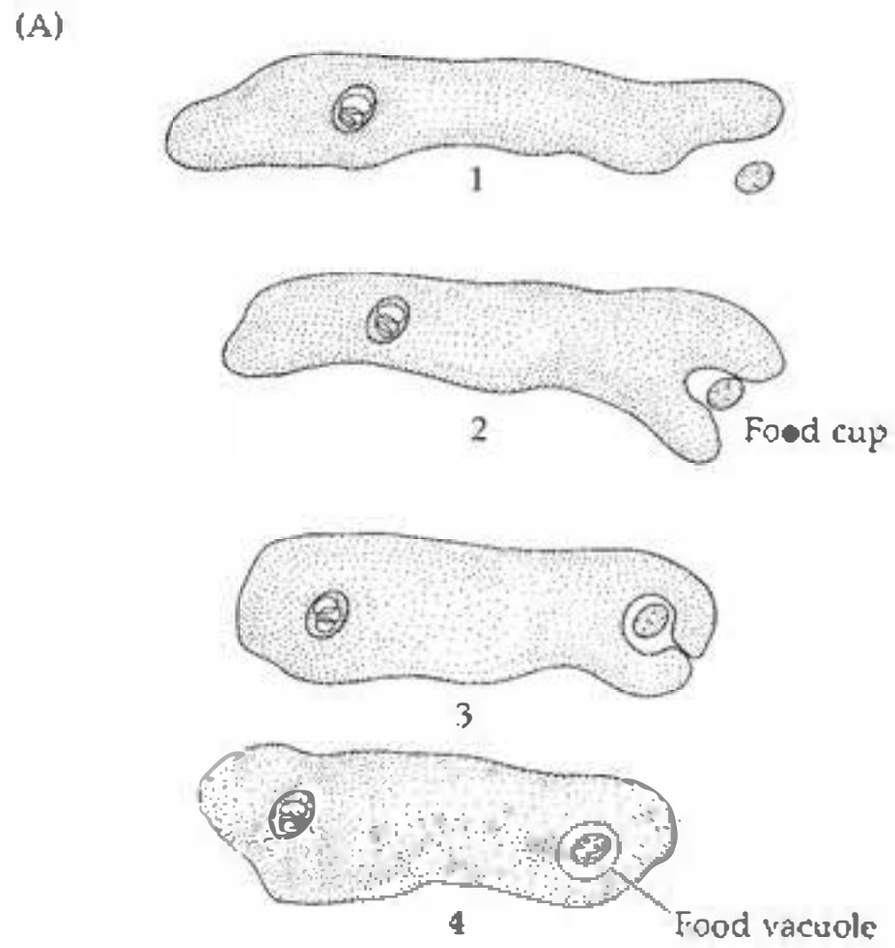
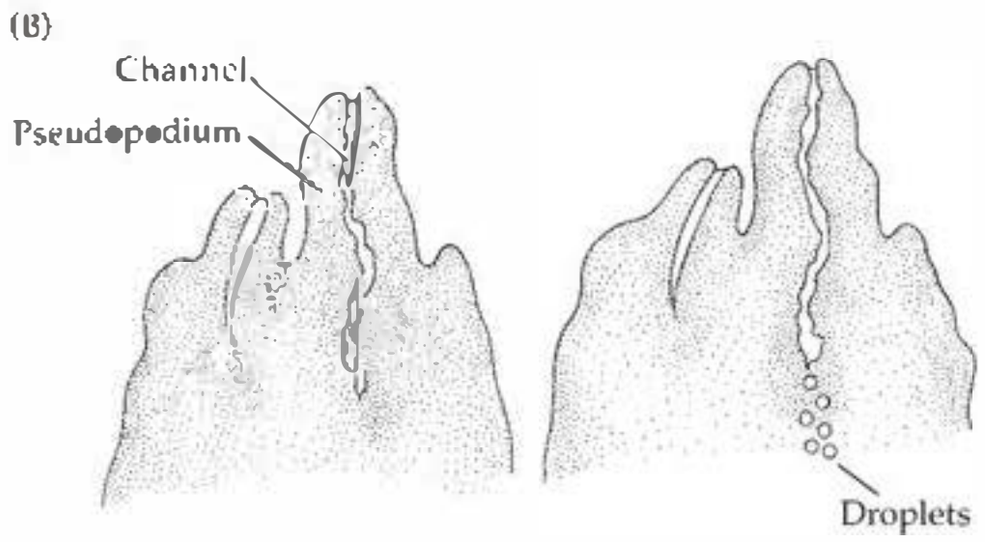
Support and Locomotion



Most amoebozoans are surrounded only by a plasma membrane. These are the so-called naked amebas (see Figures 3.7A–C and 3.8). Others, known as testate amebas, have the plasma membrane covered by some sort of test (see Figure 3.7D–E). The tests of amoebozoans may be composed primarily of particulate material either gathered from the environment (e.g., *Difflugia*) or secreted by the cell itself (e.g., *Arcella*). A few species produce an external covering of very small scales. Some of the naked amebas (e.g., the genus *Amoeba*) may secrete a mucopolysaccharide layer, called the glycocalyx, on the outside of the plasma membrane. Sometimes there may be flexible, sticky structures protruding from the glycocalyx, which are thought to aid in the capture and ingestion of bacteria during feeding.



Amoebozoans use pseudopodia for feeding and locomotion. Although pseudopodia vary in shape among protists, there are two primary types—lobopods and filopods (sometimes called rhizopods). Amoebozoans have only lobopods, which are blunt and rounded at the tip (filopods are thin and tapering) (Figure 3.9A,E). Some amoebozoans produce several pseudopodia, or lobopods, that extend in different directions at the same time. Probably the most familiar organism that produces multiple lobopods is *Amoeba proteus* (see Figure 3.9A). Similar pseudopodia are formed by some testate amoebozoans such as *Arcella*, *Centropyxis*, and *Difflugia*. Some amoebozoans that produce multiple lobopods also produce subpseudopodia on the surfaces of their lobopods. This condition is found in the genus *Mayorella*, which forms fingerlike subpseudopodia, and *Acanthamoeba*, which forms thin subpseudopodia called acanthopods.

Some amoebozoans produce only a single lobopod. One such group is the so-called limax amoebozoans, which form a single fingerlike "anterior" lobopod (giving the organism a sluglike, or *Limax*, appearance) (Figure 3.9B). Limicine locomotion is commonly found in amoebozoans that dwell in soil (e.g., *Chaos*, *Euhyperamoeba*, *Hartmanella*, *Pelomyxa*). Other amoebozoans that produce a single lobopod include the genera *Thecamoeba* and *Vannella*. In *Vannella*, the lobopod is shaped such that it gives the body a fanlike appearance (see Figure 3.7C), while in *Thecamoeba*, the lobopod has a somewhat indefinite shape and creates the impression that the cell rolls like the tread of a tractor or tank, the leading surface adhering temporarily to the substratum as the organism progresses (Figure 3.9C).

As described in Chapter 4, the physical processes involved in pseudopodial movement are still not fully understood. It is likely that more than one method of pseudopod formation occurs among the different amoebozoans; certainly the gross mechanics involved in the actual use of pseudopodia vary greatly (see Figure 3.9). Recall the typical differentiation of the cytoplasm into ectoplasm (plasmagel) and endoplasm (plasmasol), the latter being much more fluid than the former. The formation of lobopods results from the streaming of the inner plasmasol into areas where the constraints of the plasmagel have been temporarily relieved.

While many amoebozoans move by "flowing" into their pseudopodia or by "creeping" with numerous filopodia, some engage in more bizarre methods of getting from one place to another. Some hold their bodies off the substratum by extending pseudopodia downward; leading pseudopodia are then produced and extended sequentially, pulling the organism along in a sort of "multilegged" walking fashion. Some of the shelled amoebozoans (e.g., *Difflugia*) that possess a single pylome extend two pseudopodia through the

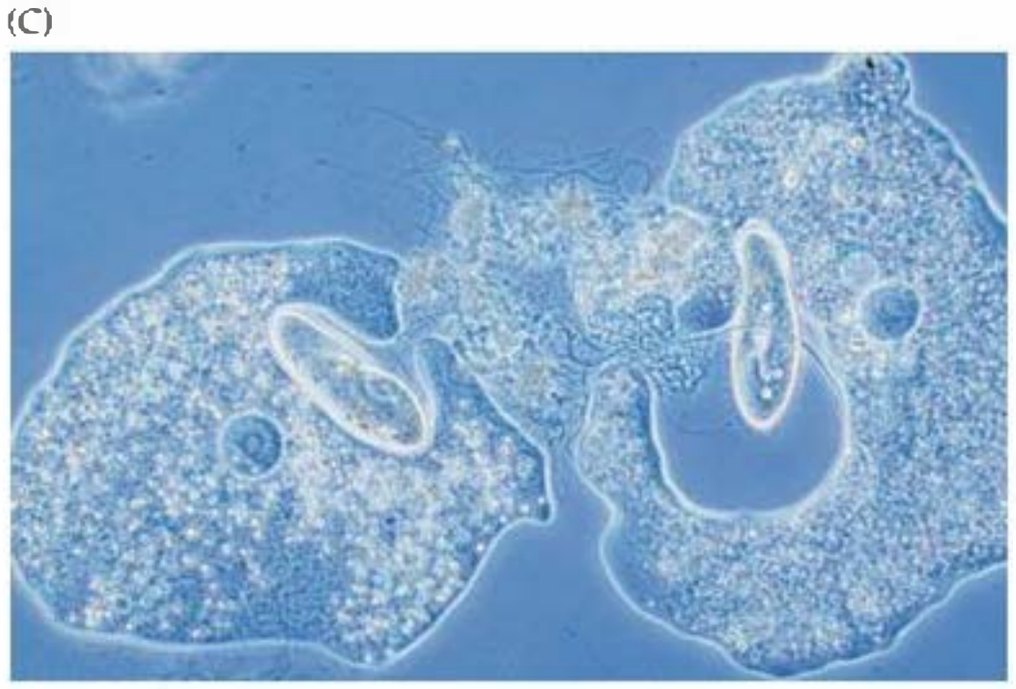


Figure 3.10 Phylum Amoebozoa. Feeding in amebas. (A) Sequence of events during which a lobopodium engulfs a food particle. (B) Uptake of dissolved nutrients through a pinocytotic channel in *Amoeba*. (C) Two soil amebas, *Vahlkampfia*, ingesting ciliates by phagocytosis.

aperture (Figure 3.9F; see also Figure 3.7B). By alternately extending and retracting these pseudopodia, the organism "steps" forward. During locomotion, one pseudopodium is extended and used to "pull" the organism along, trailing the other pseudopodium behind the cell.

Nutrition

While there is little doubt that amoebozoans take up dissolved organics directly across the cell membrane, the most common mechanisms of ingestion are pinocytosis and phagocytosis (Figure 3.10). The size of the food vacuoles varies greatly, depending primarily on the size of the food material ingested. Generally, ingestion can occur anywhere on the surface of the body, there being no distinct cytostome. Most large amoebozoans are carnivores and are frequently predators, whereas the smallest species mostly eat prokaryotes. Some, such as *Pelomyxa*, inhabit soils or muds and are predominantly herbivorous, but they are known to ingest nearly any sort of organic matter in their environment. As explained earlier, a food vacuole forms from an invagination in the cell surface—sometimes called a food cup—that pinches off and drops inward. This process, sometimes called endocytosis, occurs in response to some stimulus at the interface between the cell membrane and the environment. Vacuole formation in amoebozoans may be induced by either mechanical or chemical stimuli; even nonfood items may be incorporated into food vacuoles, but they are soon egested.

Not only the size of a food item, but also the amount of water taken in during feeding determine the size of the food vacuole. Frequently, pseudopodia that form a food cup do not actually contact the food item; thus a packet of the environmental medium is taken in with the food. In other cases, the walls forming the vacuole press closely against the food material; thus, little water is included in the vacuole. Food vacuoles move about the cytoplasm and sometimes coalesce. If live prey have been ingested, they generally die within a few minutes from the paralytic and proteolytic enzymes present in the vacuole. Undigested material that remains within the vacuole is eventually expelled from the cell when the vacuole wall reincorporates into the cell membrane. In most amoebozoans this process of cell defecation may occur anywhere on the body, but in some active forms it tends to take place at or near the trailing end of the moving cell.

Feeding in amoebozoans with skeletal elements varies with the form of the test and the type of pseudopodia. Amebas with a relatively large single aperture or opening, such as *Arcella* and *Difflugia*, feed much as described above. By extending lobopods through the aperture, they engulf food in typical vacuoles.

Reproduction

Simple binary fission is the most common form of asexual reproduction, differing only in minor details among the different groups (Figure 3.11). In the naked amoebozoans, nuclear division occurs first and then cytoplasmic division follows. During cytoplasmic division, the

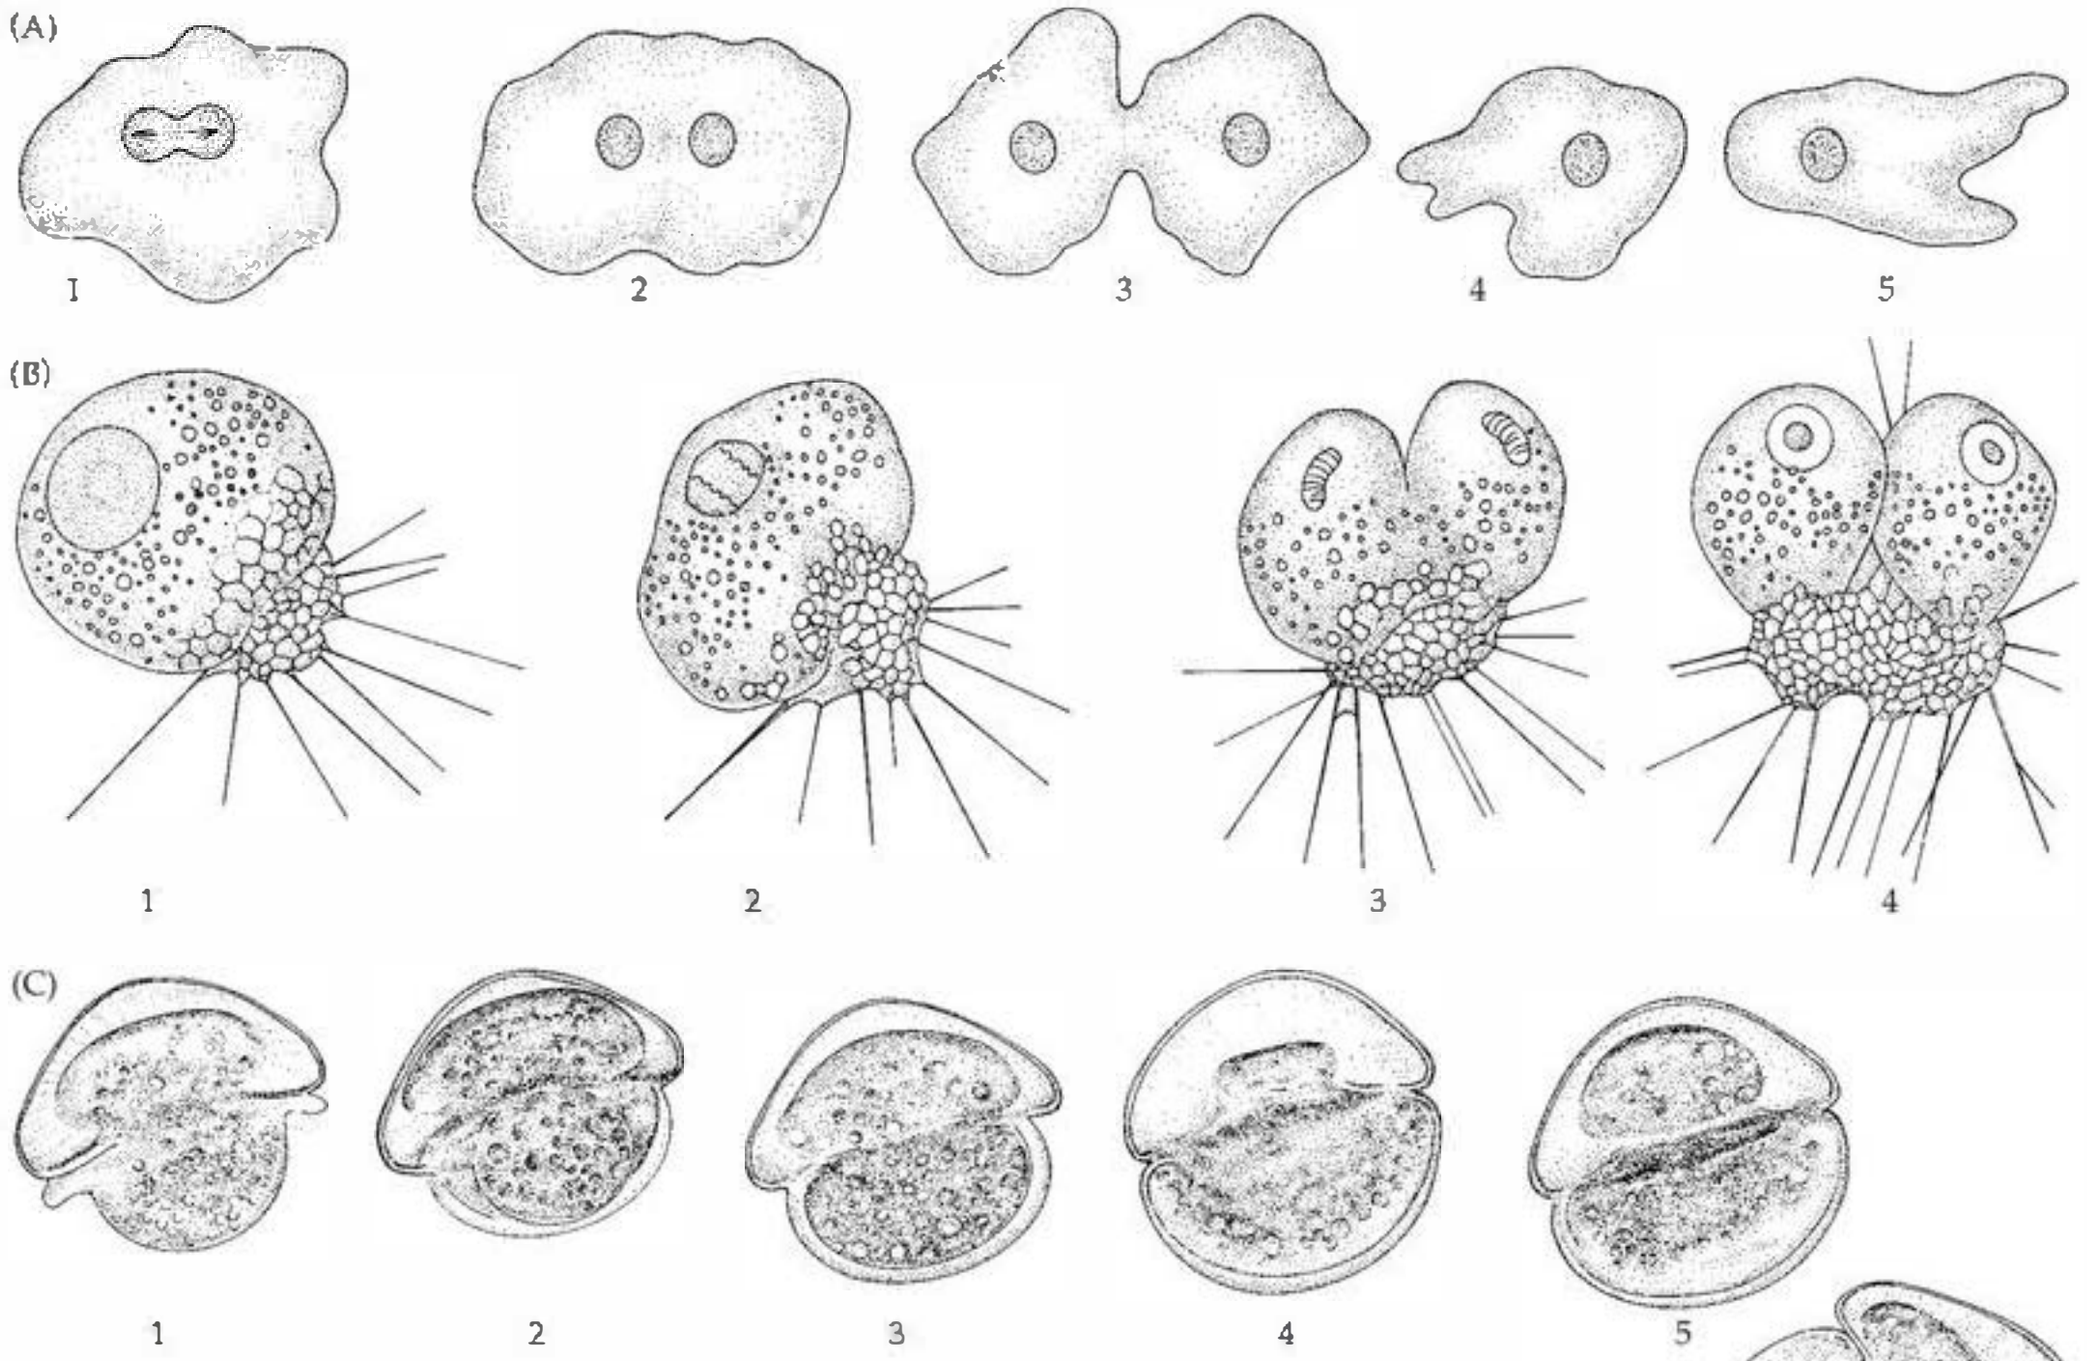

Figure 3.11 Phylum Amoebozoa. Asexual reproduction in Amoebozoans. (A) Simple binary fission in *Amoeba*. (B) Binary fission in the shelled ameba *Pamphagus*; the test is partitioned more or less equally between the two daughter cells. (C) Binary fission in *Arcella*; the parent test is retained by one daughter cell, and a new test is produced by the other daughter cell.

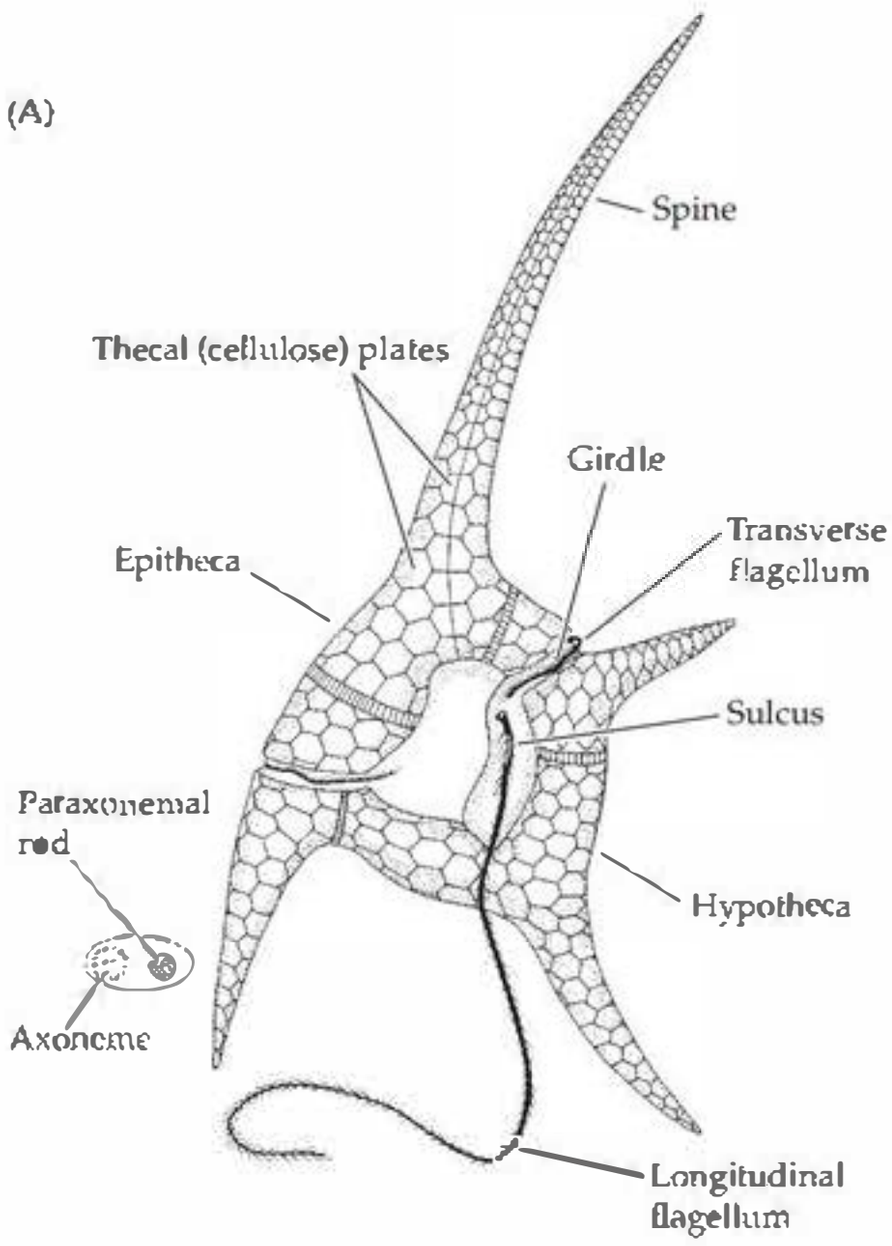
two potential daughter cells form locomotor pseudopodia and pull away from each other. In species with an external test, the shell itself may divide more or less equally in conjunction with the formation of daughter cells (e.g., *Pamphagus*); or, as occurs more frequently, the shell may be retained by one daughter cell, the other producing a new shell (e.g., *Arcella*). Multiple fission is also known among many amoebozoans. Certain endosymbiotic naked species, including *Entamoeba histolytica*, produce cysts in which multiple fission takes place.

Cyst formation during unfavorable environmental conditions is well developed in some amoebozoans, including all testate amebas, most soil amebas, and the parasitic amebas. In the parasitic amebas (e.g., *Entamoeba*), cysts protect the organism as it passes through the digestive tract of the host.



Mitotic patterns in amoebozoans vary and have been used as a criterion for classification within the phylum. In most species, mitosis is characterized as open orthomitosis without centrioles; in some, the breakdown of the nucleus and nucleolus is delayed. Closed intranuclear orthomitosis with a persistent nucleolus occurs in some amoebozoans, such as *Entamoeba*.

Although there have been suggestions that sexual reproduction might occur in amoebozoans, there has been little evidence to support this possibility, other than in the slime molds.

GROUP 2: CHROMALVEOLATA

Phylum Dinoflagellata: Dinoflagellates

The Dinoflagellata comprise about 4,000 described species, including the known extinct forms. Although unquestionable fossil dinoflagellates date back to the Triassic (240 Ma), evidence from organic markers in early Cambrian rocks suggests that they might have been abundant as early as 540 million years ago. The fossil record suggests that dinoflagellate biodiversity was low after the End-Permian mass extinction event, recovered by the early Eocene (~55 Ma), and then subsequently began a long-term decline that continues to the present (also see Chapter 1). The historical patterns of diversity of dinoflagellates and coccolithophores are roughly concordant, but contrast

Other thecate species include: (B) the heavily armored *Peridinium* sp.; (C) an ornate species of *Gonyaulax*; (D) the highly specialized parasitic dinoflagellate *Haplozoon axiothellae* (from the intestine of a maldanid polychaete, *Axiothella rubrocincta*); (E) the red tide producing *Protoperidinium depressum*. (F) Dinoflagellate bloom ("red tide") in Florida.

with that of diatoms—the former peaked in diversity in Mesozoic seas, whereas diatoms began their broad evolutionary radiation much more recently, in the early Cenozoic, corresponding to the onset of major polar ice caps and increased oceanic thermohaline circulation.

Dinoflagellates are common in all aquatic environments, but about 90% of the described species are planktonic in the world's seas (Figure 3.12). Approximately half of the living species of dinoflagellates are photosynthetic, and these are important primary producers in many aquatic environments. They can be quite

BOX 3E Characteristics of the Phylum Dinoflagellata

1. Shape of cell maintained by pellicle consisting of alveolar vesicles beneath the plasma membrane; in some species (thecate species) alveoli may be filled with polysaccharides, usually cellulose; species with "empty" alveoli are said to be naked (athecate)
2. Most species are unicellular; some form filamentous coenobia. Endosymbiotic marine species (zooxanthellae) occur as coccoid cells inside their invertebrate or protist hosts, but produce motile cells periodically
3. Usually with two flagella for locomotion: one is transverse and has a single row of hairs, the other is longitudinal and has two rows of hairs; both flagella are supported by a paraxonema rod. Flagella usually oriented in longitudinal groove and equatorial groove (a diagnostic feature of this group)
4. Mitochondria with tubular cristae
5. With both autotrophic and heterotrophic species (and many can switch back and forth). Most photosynthetic species (about half of all species in the phylum) have chlorophylls a and c_2. Accessory pigments (phycobilins, carotenoids, xanthophylls) often give cells a brownish color. Predatory species often with extrusomes (e.g., trichocysts, mucocysts, nematocysts)
6. Many dinoflagellates are capable of bioluminescence (using a luciferin-luciferase system).
7. Thylakoids occur in stacks of three, with three surrounding membranes; the outer membrane is not continuous with nuclear membrane. Various species show evidence of plastid origin via secondary and even tertiary endosymbioses with a variety of other protists.
8. Food reserves stored as starch and oils
9. Many with unique system of pusules for osmoregulation, excretion, or buoyancy regulation
10. Nuclei contain permanently condensed chromosomes; few or no histone proteins associated with DNA
11. Nuclear division occurs by closed extranuclear pleuromitosis without centrioles; no obvious organizing center for mitotic spindle
12. Asexual reproduction by binary fission along the longitudinal plane
13. Sexual reproduction occurs in some. Meiosis involves two divisions, one just after nuclei from a pair of gametes fuse, and one after cell undergoes period of dormancy.

beautiful and many are capable of bioluminescence (e.g., *Gonyaulax*) using a luciferin–luciferase system. Although most are unicellular, some form filamentous, multicellular colonies Dinoflagellates have two flagella, positioned such that they whirl or spin as they swim (see Figures 3.1A,G), the attribute for which they are named (Greek *dinos*, "whirling, turning") (Box 3E).

Endosymbiotic, photosynthetic, marine dinoflagellates that occur as coccoid cells when inside their invertebrate or protist hosts, but produce motile cells periodically, are called zooxanthellae. They belong to the poorly understood but vastly important genera *Zooxanthella* (symbionts of radiolarians), *Symbiodinium* (symbionts of cnidarians and some other metazoans), and *Zoochlorella* (primarily symbionts of various freshwater organisms). Species of *Symbiodinium* are best known as critically important mutualistic symbionts of hermatypic corals. There are several species of *Symbiodinium* in corals. All are photosynthetic and provide nutrients to the corals and help create the internal chemical environment necessary for the coral to secrete its calcium carbonate skeleton. Zooxanthellae also occur in many cnidarians other than scleractinian corals, such as milleporinids, chondrophorans, sea anemones, and various medusae. *Symbiodinium* has even been found as an endosymbiont in certain ciliates (as have green algal symbionts of the genus *Chlorella*).

Some planktonic dinoflagellates occasionally undergo periodic bursts of population growth to produce red tides. Red tides have nothing to do with actual tides, and they are only rarely red. A red tide is simply a streak or patch of ocean water discolored, generally a pinkish orange or reddish-brown, by the presence of trillions of dinoflagellates (and occasionally diatoms or other algae). During a red tide, densities of these protists may be as high as 10 to 100 million cells per liter of seawater. Organic pollutants in terrestrial runoff (e.g., from agriculture and from animal farms) are tied to increased occurrences of red tides worldwide. Many red tide organisms are also bioluminescent, so observers are treated to the spectacular demonstrations of their abundance during both day and night observations!

Many red tide organisms manufacture toxic substances, and some are among the strongest known poisons. One group of toxins produced by dinoflagellate species such as *Gymnodinium catenatum*, *Pyrodinium bahamense*, and *Alexandrium* spp., is called saxitoxins. Saxitoxins are tasteless, odorless, and watersoluble, with a toxicity similar to that of the biological-weapon poison ricin. Saxitoxins block the sodium–potassium pump of nerve cells and prevent normal impulse transmission. When suspension feeders such as mussels and clams eat these dinoflagellates, they store the toxins in their bodies. Extremely high concentrations of toxic dinoflagellates will even kill suspension feeders and occasionally also fish caught in the thick of the bloom. The shellfish feeding on the protists become toxic to animals that eat them. In humans, the result is a disease known as paralytic shellfish poisoning (PSP). Extreme cases of PSP result in muscular paralysis and

respiratory failure. Over 300 human deaths worldwide have been documented from PSP, and this number is growing as red tides become increasingly frequent around the world (linked to anthropogenic disturbances of coastal environments).[5]

The dinoflagellate *Karenia brevis* (formerly known as *Gymnodinium breve*) releases a family of toxins called brevetoxins that result in neurotoxic shellfish poisoning (NSP). Humans consuming animals that have this toxin accumulated in their tissues experience uncomfortable gastrointestinal side effects such as diarrhea, vomiting, and abdominal pain, and also neurological problems, including dizziness and an odd reversal of temperature sensation. Though temporarily incapacitating, no human deaths have been reported from NSP. Ocean spray containing *K. brevis* toxins can blow ashore and cause temporary health problems for seaside residents and visitors (skin, eye, and throat problems). *Karenia brevis* is responsible for producing devastating red tides that have produced massive kills of fish, sea birds, sea turtles, manatees, and dolphins all along the coastline of the Gulf of Mexico. One of the worst blooms of *K. brevis* ever recorded was from January 2005 to January 2006, along the coast of west central Florida, an event that resulted in widespread hypoxia and the death of tens of thousands of fish, turtles, and marine mammals.

In recent years, two newly discovered species of dinoflagellate called *Pfiesteria piscicida* and *P. shumwayae* have been creating havoc in the coastal areas of the eastern United States. *Pfiesteria piscicida* normally exists in a benign state, and it reportedly can even utilize photosynthesis if it consumes certain other protists that contain chloroplasts it can co-opt. However, with the proper stimulation, which is believed to be high levels of fish oils or fish excrement in the water, *P. piscicida* becomes a voracious predator. It first produces a toxin that causes fish to become lethargic and then releases other toxins that cause open sores to form on the fish's body, exposing the tissues on which it feeds. The toxins of *P. piscicida* have been reported to affect humans but have caused no known deaths. In the Carolinas, it has been claimed that outbreaks of *Pfiesteria* might be linked to large-scale hog farming in North Carolina. The industry dumps hundreds of millions of gallons of untreated hog feces and urine into earthen lagoons along the coast that often leak or collapse. In 1995, 25 million gallons of liquid swine manure (more than twice the size of the Exxon Valdez oil spill) flowed into the New River when a lagoon was breached.

In 2009 red tides caused by the dinoflagellate *Akashiwo sanguinea* in Monterey Bay (California) caused a mass stranding and high mortality of seabirds, not due to toxins but due to their sheer numbers. The birds' plumage became coated in a sticky green froth exuded from the algae that contained surfactant mycosporine-like amino acids, which acted like a detergent to strip the feathers of their natural waterproofing oils.

About half the known dinoflagellates are not photosynthetic (i.e., they are plastid-free), whereas most with plastids have one basic form—a peridinin containing plastid surrounded by three membranes. These plastids are presumed to have derived from a singular event of secondary endosymbiosis. A minority of plastid containing dinoflagellates have plastids derived from other sources. One group has a plastid derived from an endosymbiotic haptophyte, thus representing a tertiary symbiosis because the haptophyte plastid itself was the product of a secondary endosymbiosis (*Karenia*, the agent of neurotoxic shellfish poisoning, is one of these). There are also groups with cryptomonad-derived or chlorophyte-derived plastids. It is thought likely that these various atypical plastids might represent plastid replacements in lineages that already had the peridininincontaining plastid, rather than original plastid acquisitions by heterotrophic lineages.

Parasitic dinoflagellates have a broad range of hosts, morphological diversity, and life histories. The genus *Haplozoon* is a small group of intestinal parasites occurring in marine worms with a highly unusual organization of differentiated cells, and a body plan so bizarre that early workers classified some of them as mesozoans and gregarine apicomplexans. Species of *Haplozoon* have long been viewed as "multicellular" or "colonial" in their organization. However, recent studies of species in this genus have revealed a unique cellular organization in which the entire organism is bounded by a single continuous membrane, suggesting that these protists are not "multicelled" but rather syncytial, composed of cell-like compartments separated by sheets of alveoli.

Support and Locomotion

The shape of dinoflagellates appears to be at least partly maintained by a system of flattened sacs, called alveoli, beneath the cell's outer (plasma) membrane, plus a layer of supporting microtubules. In some, the alveoli are filled to form plates of polysaccharides, typically cellulose, and these dinoflagellates are said to be thecate, or armored (e.g., *Protoperidinium*, *Ceratium*). Dinoflagellates that have empty alveoli are said to be athecate, or naked (e.g., *Noctiluca*). The part of the theca above the girdle is called the epitheca in armored species and the epicone in naked species; the part below the girdle is the hypotheca in armored species and the hypocone in naked species (see Figure 3.12).

Dinoflagellates possess two flagella that enable their locomotion. A transverse flagellum with a row

[5] Pilots who flew U-2 spy missions over the Soviet Union were reportedly given tiny pellets of saxitoxin extracted from dinoflagellates and instructed to take the suicide capsules if they were shot down.

of slender hairs wraps around the cell in a groove, or girdle (see Figure 3.12). When it beats, this flagellum spins the cell around, effectively pushing it through the water like a screw. The transverse flagellum provides much, if not most of the forward propulsion. The second, longitudinal flagellum has two rows of hairs and also lies in a groove on the cell's surface, called the sulcus. It extends posteriorly behind the cell and its beat adds to the forward propulsion. Both flagella are supported by a paraxonemal rod of uncertain function but similar to that found in the kinetoplastids, euglenids, and others.[6]

Osmoregulation

Most freshwater and some marine dinoflagellates have a unique system of double-membrane–bound tubules called pusules, which open to the outside via a canal. The two membranes of the pusules distinguish them from water expulsion vesicles, but apparently these membranes have a similar function—osmoregulation.

Nutrition

Dinoflagellates exhibit wide variation in feeding habits. Approximately half of the living species are photosynthetic, but most of these also are heterotrophic to some extent, and some dinoflagellates with functional chloroplasts can switch entirely to heterotrophy in the absence of sufficient light.

In most photosynthetic species the chloroplasts are surrounded by three membranes, and thylakoids are arranged in stacks of three (see Figure 3.3). Some contain eyespots (stigmata) that can be very simple pigment spots or more complex organelles with lens-like structures that apparently focus the light. Photosynthetic pigments include chlorophylls *a* and c_2, phycobilins, carotenoids (e.g., β carotene), and also xanthophyll pigments known as **peridinin**, found only in dinoflagellates (neoperidinin, dinoxanthin, neodinoxanthin). These xanthophylls mask the chlorophyll pigments and account for the golden or brown color that is commonly seen in dinoflagellates.

Some dinoflagellates always lack chloroplasts and are obligate heterotrophs. Most of these are free living, but some parasitic species are known. The feeding mechanisms of heterotrophic dinoflagellates are quite diverse. Both free living and endoparasitic dinoflagellates that live in environments rich in dissolved organic compounds take in dissolved organic nutrients by saprotrophy. Other dinoflagellates ingest food particles by phagocytosis. Many, in fact, are voracious predators that ingest other protists and microinvertebrates or use specialized cellular appendages to pierce prey and suck out their cytoplasmic contents.

Some dinoflagellates (e.g., *Kofoidinium* and *Noctiluca*) have a permanent cell mouth or cytostome supported by sheets of microtubules. The cytostome is often surrounded by extrusomes, of three types: trichocysts, mucocysts, and nematocysts. The most common are trichocysts (similar to those found in ciliates), which are fired in defense or to capture and bind prey. Sac-like mucocysts secrete sticky mucous material onto the surface of the cell. This may aid in attachment to substrata (e.g., *Amphidinium*) or may help to capture prey (e.g., *Noctiluca*). Other dinoflagellates (e.g., *Nematodinium*, *Nematopsides*, *Polykrikos*) have "nematocysts" that resemble, but probably are not homologous to, the stinging organelles of cnidarians of the same name.

Reproduction

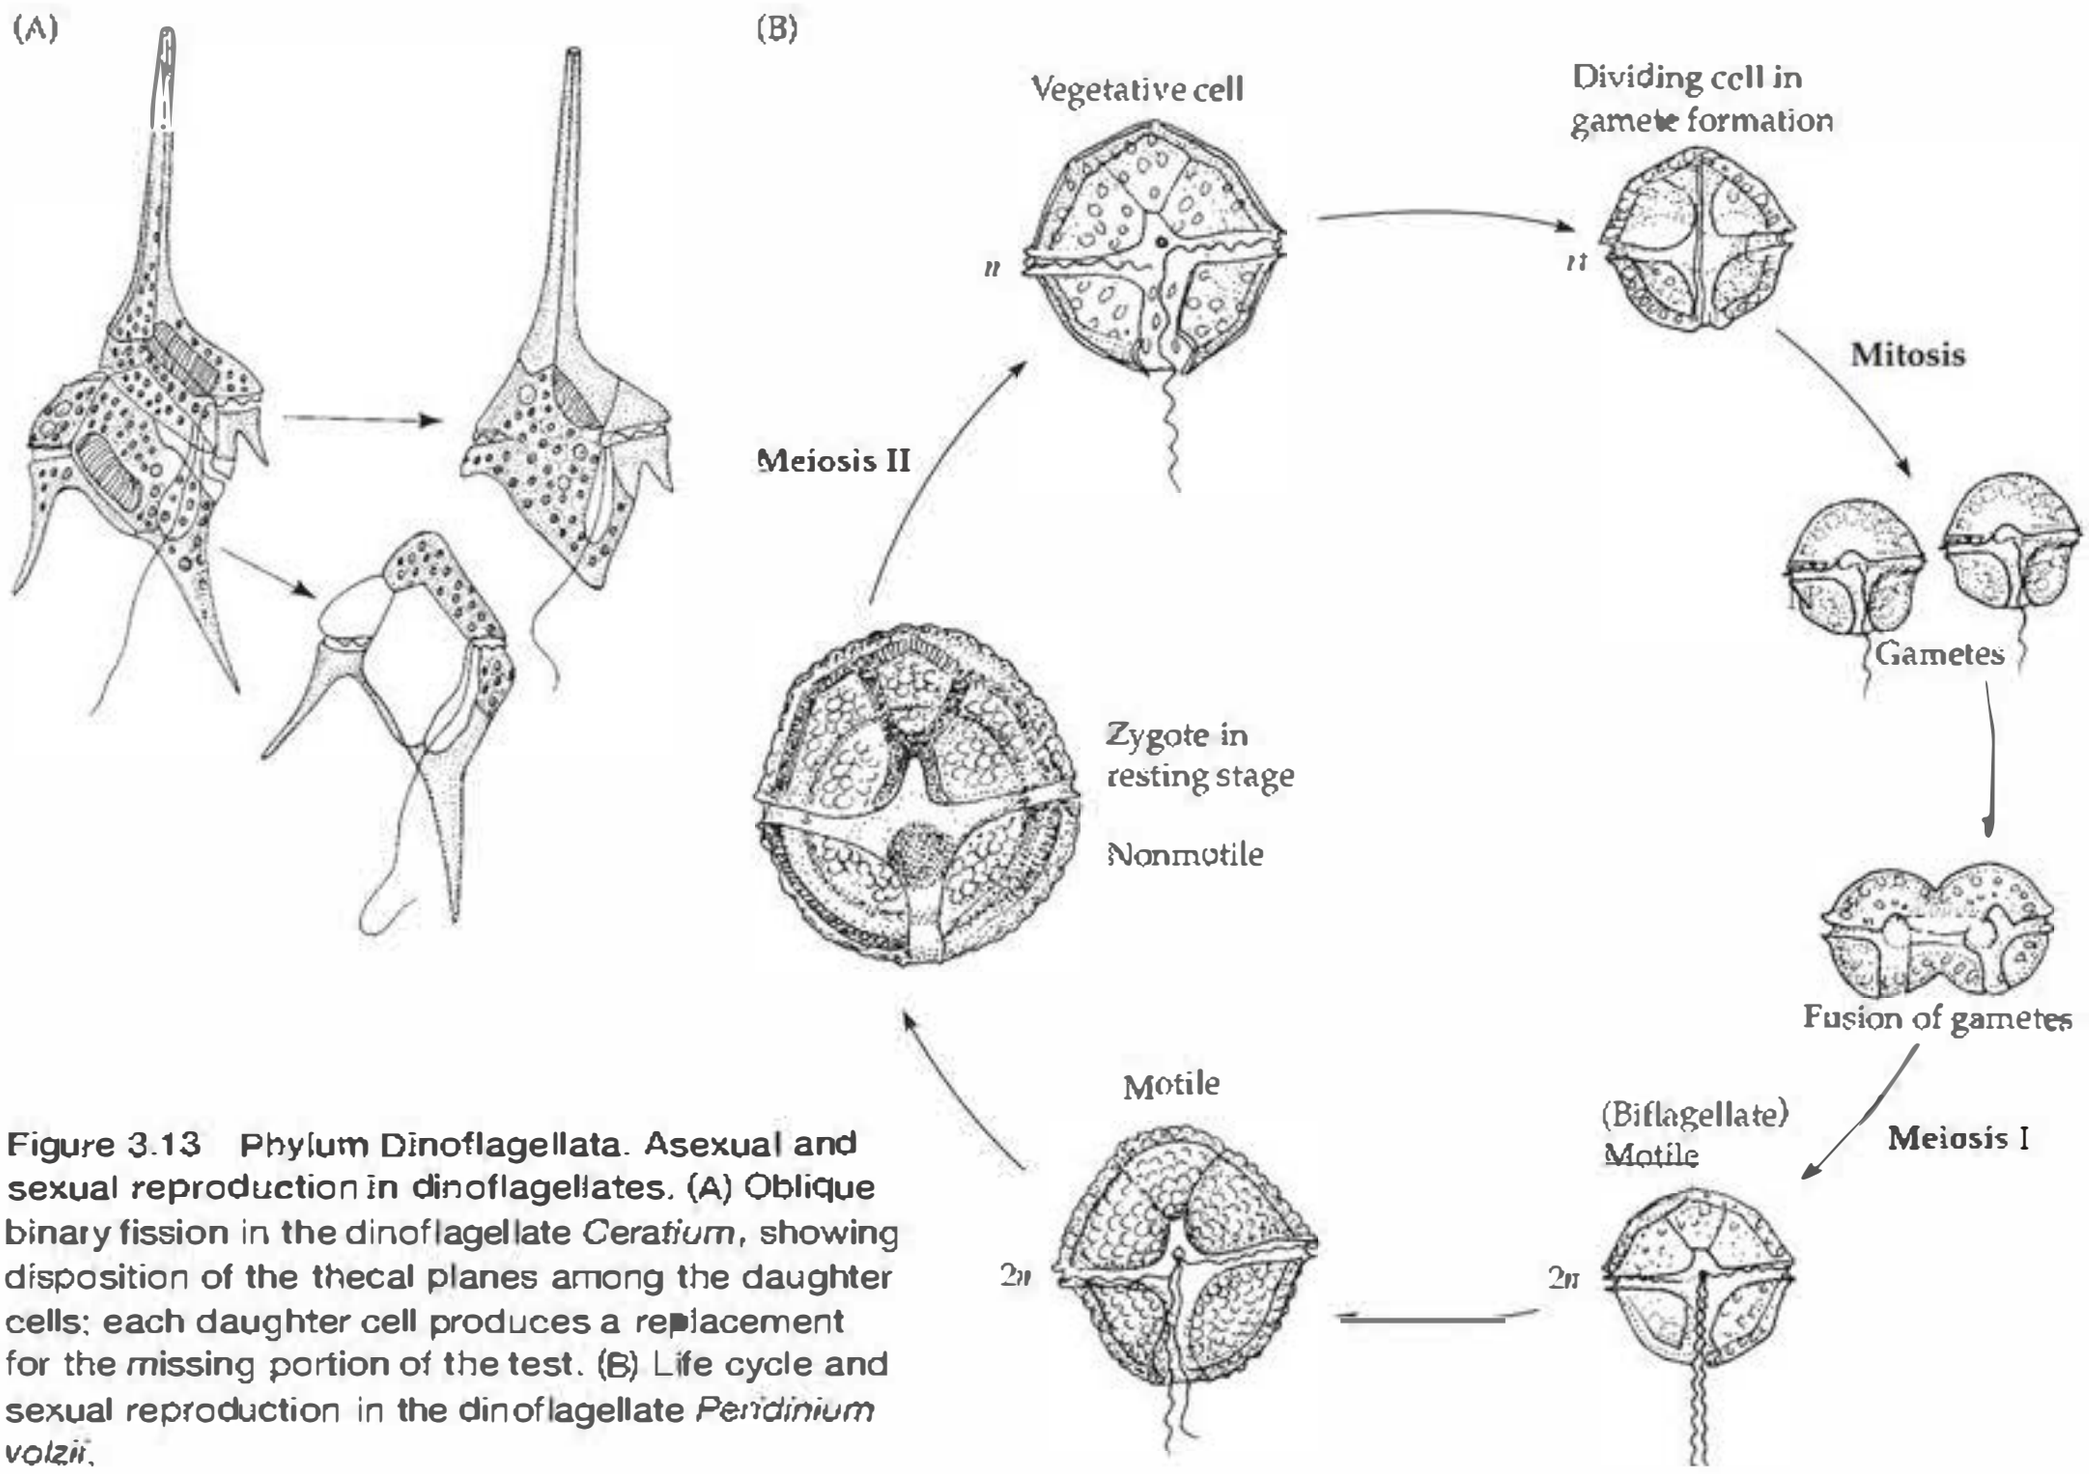
The nuclei of dinoflagellates have three unusual features: (1) they contain five to ten times the amount of DNA that is found in most eukaryotic cells; (2) the five histone proteins that are typically associated with the DNA of other eukaryotic cells are absent; and (3) the chromosomes of dinoflagellates remain condensed and the nucleolus remains intact during interphase and mitosis. Most dinoflagellates (but not *Noctiluca*) spend much of their lives as haploid cells, called vegetative cells to distinguish them from haploid gametes.

Nuclear division is by closed extranuclear pleuromitosis. No centrioles are present, and the organizing center for the mitotic spindle is not obvious. Asexual reproduction occurs by oblique, longitudinal fission, beginning at the posterior end of the cell. The thecate forms may divide the thecal plates between the two daughter cells (e.g., *Ceratium*), or they may shed the thecal plates prior to cell division (Figure 3.13A). In the former case, each daughter cell synthesizes the missing plates; in the latter case, each daughter cell synthesizes all of the thecal plates anew.

Sexual reproduction begins when the haploid vegetative cells divide by mitosis to produce two flagellated daughter cells, which act as gametes. When a pair of gametes fuses to form a zygote, a fertilization tube develops beneath the basal bodies of its flagella. The nucleus from each gamete enters the tube where they fuse. The first meiotic division follows shortly after nuclear fusion. Over the next few weeks, the zygote grows in size and then enters a resting stage, or cyst. The cyst develops a resistant outer wall and remains dormant for an indefinite period of time. Eventually the second meiotic division occurs, all but one of the nuclei disintegrate, and a haploid vegetative cell emerges from the cyst (Figure 3.13B).

---

[6]Paraxonemal rods are internal, solid or hollow, proteinaceous rods that extend nearly the entire length of a flagellum/cilium. They are located between the axoneme and flagellar membrane, and usually are connected to the axoneme and membrane by specific links. Although they are seen in dinoflagellates, euglenids, kinetoplastids, silicoflagellates, and others, they differ in ultrastructure and biochemical composition and their homology seems unlikely. They also are known as "flagellar rods," "paraxial rods," and "paraflagellar rods." Similar structures (also called "paraxonemal rods") have even been described from the flagella of certain vertebrate spermatozoa.



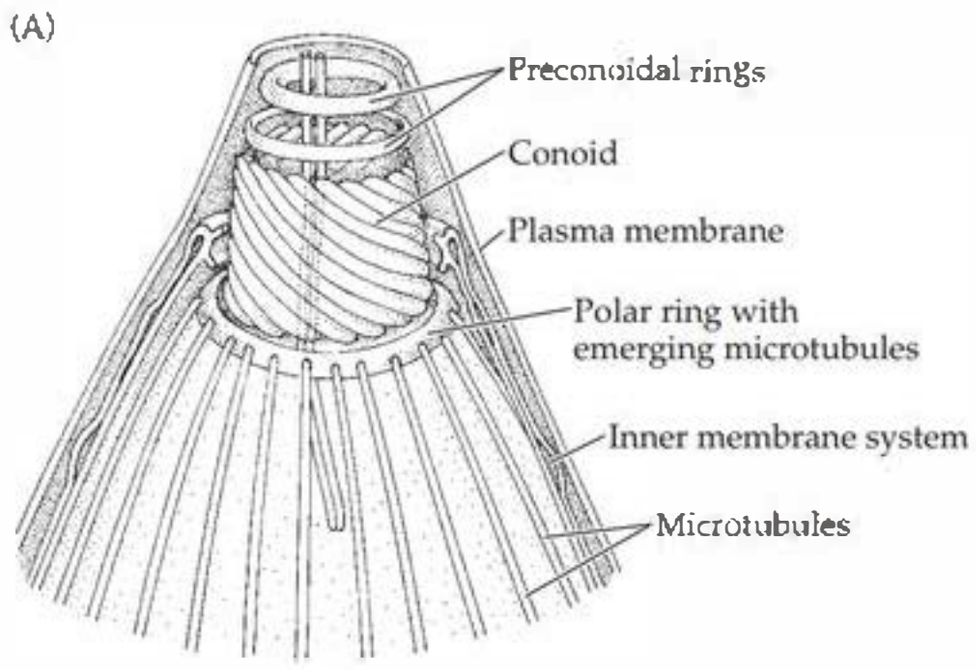


Figure 3.13 Phylum Dinoflagellata. Asexual and sexual reproduction in dinoflagellates. (A) Oblique binary fission in the dinoflagellate *Ceratium*, showing disposition of the thecal planes among the daughter cells; each daughter cell produces a replacement for the missing portion of the test. (B) Life cycle and sexual reproduction in the dinoflagellate *Peridinium volzii*.

Phylum Apicomplexa: Gregarines, Coccidians, Haemosporidians, and Their Kin

The phylum Apicomplexa, with more than 5,000 species, is arguably the most successful group of specialist parasites on Earth. This phylum includes the gregarines, coccidians, haemosporidians, and piroplasms. Among these is the vastly important human pathogen *Plasmodium* (the causative agent of malaria), as well as the human disease causing genera *Toxoplasma* and *Cryptosporidium*. All apicomplexans are parasitic, and the group is characterized by the presence of a unique combination of organelles at the anterior end of the cell called the **apical complex** (Figure 3.14A). The apical complex apparently attaches the parasite to a host cell and releases a substance that causes the host cell membrane to invaginate and draw the parasite into its cytoplasm in a vacuole. Some apicomplexans also possess a bizarre, vestigial plastid, the **apicoplast**. This DNA-containing organelle is the remnant of a secondary endosymbiosis involving a red algal "prey" cell and an apicomplexan. In these species, the apicoplast appears to be necessary for the survival of the "host" cell, and functions in fatty acid, heme, and isoprynoid synthesis (Box 3F).

Gregarines comprise a large group of apicomplexans that occupy the guts, reproductive systems, and other body cavities of numerous phyla of invertebrates, including annelids, molluscs, nemerteans, sipunculans, tunicates, echinoderms, phoronids, hemichordates, appendicularians, and arthropods. The genus *Gregarina* itself has nearly a thousand described species, mostly insect parasites. The trophozoites (motile cells) of gregarines are often very large cells. Unlike most other Apicomplexa, gregarines are largely extracellular, rather than intracellular parasites. Their apical complex is generally specialized for attachment to the host's epithelia, rather than for host cell invasion, and thus is typically equipped with hooks or suckers (Figure 3.14B–D). Although both cellular and molecular data indicate gregarines diverged early within the radiation of Apicomplexa, these are highly-derived/specialized parasites that have many novel ultrastructural and behavioral adaptations, and many of the marine species have become giants among single-celled organisms.

The coccidians are parasites of several groups of animals, mostly vertebrates. They typically reside within the epithelial cells of their host's gut, at least during some stages, and many are pathogenic. Some coccidians pass their entire life cycle within a single host;

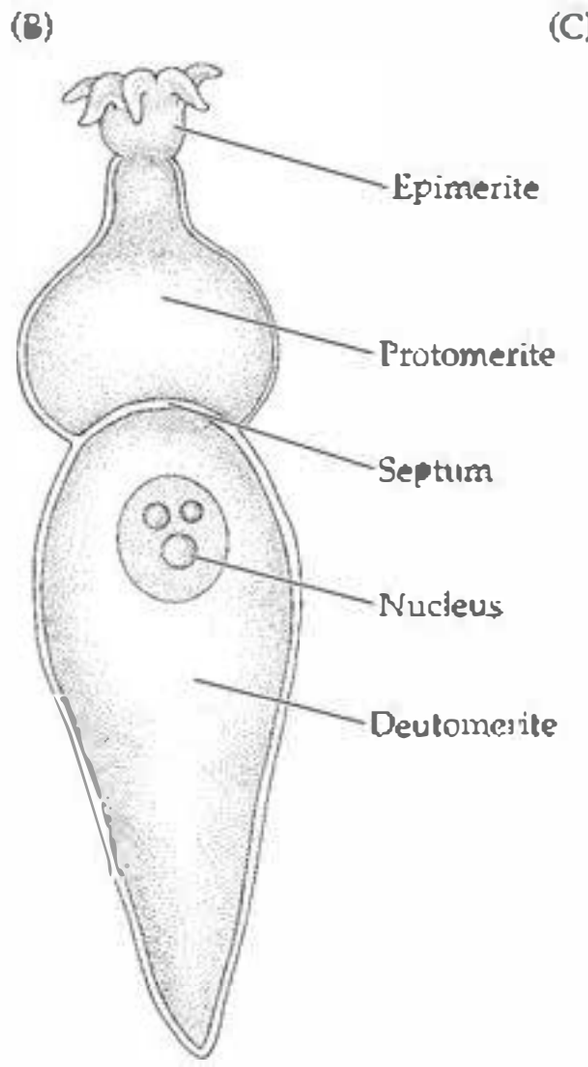

Figure 3.14 Phylum Apicomplexa. (A) Microstructure of the apical complex. (B) The body of a gregarine is commonly divided into three recognizable regions. (C) Septate gregarines (gamonts) undergoing syzygy. (D) *Pterospora floridiensis*, a gregarine that lives in the coelom of maldanid polychaetes (*Axiothella rubrocincta*).

many others require an intermediate host that serves as a vector. Coccidians are responsible for a variety of diseases, including coccidiosis in rabbits, cats, and birds, and toxoplasmosis in people and many other mammals. Piroplasms and haemosporidians are both parasites of vertebrates. The piroplasms are transmitted by ticks and are responsible for some serious diseases of domestic animals, including red-water fever in cattle. The coccidian genus *Eimeria* causes a disease known as cecal coccidiosis in chickens. This disease was estimated by the USDA to cost American poultry farmers more than $600 million dollars annually in lost animals, medication, and additional labor.

Haemosporidians are blood parasites of vertebrates that are transmitted by biting insects and include the organisms that cause malaria and malaria-like ailments in humans, birds, and other vertebrates. Human malaria, which affects people in over 100 countries, is caused by four species of the genus *Plasmodium* (Box 3G). More people have died of malaria than from any other disease in history. Although malaria was greatly reduced worldwide during the 1960s, it is making an alarming comeback, and it is one of the most prevalent and severe health problems in the developing world. Nearly a quarter-million new cases of malaria are contracted each year, and over one-half million deaths occur annually due to the disease, most of them children and 90% of them in Africa where *Anopheles gambiae* mosquitoes are the major vectors of *Plasmodium falciparum*. Although *Anopheles* mosquitoes are the only insects capable of harboring the human malaria parasite, the complex life cycle of this parasite challenges researchers (some *A. gambiae* strains are completely resistant to *Plasmodium* infections). Individuals of the *Plasmodium* parasite differentiate into a series of morphologically distinct forms in both the vertebrate and mosquito hosts. They alternate between morphologically related invasive stages (sporozoites, merozoites, ookinetes) and replicative stages (pre-erythrocytic, erythrocytic-schizont, oocyst) interposed by a single phase of sexual development that mediates transmission from the human host to the anopheline vector. In all, in its two hosts, human *Plasmodium* parasites undergo 10 morphological transitions in five different host tissues. Recent genomic studies have revealed that *Plasmodium* has many genes with no known homologs in other species, indicating its machinery for interacting with the host environment is highly specialized. Rodent malaria parasite species provide model systems that facilitate research not easily accomplished in humans, and three species are in common laboratory use (*Plasmodium berghei, P. chabaudi, P. yoelii*). Other malaria-like genera (e.g., *Haemoproteus, Leucocytozoon*) are parasites of birds and reptiles but have life cycles similar to *Plasmodium* and also utilize mosquitoes as vectors. In the Old World, migrating birds can pick up various species of malaria parasites while overwintering in the tropics. A

BOX 3F Characteristics of the Phylum Apicomplexa

1. Shape of cell maintained by pellicle consisting of alveolar vesicles beneath plasma membrane, and by supporting microtubules
2. Locomotion characterized as gliding, but cilia/flagella absent (although some species produce flagellated or ameboid gametes)
3. With unique system of organelles—the apical complex—in anterior region of cell. These function in host cell attachment and/or host cell invasion.
4. All species are parasitic
5. Carbohydrates stored as paraglycogen (= amylopectin)
6. Some species with nonphotosynthetic plastid—the apicoplast—which fulfills essential biosynthetic functions
7. Mitochondria with vesicular cristae
8. With single vesicular nucleus
9. Nuclear division occurs by semi-open pleuromitosis in all except gregarines, which show much diversity in their mitoses: mitotic spindle organizers are disks, plugs, or electrondense crescents on nuclear envelope in the location of fenestrae. In coccidians, centrioles are associated with spindle organizers; in haemosporidians and piroplasms, centrioles absent.
10. Asexual reproduction by binary fission, multiple fission, or endopolygeny
11. Sexual reproduction is gametic; gametes either isogametous or anisogametous; meiosis involves single division after formation of zygote

recent study of migrant great reed warblers, which nest in Sweden and overwinter in Africa, found that birds infected with species of *Plasmodium* and *Haemoproteus* laid fewer eggs in their lifetime, were less successful at rearing offspring, and died at a younger age (probably due to telomere damage).

Toxoplasma gondii is extraordinarily prevalent in the developed world, and it is a source of congenital neurological birth defects in children whose mother happen to be exposed during pregnancy. In adults, *Toxoplasma* usually produces no symptoms, or only mild symptoms, but it and another apicomplexan, *Cryptosporidium*, have been increasingly problematic in AIDS patients and other immunosuppressed people. Transmission of *Toxoplasma* parasites is thought to be via raw or undercooked meat (beef, pork, lamb), through fecal contamination from pet cats, or by way of flies and cockroaches (which can carry the *T. gondii* cysts from a cat's litter box to the table). In 1982 Martina Navratilova lost the U.S. Open Tennis Championship (and a half-million dollars) when she had toxoplasmosis.

Support and Locomotion

The fixed shape of apicomplexans is maintained by a pellicle composed of inner membrane sacs, or alveoli, which lie just beneath the plasma membrane. Microtubules originate at the apical complex and run beneath the alveoli, providing additional support. Apicomplexa do not have cilia, flagella or pseudopodia (except in some microgametes). Nevertheless, they can be observed flexing and gliding along surfaces, and this movement is produced by microtubules and microfilaments underneath the alveoli. The motion involves attachment proteins that are released to the cell membrane from vesicles in the apical complex, and actin-myosin interactions, that is the same fundamental motor system that powers muscle cells in Metazoa.

Nutrition

The alveoli are interrupted at both the anterior and posterior ends, and at tiny invaginations of the cell membrane called **micropores**, which have been implicated in feeding. Nutrient ingestion is thought to occur primarily by pinocytosis at the microspores. In the haemosporidians, ingestion of the host's cytoplasm through the microspores has been observed. Absorption of nutrients has also been reported in some gregarines at the point where the parasite attaches to the host's cell.

Reproduction and Life Cycles

Asexual reproduction in Apicomplexa is by binary fission, multiple fission, or endopolygeny. During multiple fission, the nucleus undergoes several divisions prior to cytokinesis (partitioning of the cytoplasm), resulting in many (e.g., 32) daughter cells. Some engage in a process called plasmotomy, considered by some to be a form of budding, in which a multinucleate adult simply divides into two multinucleate daughter cells. Other members of the Apicomplexa undergo a type of internal budding called **endopolygeny**, during which daughter cells actually form within the cytoplasm of the mother cell.

Mitosis is a semi-open pleuromitosis in all apicomplexans except for some gregarines. Gregarines undergo a variety of mitoses, depending on the species. For example, *Diplauxis hatti* and *Lecudina tuzetae* undergo semi open orthomitosis, *Monocystis* sp. and *Stylocephalus* sp. undergo open orthomitosis, and *Didymophyes gigantea* undergoes closed intranuclear orthomitosis. Sexual reproduction occurs by a union of haploid gametes, which can be the same size (isogametous) or different sizes (anisogametous), and may be flagellated or form pseudopodia.

The life cycle varies somewhat between the different groups of apicomplexan protists, but can be divided into three general stages: (1) **gamontogony** (the sexual phase), (2) **sporogony** (the spore-forming stage), and (3) **merogony** or **schizogony** (the growth phase).

BOX 3G Malaria

Human malaria has been known since antiquity. Egyptian mummies show signs of malaria, and descriptions of the disease are found in Egyptian papyruses and temple hieroglyphs (outbreaks followed the annual flooding of the Nile). Alexander the Great likely died of it, leading to the unraveling of the Greek Empire. Malaria might have been what stopped the armies of both Attila the Hun and Genghis Khan. Malaria was almost certainly brought to the New World by the conquering Spaniards and their African slaves. At least four popes died of it. George Washington, Abraham Lincoln, and Ulysses S. Grant all suffered from it. During World War II, there were more casualties in the Pacific theater from malaria than from combat. Some scientists believe that one out of every two people who have ever lived have died of malaria. In 1946, the Centers for Disease Control was founded in Atlanta specifically to combat malaria. Other forms of vertebrate malaria are probably hundreds of millions of years old—some evidence suggests dinosaurs might have had malaria. Mice, birds, porcupines, emurs, monkeys and apes, bats, snakes and flying squirrels all have their own forms of malaria. In 2002, scientists sequenced the genome of *Plasmodium falciparum*, the most deadly species of malaria parasite, and in 2010 they concluded that this parasite was descended from a single lineage (*P. reichenowi*) that jumped from gorillas or chimpanzees a few million years ago. And in 2014, Neafsey et al. published an analysis of the genomes of 16 species of *Anopheles* mosquitoes, providing detailed insight into the evolution of these insects.

The relationship between malaria in humans and the smell of nearby swampland led to the belief that it could be contracted by breathing "bad air" (from the Italian, *mal aria*)—hence the origin of the name. It was not until 1897 that Britain's Sir Ronald Ross discovered that the malaria parasite is transmitted by the *Anopheles* mosquito. By the time the Panama Canal was built, malaria (and yellow fever) was well established in the New World, and until the twentieth century the disease occurred as far north as the American Midwest. The presence of malaria (and yellow fever) was the principal reason the French failed in their attempt to construct the Panama Canal. William Gorgas, the medical officer in charge during the U.S. phase of the canal's construction, became a hero when his mosquito-control efforts allowed for the canal's successful completion by U.S. engineers. The president made Gorgas Surgeon General, Oxford University gave him an honorary doctorate and the King of England knighted him.

The first effective remedy for human malaria—the bark of the cinchona tree (a close cousin of coffee)—was discovered in Peru and Ecuador. This remedy came to be distributed worldwide as quinine. The cinchona tree was eventually established on plantations in India and elsewhere. Quinine disrupts the parasite's reproductive process; however it is short acting, and if taken too frequently can cause serious side effects, including hearing loss. In the 1940s synthetic malaria medicine was developed—initially a drug named chloroquine which worked as both a prophylactic and a parasite remedy. Today, however, most strains of *Plasmodium falciparum* have developed chloroquine resistance, apparently through a simple mutation in a single gene. In the mid twentieth century DDT (dichlorodiphenyltrichloroethane) was invented by the Swiss chemist Paul Müller, and this potent insecticide quickly became the centerpiece of global mosquito eradication. Today, however, the use of DDT is illegal almost everywhere. Most recently, the discovery of the potent antimalarial properties of artemisinin has helped helped turn the tide against malaria, especially when used in combination therapies and in association with insecticide-treated bednets. Chinese scientists isolated artemisinin in the 1970s from sweet wormwood (*Artemisia annua*), a plant used to treat fever for centuries. However, it may be only a matter of time until the highly adaptable *P. falciparum* parasite develops a resistance to artemisinin.

Among the many symptoms of malaria are cyclical paroxysms, wherein the patient feels intensely cold as the hypothalamus (the body's thermostat) is activated; body temperature then rises rapidly to 104°–106° F. Nausea and vomiting are usual. Copious perspiration signals the end of the hot stage, and the temperature drops back to normal within 2 or 3 hours. The entire paroxysm is over within 8 to 12 hours. It is thought that these episodes are stimulated by the appearance of the waste products of parasites feeding on erythrocytes, which are released when the blood cells lyse. Secondary symptoms include anemia due to the red blood cell destruction. In extreme cases of falciparum malaria, massive lysis of erythrocytes results in high levels of free hemoglobin and various breakdown products that circulate in the blood and urine, resulting in a darkening of these fluids, hence the condition called blackwater fever.

One of the principal causes of the recent malaria resurgence is the dramatic rise in the numbers of pesticide-resistant strains of *Anopheles* mosquitoes, the insect vector for *Plasmodium*. The development of a malaria vaccine continues to elude researchers; in fact, vaccines do not exist for any human metazoan parasitic disease. By 1968, 38 strains or species of *Anopheles* in India alone had been identified as largely pesticide resistant; and between 1965 and 1975 the incidence of malaria in Central America tripled. Researchers have recently discovered that *Plasmodium* species, like *Trypanosoma*, have the ability to avoid detection by the human immune system by switching among as many as 150 genes that code for different versions of the protein that coats the surface of their cells (it is this protein coat that the human immune system recognizes as a recognition factor). This trick is known as **antigenic variation**. Furthermore, because the parasite sequesters itself in developed blood cells it is largely protected from most drugs. Recent evidence also suggests that one effect the parasite may have on its mosquito host is inducing it to bite more frequently than uninfected mosquitoes.

At least one of the four malaria causing *Plasmodium* species occurs on every continent save Antarctica, and the disease threatens nearly half the world's population. The less deadly *Plasmodium vivax* occurs mainly in South America and Asia. Today, sub-Saharan Africa is not only the largest remaining sanctuary of the deadly *P. falciparum*, but also the home of *Anopheles gambiae*, the most aggressive of the more than 60 mosquito species that transmit malaria to people. Falciparum malaria can be devastating, and infected individuals commonly suffer seizures, coma, heart, and lung failure. Those who survive can suffer mental or physical handicaps or chronic debilitation. Most of the genome of *Plasmodium falciparum*, and its host mosquito *Anopheles gambiae*, have now been sequenced, opening doors to possible new control measures for this deadly disease. The battle against malaria got a big boost in 2005 when the Bill and Melinda Gates Foundation announced grants totaling $258 million to support development of new drugs and improved mosquito control methods.

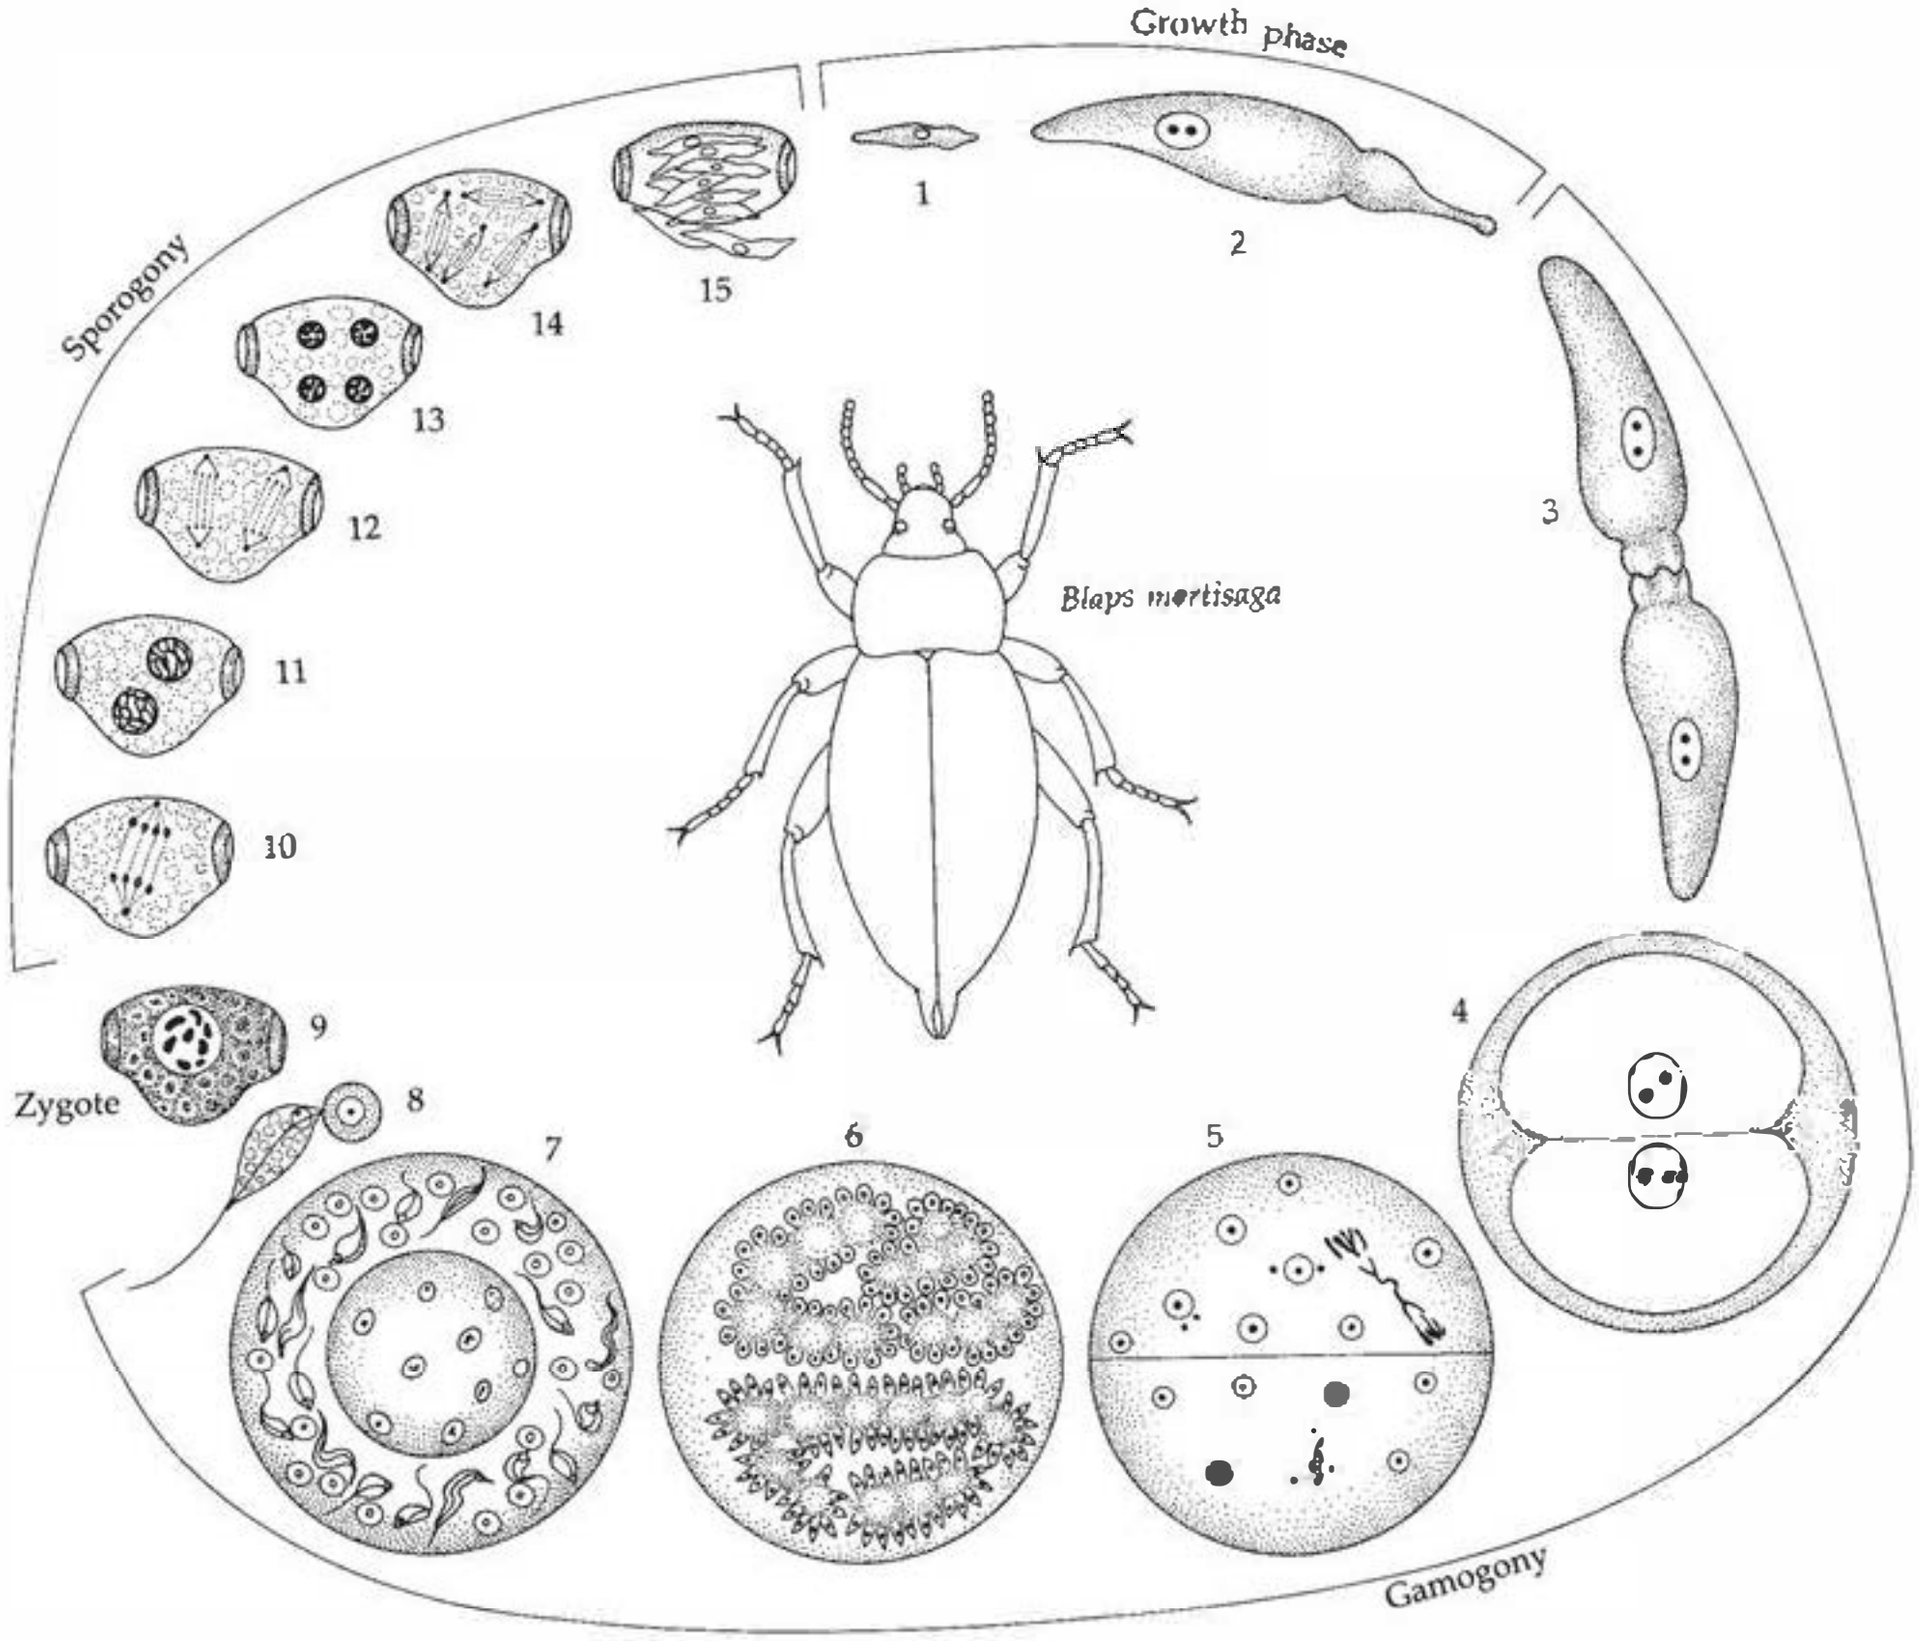

Figure 3.15 Phylum Apicomplexa Life cycle of the gregarine *Stylocephalus longicollis*, a gut parasite of the Old World "churchyard beetle" (Tenebrionidae: *Blaps mortisaga*). Stages 1–4 take place within the host, 5–15 outside the host. The spores (15) are ingested by the beetle and release sporozoites within the gut lumen. Each sporozoite grows into a gamont (2); the gamonts subsequently mate (3–4), becoming enclosed within a mating cyst, which leaves the host with the feces. Repeated mitotic divisions within the cyst produce anisogametes (5–7); these ultimately fuse (8) to produce a zygote (9), which eventually becomes a spore. The first divisions of the spore cell are meiotic (10), so all subsequent stages leading back to gamete fusion are haploid.

A great deal has been written about the life cycles of these protists and a full description is beyond the scope of this text, however, it is worth noting that typical Apicomplexa are haploid for most of their life cycle. The life cycles of the gregarine *Stylocephalus* and the haemosporidan *Plasmodium* are given as examples to illustrate the basic themes and variations in apicomplexan reproduction.

The life cycle of gregarines is usually **monoxenous**—it involves only one host. Some of the best-studied gregarines are those found in coleopterans (beetles), and the life cycles of these are well understood (the life cycle of *Stylocephalus longicollis* is diagrammed in Figure 3.15). Once two trophozoites join together for sex, a process called **syzygy**, the cells are called **gamonts**. A wall forms around the gamonts forming a **gametocyst**, within which several rounds of mitosis produce hundreds of gametes. Both isogamy and anisogamy are known among different gregarines. Zygotes (the fleeting diploid stage) are formed after one gamete from each gamont fuse together. Each zygote that is formed by the fusion of two gametes becomes a thick-walled **sporocyst**, which undergoes meiosis to produce four or more sporozoites. Sporozoite-filled gametocysts are released into the environment by way of host feces, host gametes, or host disintegration. New hosts inadvertently consume sporocysts in their environment, and these find their way to the appropriate body cavity and penetrate the host cells, completing the cycle.

The life cycle of haemosporidians is **heteroxenous**, which means it involves two hosts, usually a vertebrate

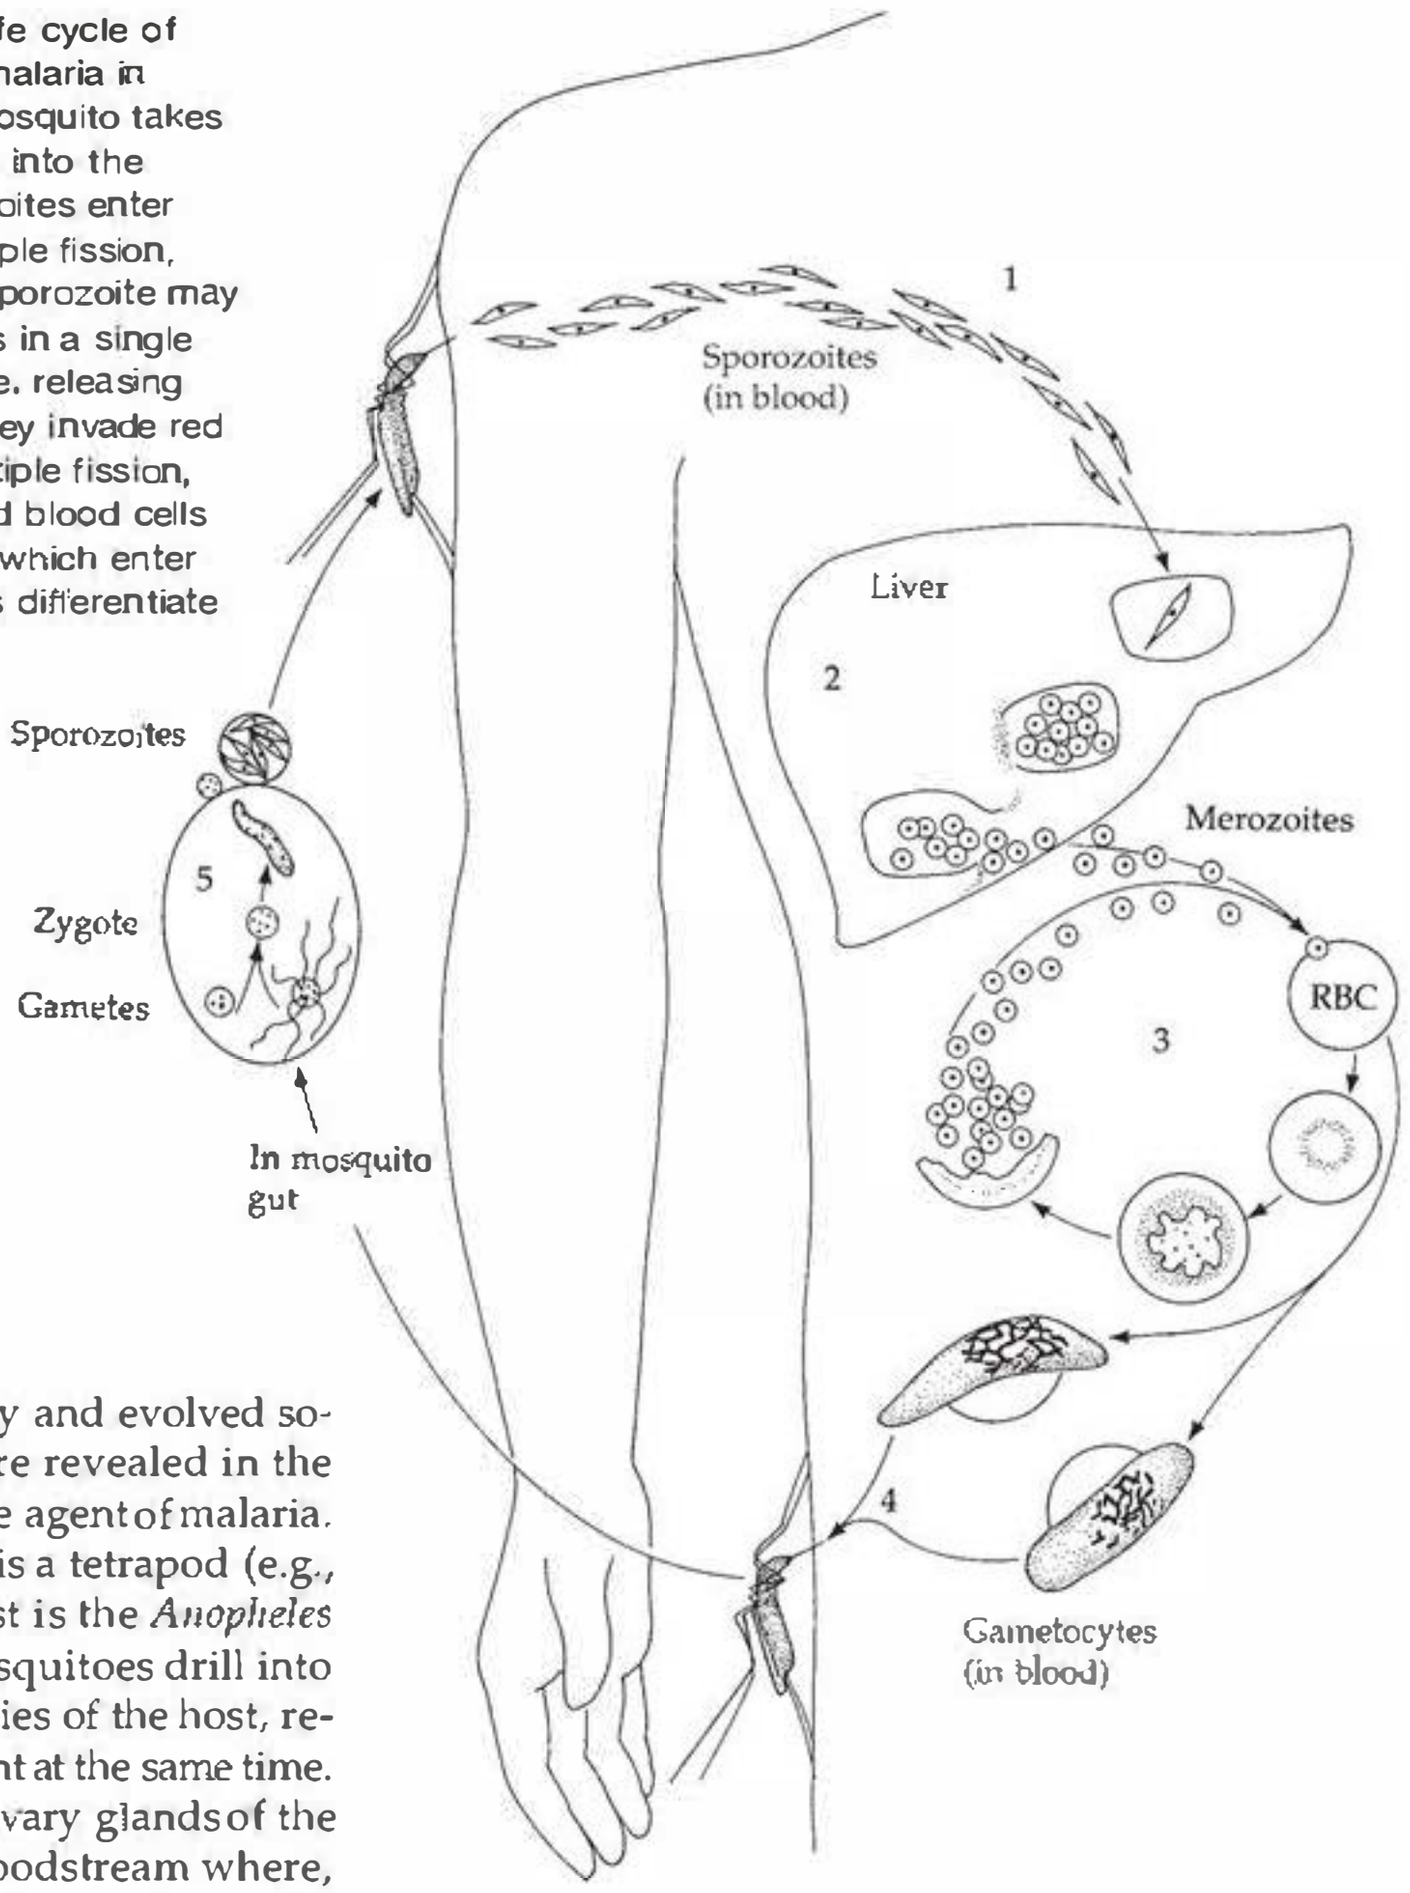

Figure 3.16 Phylum Apicomplexa. Life cycle of *Plasmodium*, the causative agent of malaria in humans. When a female anopheline mosquito takes a blood meal, she releases sporozoites into the victim's bloodstream (1). These sporozoites enter the host's liver cells and undergo multiple fission, producing many merozoites (2); each sporozoite may produce as many as 20,000 merozoites in a single liver cell. The infected liver cells rupture, releasing the merozoites into the blood where they invade red blood cells (3). Through continued multiple fission, more merozoites are produced. The red blood cells eventually burst, releasing merozoites, which enter other red blood cells. Some merozoites differentiate to become gametocytes (4), which are picked up by mosquitoes. The female gametocyte forms a single macrogamete; the male gametocyte typically undergoes multiple fission to produce several motile, flagellated microgametes within the gut of the mosquito (5). After fertilization occurs, the zygote migrates to the mosquito's salivary glands and divides to form numerous sporozoites, thereby completing the life cycle.

and an invertebrate. The complexity and evolved sophistication of haemosporidians are revealed in the lifecycle of *Plasmodium*, the causative agent of malaria. In *Plasmodium*, the vertebrate host is a tetrapod (e.g., humans), and the invertebrate host is the *Anopheles* mosquito (Figure 3.16). Female mosquitoes drill into the network of blood-filled capillaries of the host, releasing an anticoagulant and lubricant at the same time. Sporozoites, which reside in the salivary glands of the mosquito, are released into the bloodstream where, within minutes, they migrate to the liver and enter the hepatocytes, or liver cells. A single successful sporozoite is enough to initiate the disease. Once in the liver cells, the sporozoites undergo multiple fission (schizogony) for a week or so, until the host cell has been entirely digested and is bulging with parasites, upon which the cell ruptures to release the merozoites. The merozoites immediately enter red blood cells (erythrocytes) and transform into trophozoites. In the erythrocytes, the trophozoites undergo schizogony again to form more merozoites (or, occasionally, they transform into gamonts), eventually bursting the erythrocyte. The released merozoites infect other red blood cells and the population of parasites grows rapidly.

The destruction of red blood cells by human *Plasmodium* parasites, and the release of metabolic byproducts, are responsible for the characteristic chills, fever, and anemia that are common symptoms of malaria. So many oxygen-carrying red cells are destroyed that the lungs must fight for air and the heart struggle to pump – and the blood acidifies. In some cases of falciparum malaria, infected red blood cells pass through the capillaries of the brain and the infection turns into cerebral malaria, the most feared manifestation of the disease. Sicklecell anemia confers partial resistance to *P. falciparum*. If the trophozoite becomes a gamont, it will be morphologically distinguishable as either a macrogamont or a microgamont. The life cycle of gamonts proceeds no further unless they are taken in by a mosquito during its blood meal (and, remember, only female mosquitoes bite). Once in the gut of the mosquito, the macrogamont becomes a spherical macrogamete, while the microgamont undergoes three nuclear divisions and develops eight projections (microgametes), which each receive a nucleus. The microgametes break away and each fertilizes a single

macrogamete to form a diploid zygote called an ookinete (this cell is the only diploid stage in the entire life cycle). The ookinete then actively burrows through the mosquito's stomach and secretes a covering around itself on the outside of the stomach, forming an oocyst. Inside the oocyst, the zygote undergoes a meiotic reduction division followed by schizogony to form haploid sporozoites that are released from the oocyst into the gut, to migrate to the salivary gland where they remain until the next time the insect feeds.

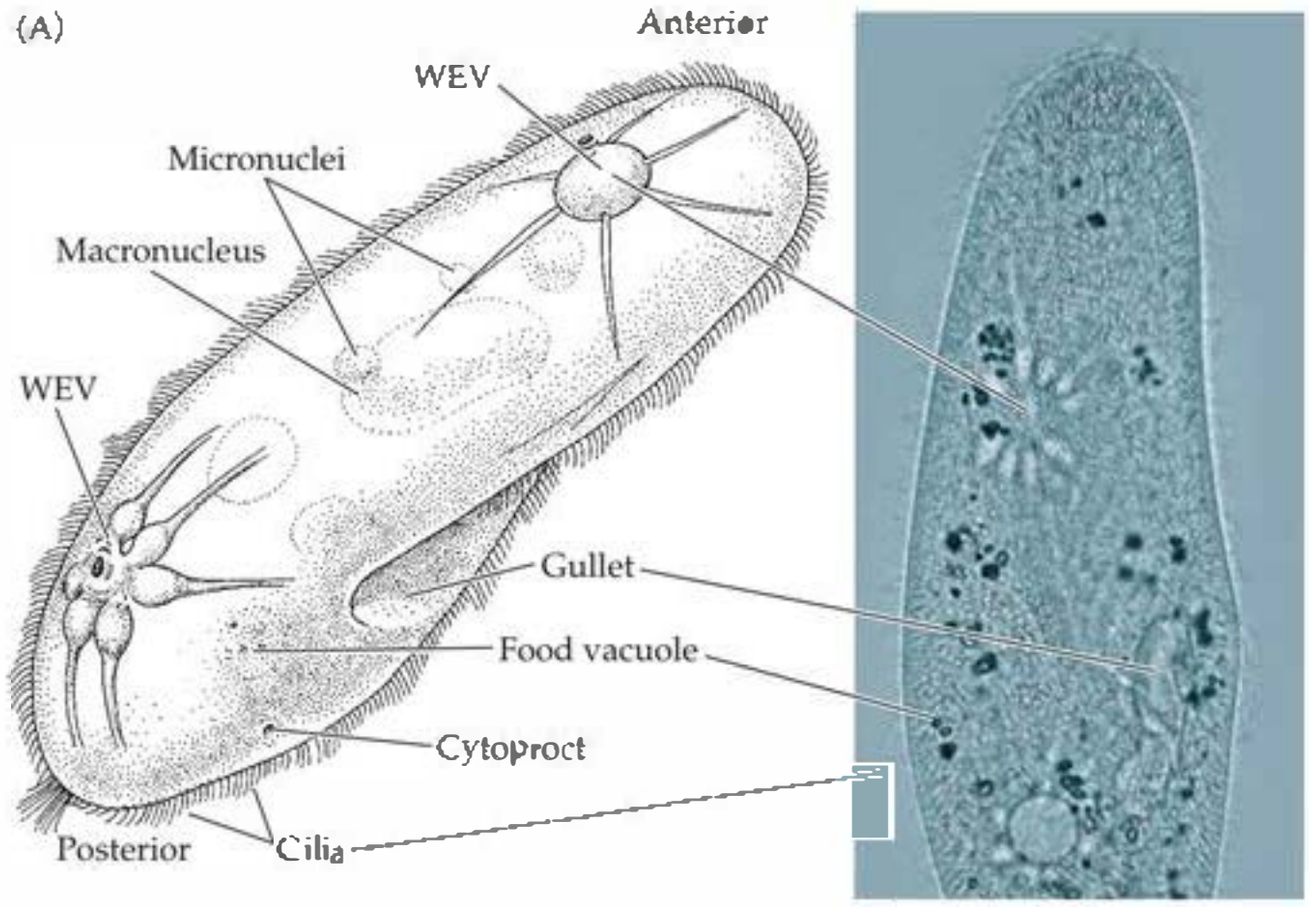
The ability of *Plasmodium* to develop within vertebrate red blood cells is a challenge met by very few intracellular parasites. Normally, "diseased" and senescent erythrocytes are cleared by the spleen, but in *Plasmodium*infected erythrocytes the parasite modifies the host cell by exporting its own proteins into the cytoplasm and plasma membrane of the red cell as an immune evasion mechanism.

Phylum Ciliata: The Ciliates

There are an estimated 10,000 to 12,000 described species of ciliates. They derive their name from the Latin word for "eyelash" ("*cilia*"). Ciliates are very common in benthic and planktonic communities in marine, brackish, and freshwater habitats, as well as in damp soils. A number are also ecto or endosymbiotic, and some are even obligate or opportunistic parasites. Members of at least one genus, *Collinia*, are marine parasitoids that infect euphausid crustaceans (krill), killing their host in order to achieve transmission and complete their life cycle. Species of *Collinia* have been reported causing mass euphausid mortality events in the North Pacific. Most ciliates occur as single cells, and some get quite large (~2 mm long). Branching and linear colonies also occur in several species. The ciliates shown in Figures 3.17 and 3.1D illustrate some of the variety of cell forms within this large and complex group of protists.

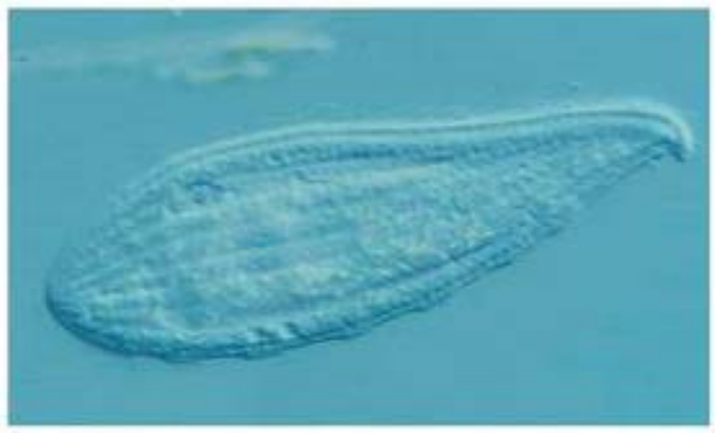
Some ciliates are important mutualistic endosymbionts of ruminants such as goats, sheep, and cattle. They are found by the millions in the digestive tracts, feeding on plant matter ingested by the host and converting it into a form that can be metabolized by the ruminant. Some ciliates parasitize fish or invertebrates (e.g., American lobster), and at least one (*Balantidium coli*) is known to be an occasional endoparasite of the human digestive tract. Ciliates such as *Tetrahymena* and *Colpidium* have been used as models in cell biology, genomics, and proteomics (especially studies of cilia). Others are widely used as indicators of water quality, and some have been used to clarify water in sewage treatment plants (Box 3H). Ribozymes (catalytic RNA molecules) and the enzyme telomerase, which is involved in creating the ends of eukaryotic chromosomes, were discovered through studies of model ciliates.

BOX 3H Characteristics of the Phylum Ciliata



1. Common in virtually all aquatic and wet environments, freshwater saltwater or soil
2. Shape of cell maintained by pellicle consisting of alveolar membrane vesicles and underlying proteinaceous layer (the epiplasm), associated with microtubules, all beneath plasma membrane Some secrete calcium carbonate plates within their alveoli; some others secrete external skeletons (loricae)
3. With cilia for locomotion. Associated with the basal bodies (kinetosomes) of cilia are two microtubular roots and one fibrous root; these roots plus basal bodies are collectively known as infraciliature. The diagnostic rows of cilia are called kinetes.
4. With extrusomes and mitochondria (with tubular cristae)
5. Without plastids
6. Carbohydrates sorted as glycogen
7. Most with buccal cavity and cytostome ("mouth"); often also a cytoproct ("anus")
8. With two distinct types of nuclei —hyperpolyploid macronuclei and diploid micronuclei
9. Micronucleus divides by closed intranuclear orthomitosis (in most) without centrioles. Electron-dense bodies inside nucleus act as organizing centers for mitotic spindle. Macronucleus divides amitotically by simple constriction.
10. Asexual reproduction by transverse binary fission (homothetogenic)
11. Sexual reproduction by conjugation: pair of cells bond together and exchange micronuclei through a cytoplasmic connection at point of joining

Support and Locomotion



The fixed cell shape of ciliates is maintained by the alveolar membrane system and an underlying proteinaceous layer called the **epiplasm**, or cortex (Figure 3.18). A few types (e.g., tintinnids) secrete external skeletons, or loricae, which have been documented in the fossil record as early as the Ordovician (500 Ma). Another common group (*Coleps* and its relatives) has calcium carbonate plates in their alveoli.

The cilia are in rows called **kineties** (sing. kinety), and the different patterns these rows create are used as taxonomic characters for identification and classification. Associated with the basal body (or centriole), which is called a **kinetosome** in ciliates, are three important cytoskeletal structures two microtubular roots, the postciliary microtubules and the transverse

The lorica can reach several millimeters in length and these ciliates are easily mistaken for small animals.

microtubules, and one fibrous root, the **kinetodesmal fiber**. These roots, together called the **infraciliature**, anchor the cilium to its neighbors and provide additional support for the cell surface (Figure 3.19). The kinetosomes of ciliates are homologous to the centrioles of other eukaryotic cells, being a tubular cylinder of nine triplets of microtubules.

The cilia can be grouped into two functional and two structural categories. Cilia associated with the cytostome and the surrounding feeding area comprise the **oral ciliature**, whereas cilia of the general body surface are the **somatic ciliature**. The cilia in both of these categories may be single (**simple cilia**), or the kinetosomes may be grouped close together to form **compound ciliature** (e.g., cirri, membranelles). Ciliatologists have developed a detailed and complicated terminology for talking about their favorite creatures. This special language reaches almost overwhelming proportions in matters of ciliature, and we present here only a necessary minimum of new words in order to adequately describe these organisms. Beyond this, we offer the reference list at the end of this chapter, especially the extensive and illustrated glossary in J. O. Corliss' *The Ciliated Protozoa* (1979).

The cilia are also, of course, the locomotory organelles of ciliate protists. Their structural similarities and homology to flagella are well known; but ciliates do not move like protists with flagella. The differences are due in large part to the facts that cilia are much more numerous and densely distributed than flagella, and the patterns of ciliation on the body are extremely varied and thus allow a range of diverse locomotor behaviors not possible with just one or a few flagella. Cilia can also play a role in feeding, sensation, and even attachment.

As discussed in Chapter 4, each individual cilium undergoes an effective (power) stroke as it beats. The cilium does not move on a single plane, but describes a distorted cone as it beats (Figure 3.19A,B). The beating of a ciliary field occurs in metachronal waves that pass over the body surface (Figure 3.19C). The coordination of these waves is apparently due largely to hydrodynamic effects generated as each cilium moves. Microdisturbances created in the water by the action of one cilium stimulate movement in the neighboring cilium, and so on over the cell surface. In ciliates, the tip of the cilium usually follows a counterclockwise path during the recovery stroke, resulting in a spiraling motion as the organism swims (Figure 3.19G). Many ciliates (e.g., *Didinium*, *Paramecium*) can vary the direction of ciliary beating and metachronal waves. In such forms, complete reversal of the body's direction of movement is possible by simply reversing the ciliary beat and wave directions.

Perhaps more than any other protist group, the ciliates have been studied for their complex locomotory behavior. *Paramecium*, a popular laboratory protist, has received most of the attention of protozoological behaviorists. When a swimming *Paramecium* encounters a mechanical or chemical environmental stimulus of sufficient intensity, it begins a series of rather intricate response activities. The protist first initiates a reversal of movement, effectively backing away from the source of the stimulus. Then, while the posterior end of the body remains more or less stationary, the anterior end swings around in a circle. This action is appropriately called the cone-swinging phase. The *Paramecium* then proceeds forward again, usually along a new pathway.

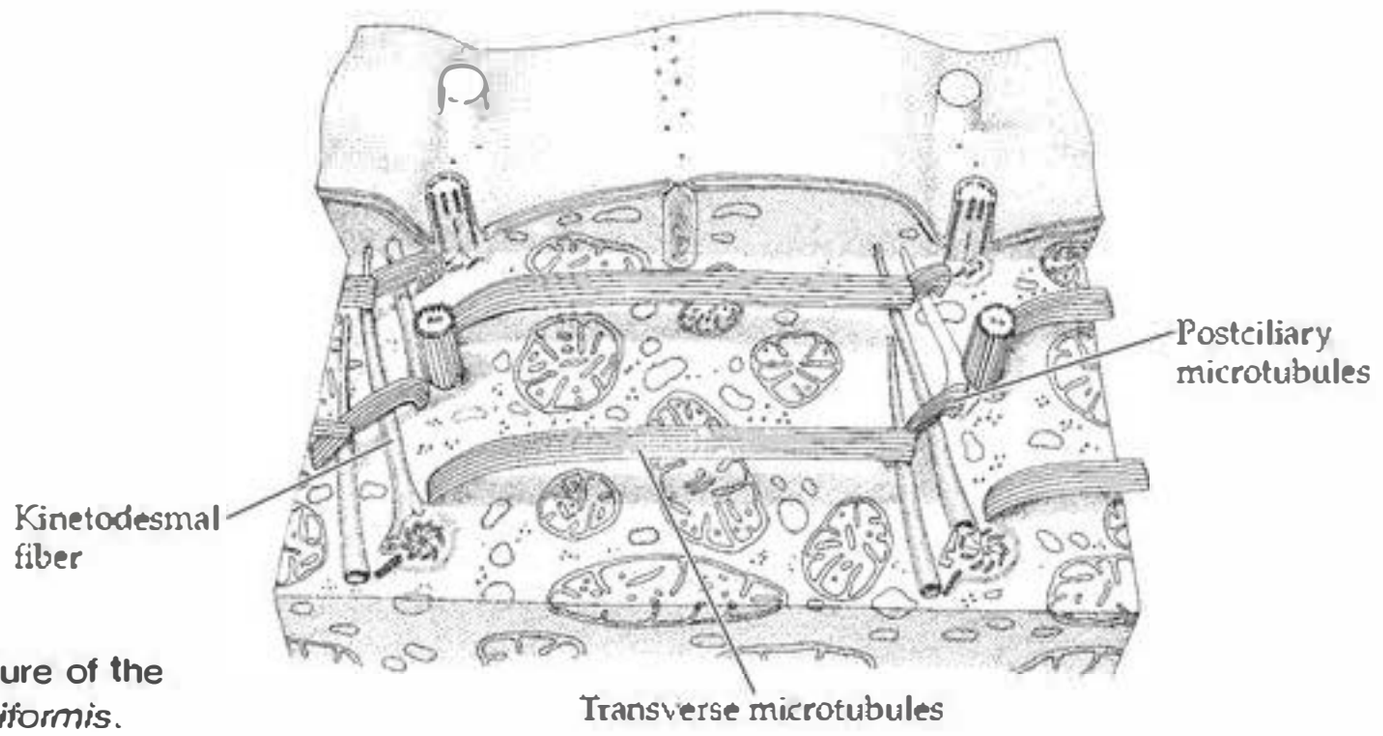

Figure 3.18 Phylum Ciliata. Fine structure of the epiplasma, or cortex of *Tetrahymena pyriformis*.

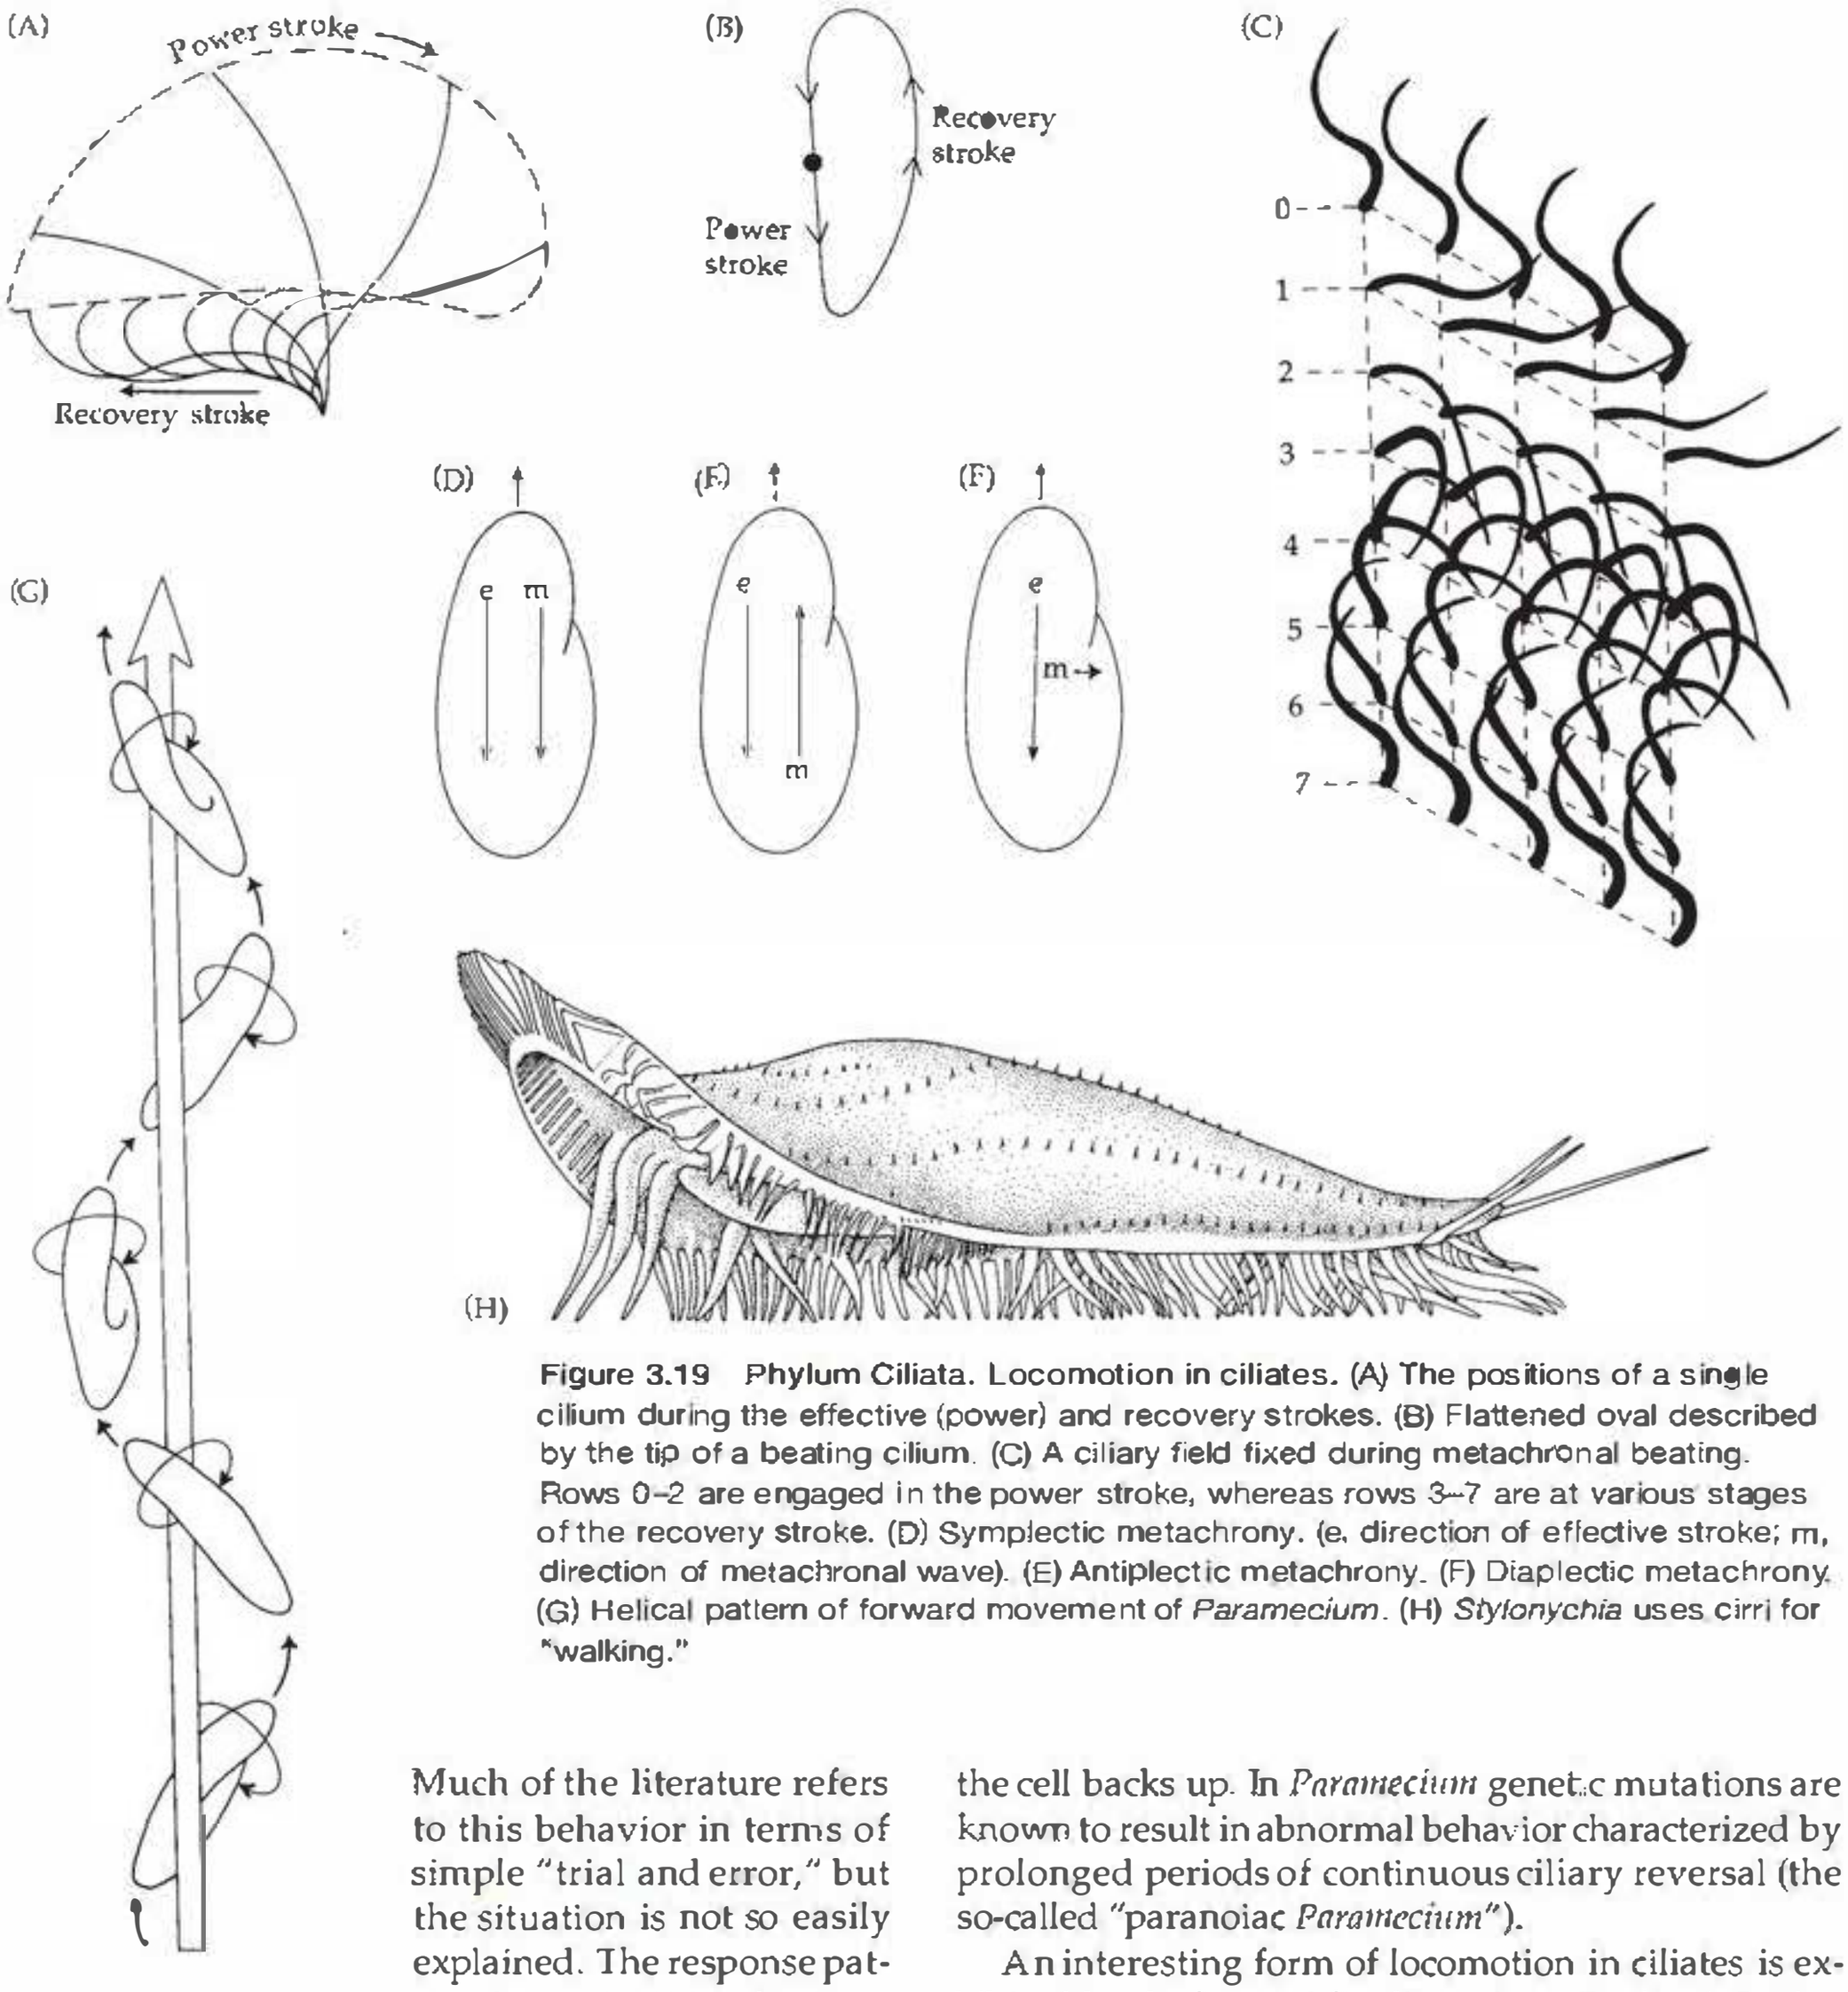

Figure 3.19 Phylum Ciliata. Locomotion in ciliates. (A) The positions of a single cilium during the effective (power) and recovery strokes. (B) Flattened oval described by the tip of a beating cilium. (C) A ciliary field fixed during metachronal beating. Rows 0–2 are engaged in the power stroke, whereas rows 3–7 are at various stages of the recovery stroke. (D) Symplectic metachrony. (e, direction of effective stroke; m, direction of metachronal wave). (E) Antiplectic metachrony. (F) Diaplectic metachrony. (G) Helical pattern of forward movement of *Paramecium*. (H) *Stylonychia* uses cirri for "walking."

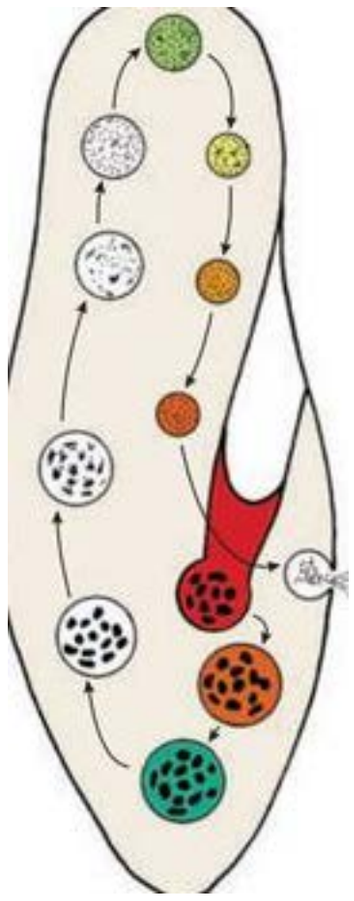
Much of the literature refers to this behavior in terms of simple "trial and error," but the situation is not so easily explained. The response pattern is not constant, because the coneswinging phase may not always occur; sometimes the cell simply changes direction in one movement and swims forward again. Furthermore, the cone-swinging phase occurs even in the absence of recognizable stimuli and thus may be regarded as a phenomenon of "normal" locomotion. Recent studies suggest that *Paramecium* swimming behavior is governed by the cell's membrane potential. When the membrane is "at rest," the cilia beat posteriorly and the cell swims forward. When the membrane becomes depolarized, the cilia beat in a reverse direction (ciliary reversal) and the cell backs up. In *Paramecium* genetic mutations are known to result in abnormal behavior characterized by prolonged periods of continuous ciliary reversal (the so-called "paranoiac *Paramecium*").

An interesting form of locomotion in ciliates is exhibited by the hypotrich ciliates (e.g., *Euplotes*). In this group, the somatic cilia are arranged in bundles called cirri, which they use to "crawl" or "walk" over surfaces (Figure 3.19H and 3.17E). Sessile ciliates are also capable of movement in response to stimuli. The attachment stalk of many peritrichs (e.g., *Vorticella*) contains contractile **myonemes**, fibrillar contractile elements in the cytoplasm, which serve to pull the cell body against the substratum. Similar myonemes are found in the cell walls of other ciliates (e.g., *Stentor*), and they are capable of contracting and extending the entire cell. Other ciliates (e.g., *Lacrymaria*) use sliding microtubules to contract.



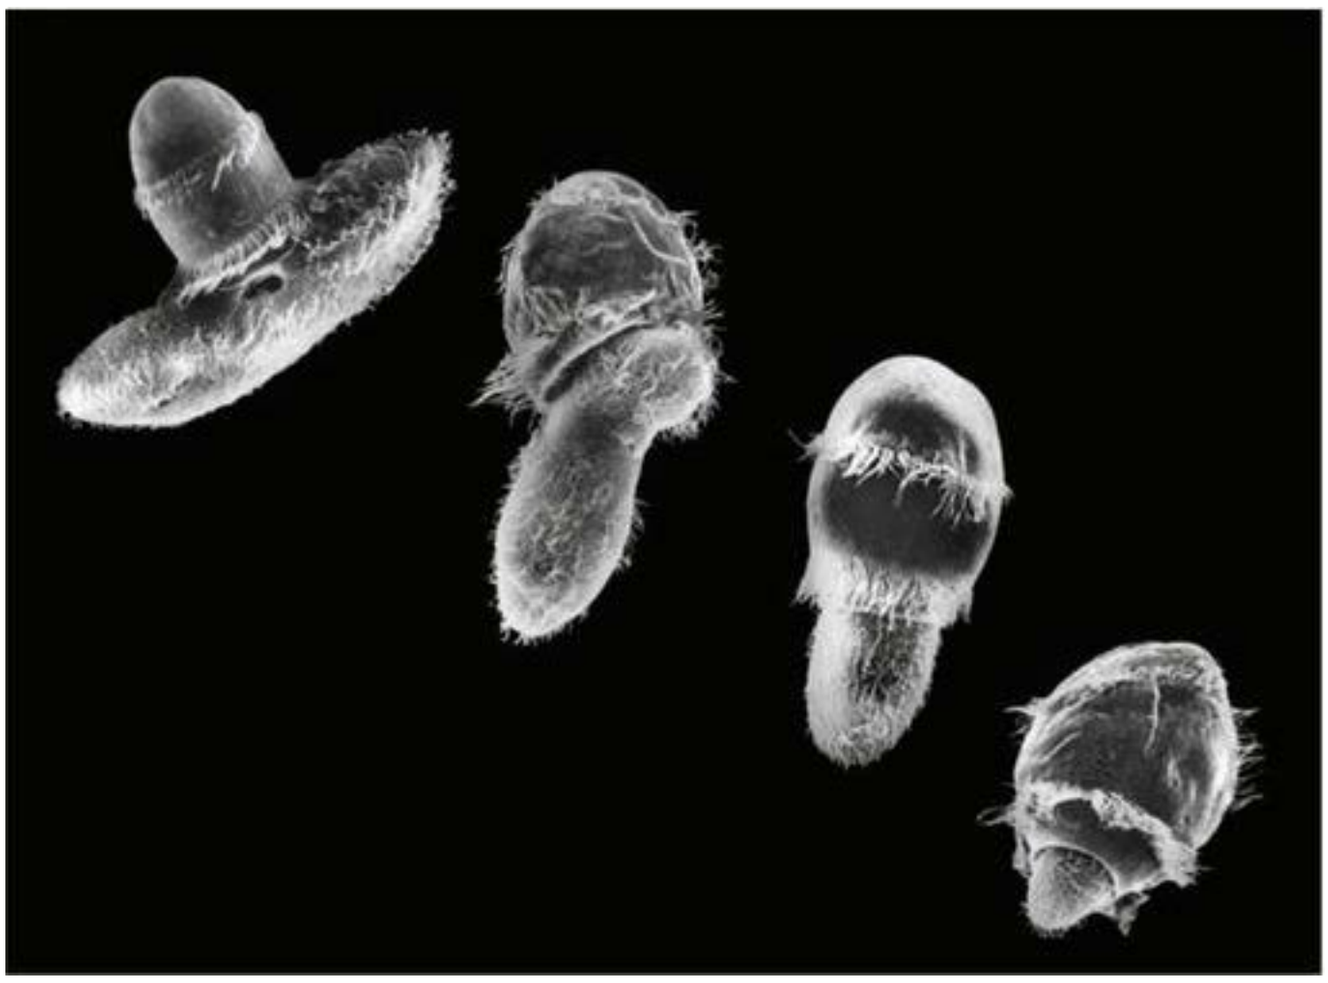


Figure 3.20 Phylum Ciliata. Formation of and digestion within a food vacuole in *Paramecium caudatum*. The sequence of digestive events may be followed by staining yeast cells with Congo red dye and allowing the stained cells to be ingested by the protist. The changes in color from red to red orange to bluegreen reflects the change to an acid condition within the food vacuole and thus the initial stage of the digestive process. The change back to red-orange occurs as the vacuole subsequently becomes more alkaline. The pattern of movement of the food vacuole (arrows) is typical of this organism or cell and is often termed cyclosis.

Nutrition

The ciliates include many different feeding types. Some are filter feeders, others capture and ingest other protists or small invertebrates, many eat algal filaments or diatoms, some graze on attached bacteria, and a few are saprophytic parasites. In almost all ciliates, feeding is restricted to a specialized oral area containing the cytostome, or "cell mouth." Food vacuoles are formed at the cytostome and then are circulated through the cytoplasm as digestion occurs (Figure 3.20). Because of the different ciliate feeding types, however, there are a variety of structures associated with, and modifications of, the cytostome

Holozoic ciliates that ingest relatively large food items usually possess a nonciliated tube, called the cytopharynx, which extends from the cytostome deep into the cytoplasm. The walls of the cytopharynx are often reinforced with stiff rods called nematodesmata, composed of microtubules. In a few forms, most notably *Didinium*, the cytopharynx is normally everted to form a projection that sticks to prey and then inverts back into the cell, thus pulling the prey into a food vacuole. In this way, *Didinium* can engulf its relatively gigantic prey, *Paramecium* and other ciliates (Figure 3.21A). Other ciliates, such as the hypostomes, have complex nematodesmal baskets in which microtubules work together to draw filaments of algae into the cytostome, reminiscent of the way a human sucks up a piece of spaghetti (Figure 3.21B). In most of these ciliates, the cilia around the mouth are relatively simple.

(A)

(B)

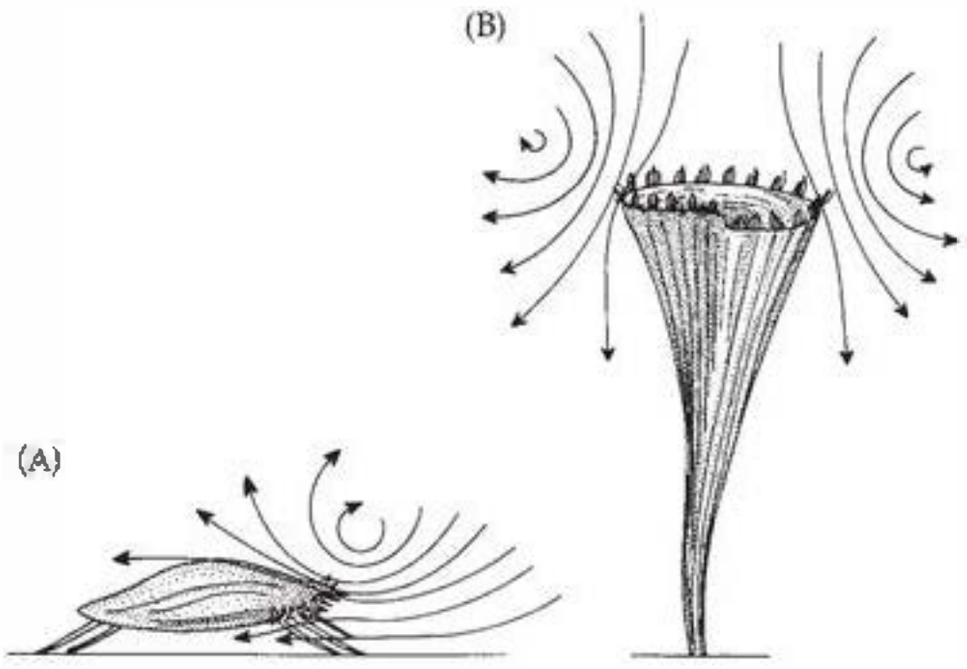

Figure 3.22 Phylum Ciliata. Feeding currents produced by two ciliates. (A) *Euplotes*. (B) *Stentor*. The ciliary currents bring suspended food to the cell, where it can be ingested.

Other ciliates, including many of the more familiar forms (e.g., *Stentor*) are suspension feeders (Figure 3.22). These often lack or have reduced cytopharynxes. Instead, they have elaborate specialized oral cilia for creating water currents, and filtering structures or scraping devices. Their cytostomes often sit in a depression on the cell surface, the buccal cavity. The size of the food eaten by such ciliates depends on the nature of the feeding current and, when present, the size of the depression. The oral ciliature often consists of compound ciliary organelles, called the **adoral zone of membranelles**, or simply the **AZM** (see Figure 3.17E,F) on one side of the cytostome, and a row of closely situated paired cilia which is frequently called the **paroral membrane** on the other side. Ciliates that feed like this include such common genera as *Euplotes*, *Stentor*, and *Vorticella*. Many hypotrichs (e.g., *Euplotes*) that move about the substratum with their oral region oriented ventrally use their specialized oral ciliature to swirl settled material into suspension and then into the buccal cavity for ingestion.

Among the most specialized ciliate feeding methods are those used by the suctorians, which lack cilia as adults and instead have knobbed feeding tentacles (Figure 3.23). A few suctorians have two types of tentacles, one form for food capture and another for ingestion. The swellings at the tips of the tentacles contain extrusomes called **haptocysts**, which are discharged upon contact with a potential prey. Portions of the haptocyst penetrate the victim and hold it to the tentacle. Sometimes prey are actually paralyzed after contact with haptocysts, presumably by enzymes released during discharge. Following attachment to the prey, a temporary tube forms within the tentacle, and the contents of the prey are sucked into the tentacle and incorporated into food vacuoles (Figure 3.23B–D).

In addition to haptocysts, several other types of extrusomes are present in ciliates. Some predatory ciliates have tubular extrusomes, called **toxicysts**, in the oral region of the cell (Figure 3.24A). During prey capture, the toxicysts are extruded and release their contents, which apparently include both paralytic and digestive enzymes. Active prey are first immobilized and then partially digested by the discharged chemicals; this partially digested food is later taken into food vacuoles. Some ciliates have extrusomes called **mucocysts** located just beneath the pellicle (Figure 3.24B). Mucocysts discharge mucus onto the surface of the cell as a protective coating; they may also play a role in cyst formation. Others have **trichocysts**, which contain nail-shaped structures that can be discharged through the pellicle. Most specialists suggest that these structures

are not used in prey capture, but serve a defensive function.

A number of ciliates are ecto- or endosymbionts associated with a variety of vertebrate and invertebrate hosts. In some cases these symbionts depend entirely upon their hosts for food. Some suctorians, for example, are true parasites, occasionally even living within the cytoplasm of other ciliates. A number of hypostome ciliates are ectoparasites on freshwater fishes and may cause significant damage to their hosts' gills. *Balantidium coli*, a large vestibuliferan ciliate, is common in pigs and occasionally is acquired by humans, where it can cause intestinal lesions. The rumen of ungulates contains whole communities of ciliates, including species that break down the grasses eaten by the host, bactivorous species, and even predators preying on the other ciliates. Members of the order Chonotrichida are mostly ectosymbiotic on crustaceans (and occasionally on whales). Chonotrichs are sessile, attaching to their hosts by a stalk produced from a special adhesive organelle. Other ciliates are symbiotic on a variety of hosts, including bivalve and cephalopod molluscs, polychaete worms, and perhaps mites.

Although plastids have not been definitely demonstrated in ciliates, several independent lineages in this group harbor photosynthetic symbionts that are intermittently replenished by feeding, especially planktonic forms (e.g., *Laboea*, *Mytridium*, *Strombidium*) that sequester photosynthetically functional plastids from ingested algae. The chloroplasts lie free in the cytoplasm, beneath the pellicle, where they actively contribute to the ciliate's carbon budget. This unusual practice has also been documented in foraminiferans. The cellular mechanisms by which the prey chloroplasts are removed, sequestered, and maintained are not known. Other ciliates maintain entire algal cells as endosymbionts. During the summer, in some areas, "photosynthetic ciliates" of one sort or the other can comprise a majority of the freshwater planktonic ciliate fauna. The common freshwater ciliate *Paramecium bursaria* typically harbors hundreds of symbiotic green algae (*Chlorella* sp.) in its cytoplasm, in a mutualistic relationship. The algal symbionts can be experimentally removed from the host, in which case growth rates decline (in the *Paramecium*). The host can regain its symbionts simply by ingesting them from the environment and incorporating them into its cytoplasm alive and well.

Reproduction

Ciliates are unique among the Eukaryota in possessing two different kinds of nuclei in each cell. The larger type—the macronucleus—controls the general operation of the cell. The macronucleus is usually hyperpolyploid (containing many sets of chromosomes) and may be compact, ribbon-like, beaded, or branched. The smaller type—the micronucleus—has a reproductive function, synthesizing the DNA associated with reproduction. It is usually diploid. In a process that is utterly unique among eukaryotes, the macronucleus is actually generated from the micronucleus by amplification of the genome (along with some heavy genetic editing). Division of the macronucleus occurs by "amitosis," the segregation of the chromosomes, by a process whose mechanism is not yet well known. This process is not perfect, and after about 200 generations the cell shows signs of aging. Thus periodically the macronuclei must be regenerated and this is accomplished during the process of conjugation (see below).

Asexual reproduction in ciliates is usually by binary fission, although multiple fission and budding are also known (Figure 3.25). Binary fission in ciliates is usually transverse. The micronucleus is the reservoir of genetic material in ciliates. As such, each micronucleus within the cell (even when there are many) forms an internal mitotic spindle during fission, thus distributing daughter micronuclei equally to the progeny of division. Macronuclear division is highly variable, although the nuclear envelope never seems to break down. The large, sometimes multiple, macronuclei usually condense into a single macronucleus which divides by constriction. Some macronuclei have internal

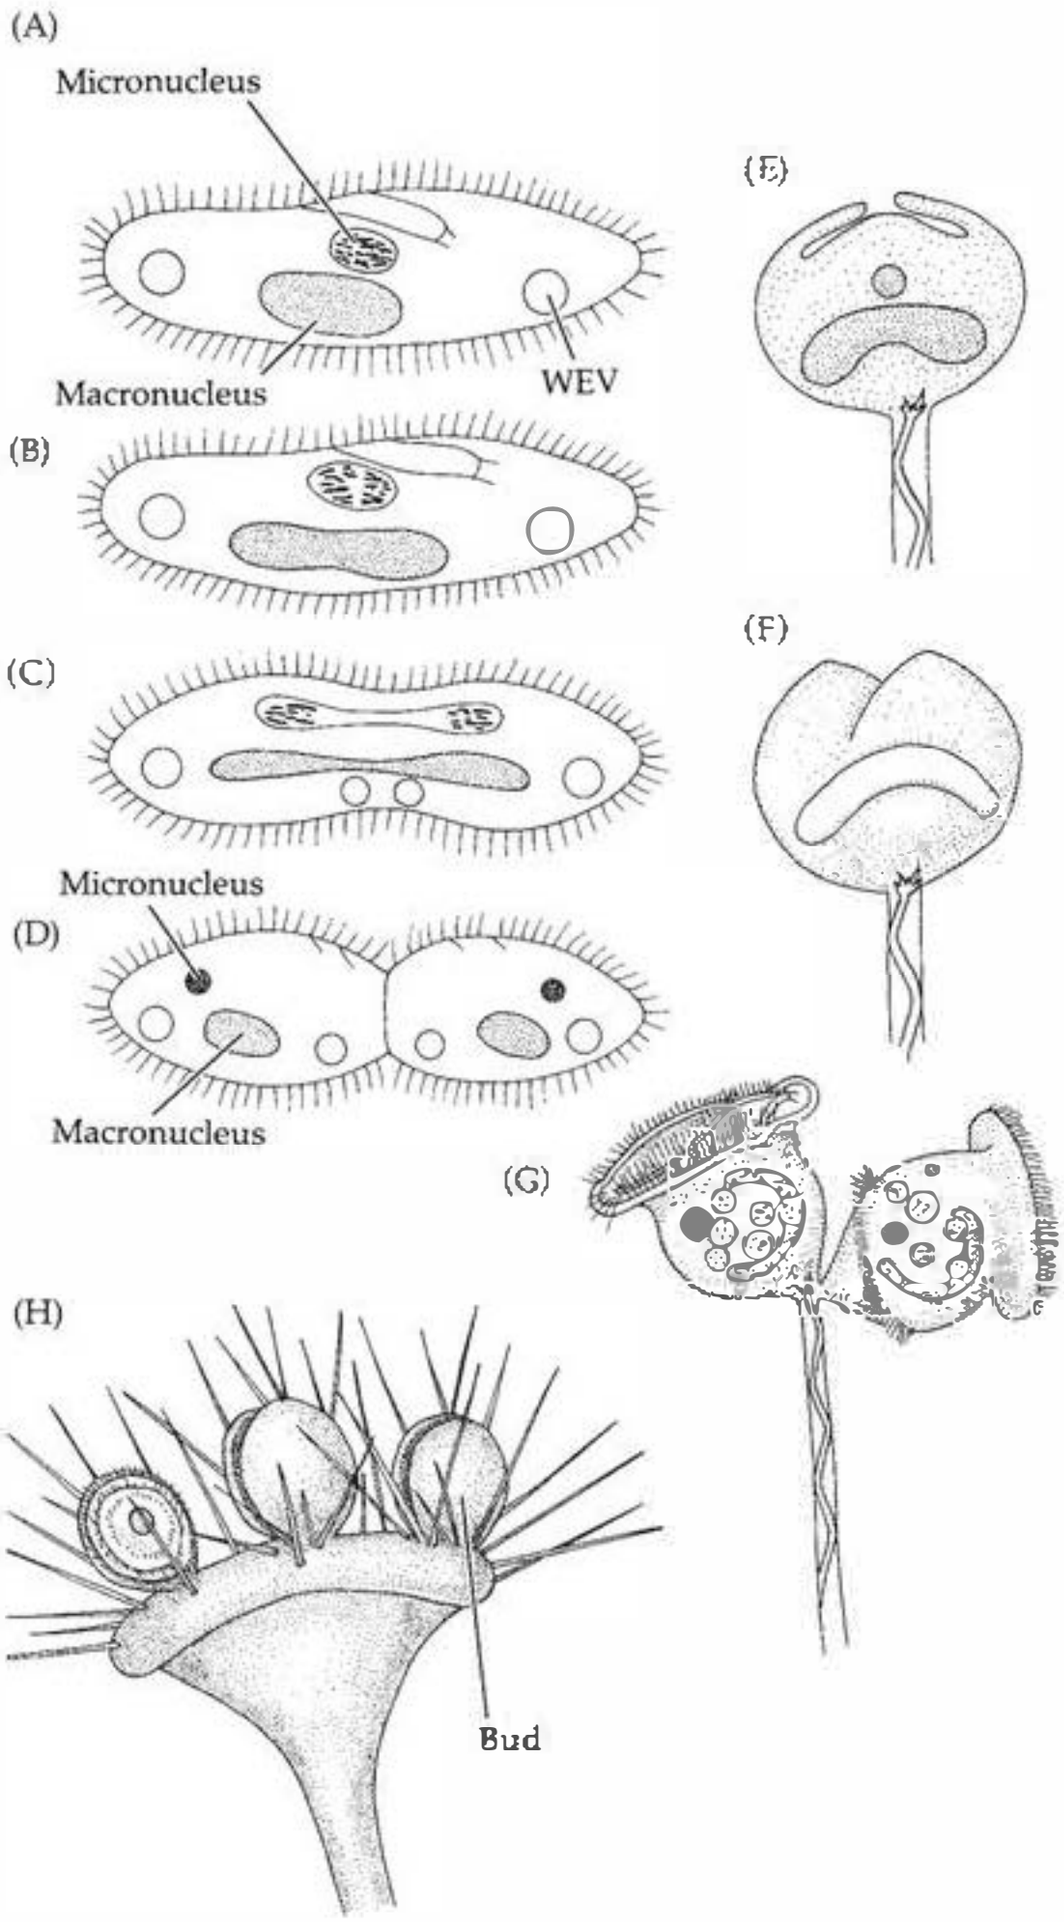

Figure 3.25 Phylum Ciliata. Asexual reproduction in ciliates. (A–D) Transverse binary fission in *Paramecium*; the micronucleus divides mitotically, whereas the macronucleus simply splits. (E–G) Binary fission in *Vorticella*. (H) Budding in the suctorian *Ephelota gigantea*.

microtubules that appear to push daughter nuclei apart, but there is never a clear, well-organized spindle. Since many ciliates are anatomically complex and frequently bear structures that are not centrally or symmetrically placed on the body (especially structures associated with the cytostome), a significant amount of reconstruction must occur following fission. Such reformation of parts or special ciliary fields does not take place haphazardly; it apparently is controlled, at least in part, by the macronucleus.

Binary fission is typical of the colonial and solitary peritrichs. In colonial species, the division is equal, with both daughter cells remaining attached to the growing colony, but in solitary species divisions may be unequal and may involve a swimming phase. A type of unequal division frequently referred to as budding occurs in a variety of sessile ciliates, including chonotrichs and suctorians. In these cases the ciliated bud is released as a so-called swarmer that swims about before adopting the adult morphology and lifestyle. In some cases, several buds are formed and released simultaneously.

True multiple fission is known in a few groups of ciliates and typically follows the production of a cyst by the prospective parent. Repeated divisions within the cyst produce numerous offspring, which are eventually released with breakdown of the cyst coating.

Sexual reproduction (or more precisely, genetic recombination) by ciliates is usually by conjugation, less commonly by autogamy. Conjugation is perhaps most easily understood by first describing it in *Paramecium*. As with any sexual process, the functional advantage of the activity is genetic mixing or recombination, and it is accomplished during conjugation by an exchange of micronuclear material. The following account (Figure 3.26) is of *Paramecium caudatum*—details vary in other species of the genus.

As paramecia move about and encounter one another, they recognize compatible "mates" (i.e., members of another clone). After making contact at their anterior ends, the "mates"—called conjugants—orient themselves side by side and attach to each other at their oral areas. In each conjugant, the micronucleus undergoes two divisions that are equivalent to meiosis and reduce the chromosome number to the haploid condition. Three of the daughter micronuclei in each conjugant disintegrate and are incorporated into the cytoplasm; the remaining haploid micronucleus in each cell divides once more by mitosis. The products of this postmeiotic micronuclear division are called **gametic nuclei**. One gametic nucleus in each conjugant remains in its "parent" conjugant while the other is transferred to the other conjugant via a cytoplasmic connection formed at the point of joining. Thus each conjugant sends a haploid micronucleus to the other, thereby accomplishing the exchange of genetic material. Each migratory gametic nucleus then fuses with the stationary micronucleus of the recipient, producing a diploid nucleus, or synkaryon, in each conjugant. This process is analogous to mutual cross-fertilization in metazoan invertebrates (e.g., land slugs).

Following nuclear exchange, the cells separate from each other and are now called **exconjugants**. The process is far from complete, however, for the new genetic combination must be incorporated into the macronucleus if it is to influence the organism's phenotype. This is accomplished as follows. The macronucleus of each exconjugant has disintegrated during the meiotic and exchange processes. The newly formed diploid

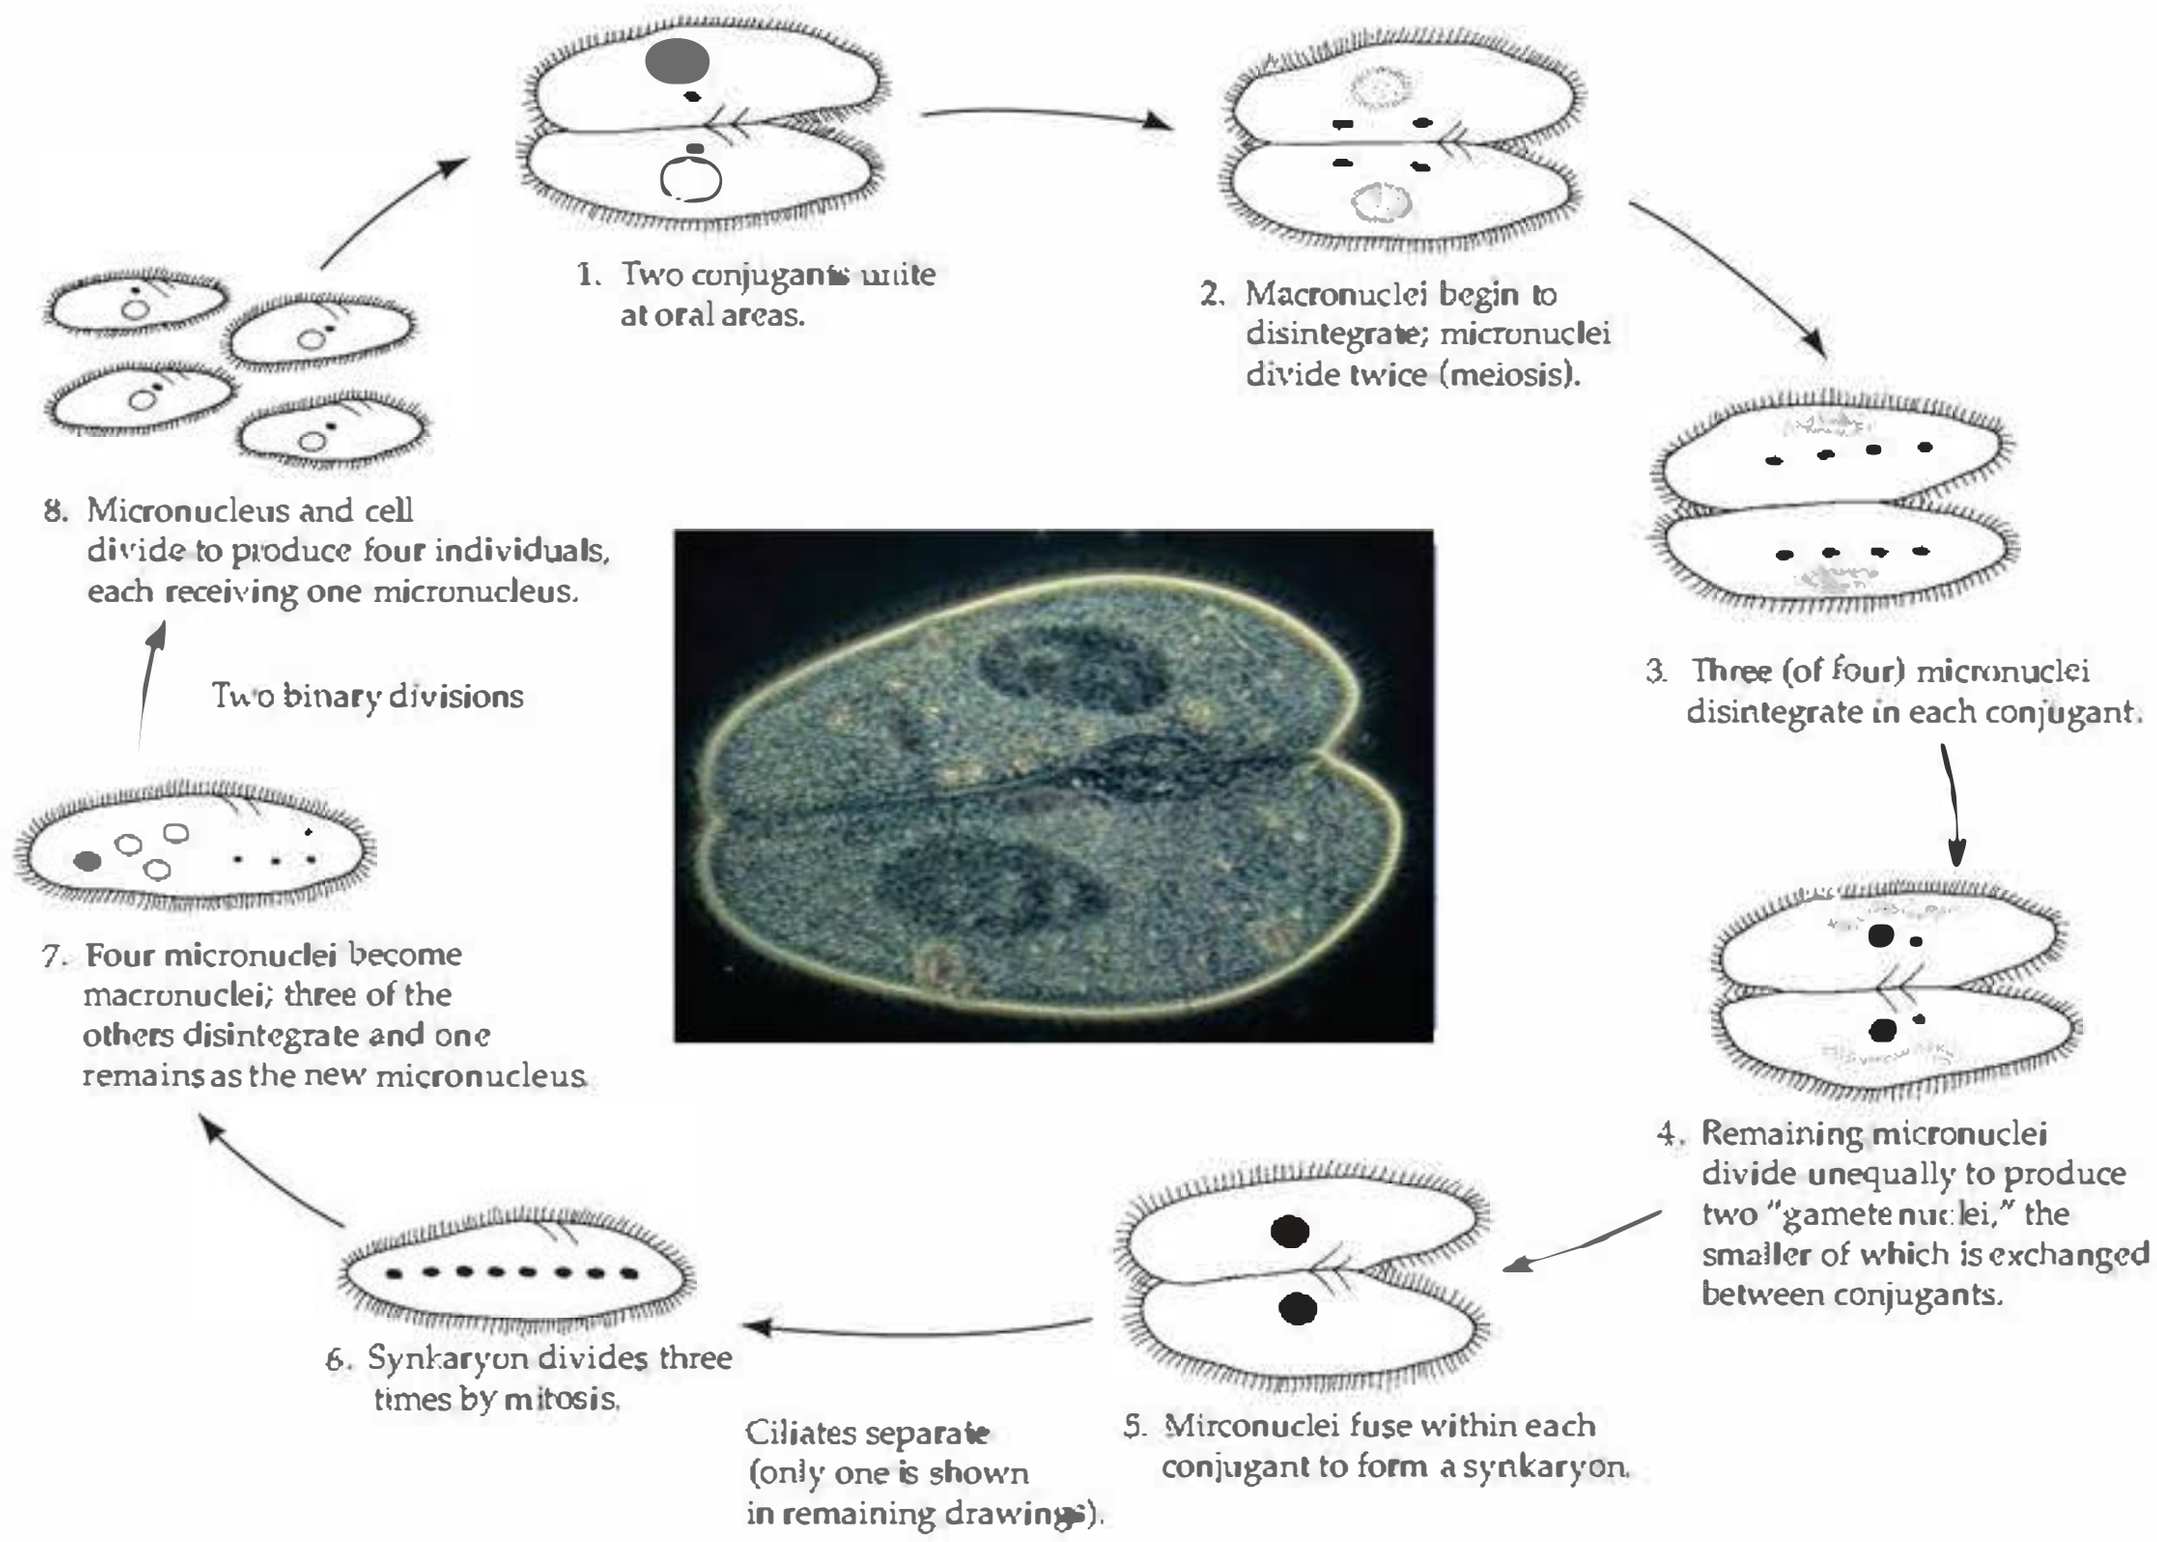

Figure 3.26 Phylum Ciliata. The photograph shows a pair of conjugating *Paramecium caudatum*.

synkaryon divides mitotically three times, producing eight small nuclei (all, remember, containing the combined genetic information from the two original conjugants). Four of the eight nuclei then enlarge to become macronuclei. Three of the remaining four small nuclei break down and are absorbed into the cytoplasm. Then the single remaining micronucleus divides twice mitotically as the entire organism undergoes two binary fissions to produce four daughter cells, each of which receives one of the four macronuclei and one micronucleus. Thus, the ultimate product of conjugation and the subsequent fissions is four new diploid daughter organisms from each original conjugant.

Variations on the sequence of events described above for *Paramecium* include differences in the number of divisions, which seem to be determined in part by the normal number of micronuclei present in the cell. Even when two or more micronuclei are present, they typically all undergo meiotic divisions. All but one disintegrate, however, and the remaining micronucleus divides again to produce the stationary and migratory gametic nuclei.

In most ciliates the members of the conjugating pair are indistinguishable from each other in terms of size, shape, and other morphological details. However, some species, especially in the Peritrichida, display distinct and predictable differences between the two conjugants, particularly in size. In such cases, the members of the mating pair are called the **microconjugant** and the **macroconjugant** (Figure 3.27). The formation of the microconjugant generally involves one or a series of unequal divisions, which may occur in a variety of ways. The critical difference between conjugation of similar mates and that of dissimilar mates is that in the latter case, there is often a one-way transfer of genetic material. The microconjugant alone contributes a haploid micronucleus to the macroconjugant; thus only the larger individual is "fertilized." Following this activity, the entire microconjugant usually is absorbed into the cytoplasm of the macroconjugant (Figure 3.27E). A similar process occurs in most chonotrichs. One conjugant appears to be swallowed into the cytostome of another, after which nuclear fusion and reorganization take place. There are several other modifications on this complex sexual process in ciliates, but all have the same fundamental result of introducing genetic variation into the populations.

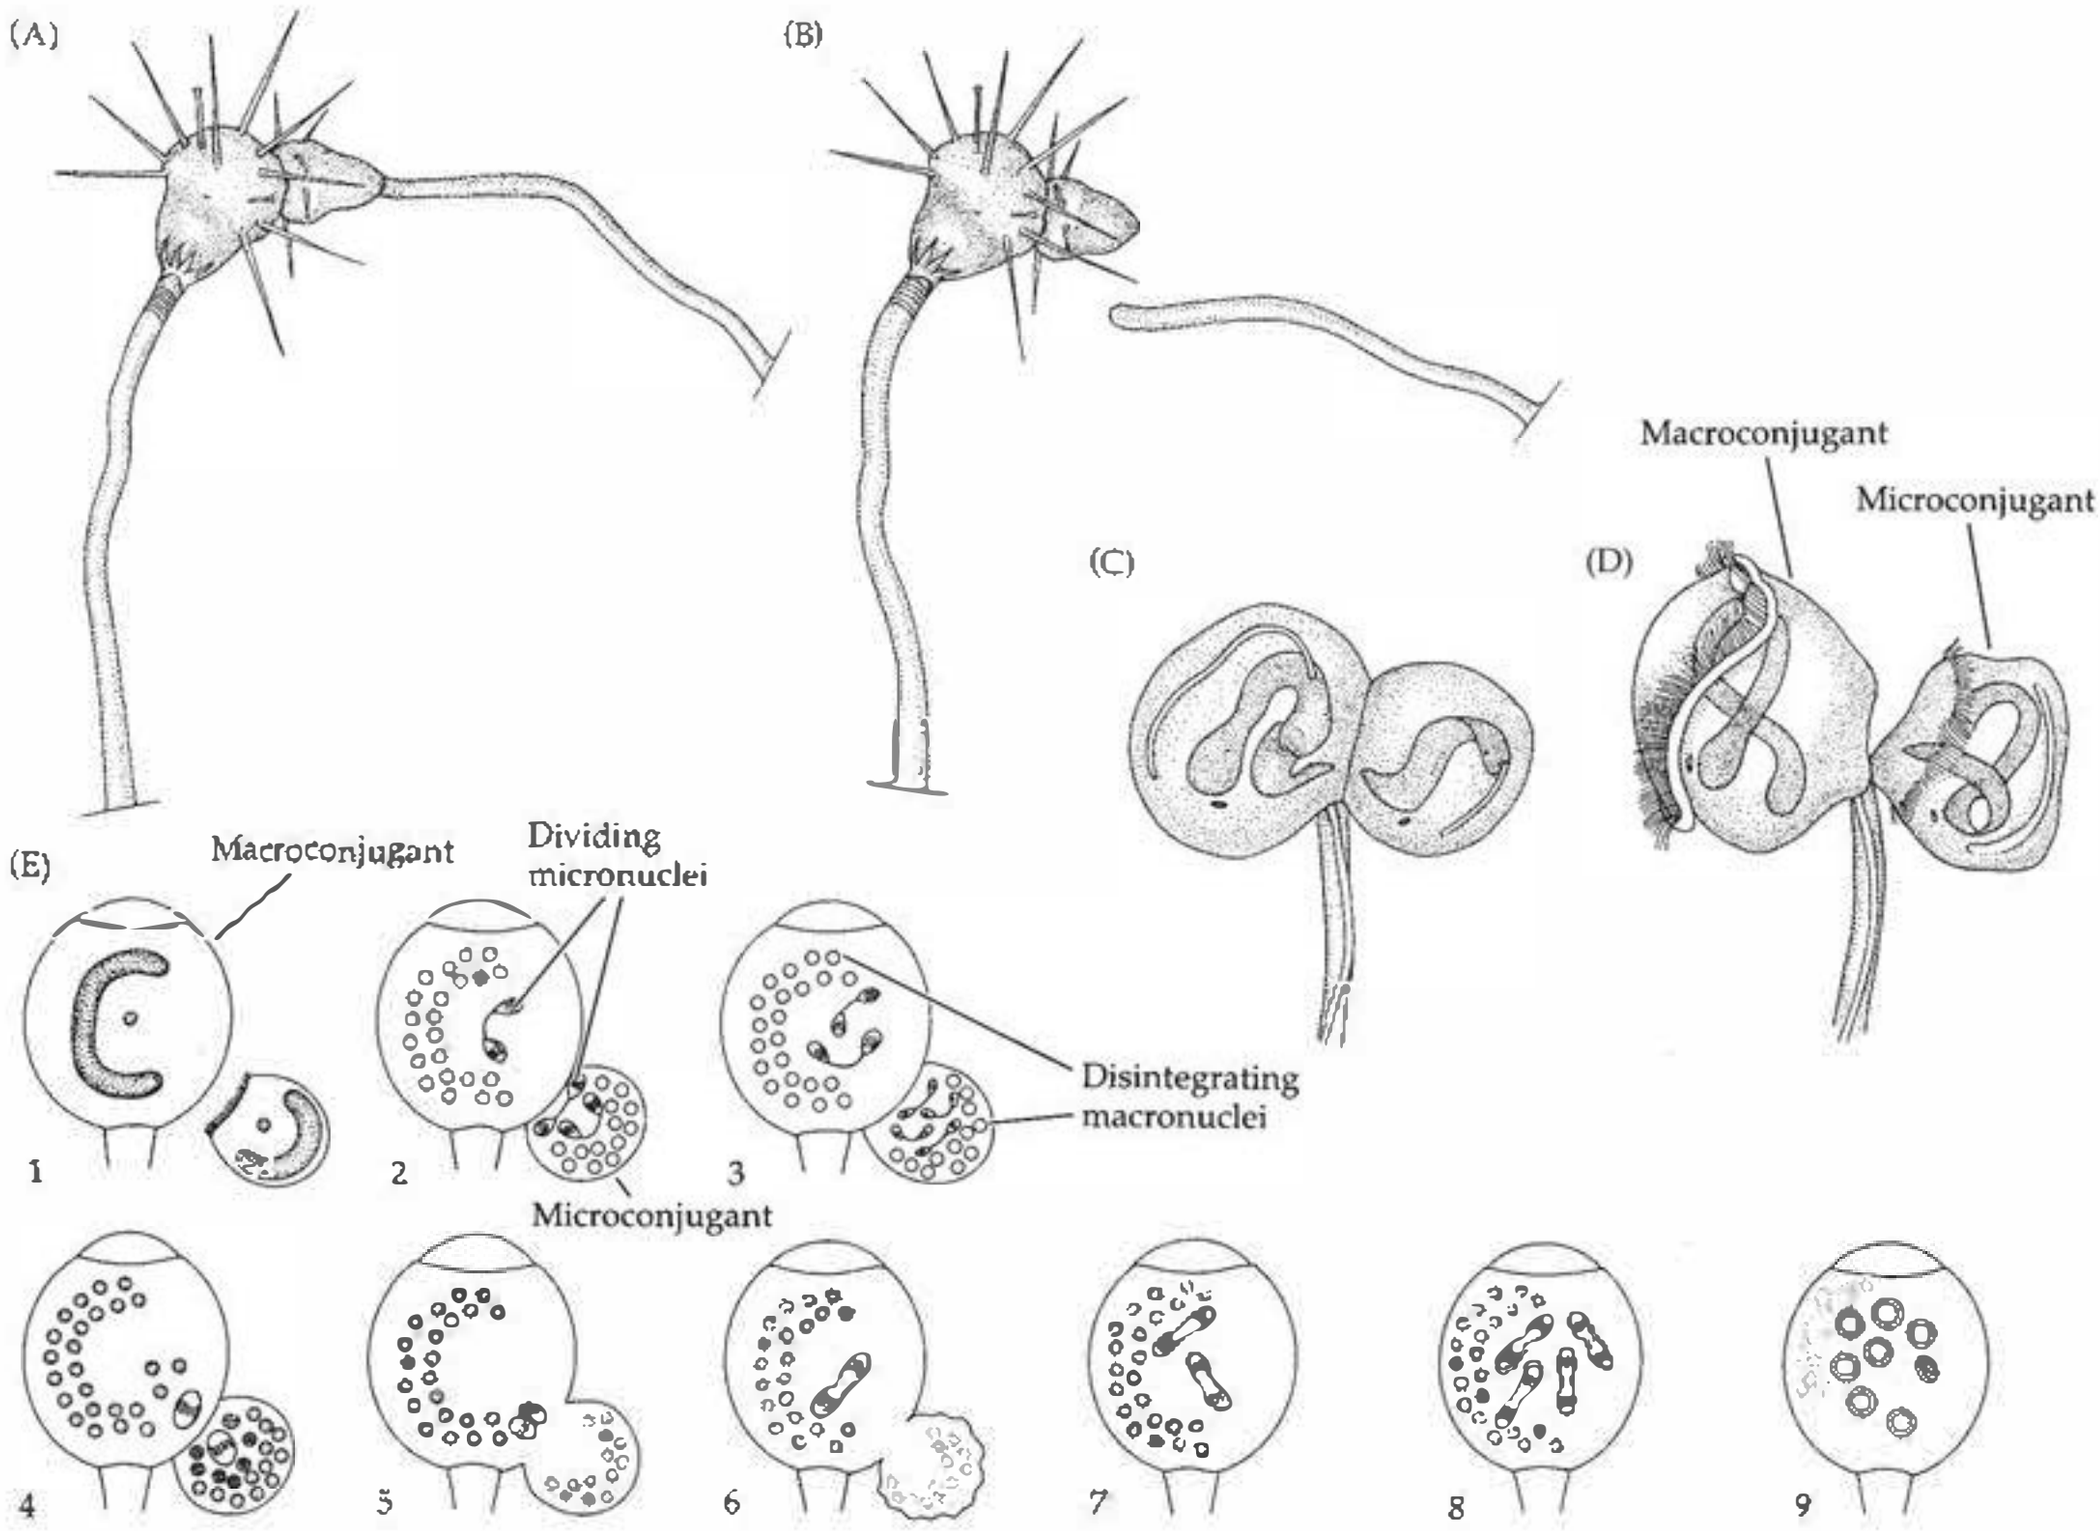

Figure 3.27 Phylum Ciliata. Sexual processes in ciliates. (A,B) *Ephelota gemmipara* (a suctorian); two mating partners of unequal sizes are attached to each other, apparently following chemical recognition. Both have undergone nuclear meiosis. The smaller mate detaches from its stalk and is absorbed by the larger one, then the gametic nuclei fuse. Subsequent nuclear divisions produce the multimicronuclear and macronuclear components of the normal individual. (C,D) Unequal divisions of *Vorticella campanula* result in macro- and microconjugants; conjugation follows. (E) Schematic diagrams of sexual activities in certain peritrichs. Unequal divisions result in macro- and microgamonts; the latter detach from their stalks and become free-swimming organisms; eventually the free-swimming microgamont attaches itself to a sessile macrogamont (1–2). The macronuclei begin to disintegrate (2) and ultimately disappear (9). The micronucleus of the macrogamont divides twice (2–3) and the micronucleus of the microgamont divides three times (2–3). All but one of the micronuclei in each gamont disintegrate, and the remaining micronucleus of the microgamont moves to fuse with the micronucleus of the macrogamont (4–5). As the zygotic nucleus (synkaryon) begins to divide, the microgamont is absorbed into the cytoplasm of the macrogamont. The synkaryon divides three times (6–8); one of the daughter nuclei becomes the micronucleus and the others eventually form the new macronucleus (9). It should be noted that the sequence of nuclear activities and numbers of divisions vary among different peritrichs.

One other aspect of conjugation that deserves mention is that of mating types. Individuals of the same genetic mating type (e.g., members of a clone produced by binary fission) cannot successfully conjugate with one another. In other words, conjugation is not a random event but can occur only between members of different mating types, or clones. This restriction presumably ensures good genetic mixing among individuals.

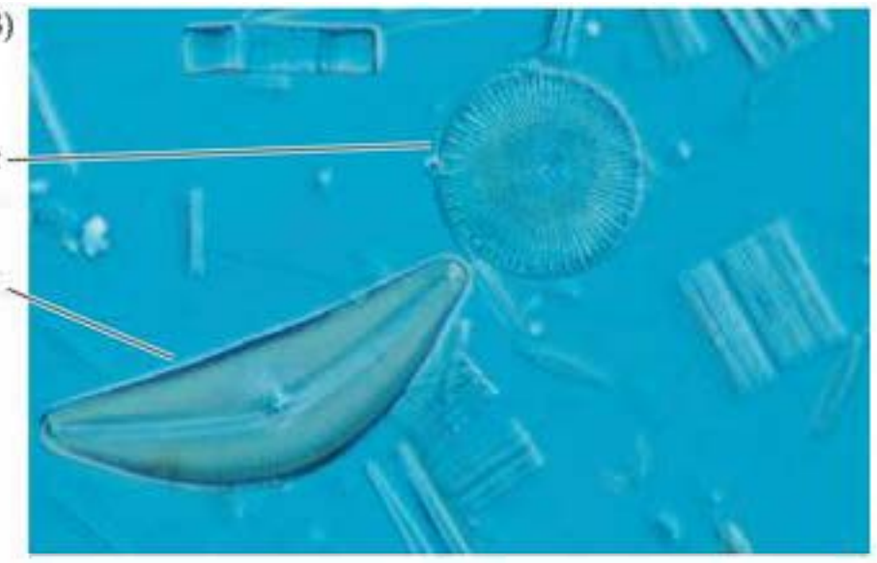
The second basic sexual process in ciliates is autogamy. Among ciliates in which it occurs (e.g., certain species of *Euplotes* and *Paramecium*), the nuclear phenomena are similar if not identical to those occurring in conjugation. However, only a single individual is involved. When the point is reached at which the cell contains two haploid micronuclei, these two nuclei fuse with one another, rather than one being transferred to a mate. Autogamy is known in relatively few ciliates, although it may actually be much more common than demonstrated thus far. Its significance in terms of genetic variation is not clear.

Phylum Stramenopila: Diatoms, Brown Algae, Golden Algae, Slime Nets, Oomycetes, etc.

The stramenopiles comprise a highly diverse taxon of some 9,000 species including diatoms, brown algae (Phaeophyta), golden algae (Chrysophytes, e.g., *Dinobryon*), some heterotrophic and parasitic flagellates, labyrinthulids (slime nets), oomycetes and hyphochytridiomycetes (the latter two groups formerly classified as fungi) (see Figures 3.28 and 3.1C,H,I) (Box 3I). Each of these groups has been placed in their own phylum in the past, but we herein follow the current convention of classifying them together in the phylum Stramenopila. A few stramenopiles, including brown seaweeds (Phaeophyta) such as the kelps are complex, differentiated organisms, and the Phaeophyta in particular may reach extremely large sizes. Brown algae are always multicellular, marine, photoautotrophs, and are predominantly marine. The largest brown algae, the kelps, may reach a hundred feet in length and resemble true plants. However, they have no vascular tissues (every cell fending for itself), the blades are not homologous to plant leaves, they do not undergo gastrulation nor produce tissues by way of embryological layering. The diversity of form in Stramenopila is staggering, and at first glance it may be difficult to imagine diatoms, kelp, and oomycete "fungi" being closely related. However, their relatedness is hypothesized on the basis that almost all have unique, complex, three-part tubular hairs on the flagella at some stage in the life cycle. The name Stramenopila (Latin *stamen*, "straw"; *pilus*, "hair") refers to the appearance of these hairs (Figure 3.29). Molecular phylogenetics also support this clade. While it might be tempting to think of some species in this clade (e.g., giant kelps) as multicellular in the sense of green plants, one key difference is that higher plants derive their adult tissues through a process of embryological tissue formation, similar though convergent to that seen in the Metazoa. Protists, including kelps, never have an embryogenic tissue-layering phase in their life history.

Stramenopiles are found in a variety of habitats, and most are very small (< 10 microns) biflagellated bacteriovores. Freshwater and marine plankton are rich in diatoms and chrysophytes, and these can also occur in moist soils, sea ice, snow, and glaciers. They have even been found alive in clouds in the atmosphere! Heterotrophic free-living stramenopiles are also found in marine, estuarine, and freshwater habitats. A few are symbiotic on other algae in marine or estuarine environments. Many produce calcite or silicon scales, shells, cysts, or tests, which are preserved in the fossil record. The oldest of these fossils are from the Cambrian/Precambrian boundary, about 550 million years ago.

BOX 3I Characteristics of the Phylum Stramenopila



1. A highly diverse group found in virtually every habitat on Earth.
2. Cell surrounded by plasma membrane, which may be supported by silica (silicon dioxide), calcium carbonate, or proteinaceous shells, scales, or tests
3. Almost all species with unique, complex, three-part tubular hairs on the flagella at some stage in life cycle. Most exhibit heterokont flagellation (i.e., with two flagella, one directed anteriorly, one directed posteriorly). Sometimes only the reproductive cells are flagellated and the trophic cells lack any obvious mode of locomotion. Opalinids are thought to have lost their flagellation and replaced it with rows of cilia (unlike those of the Ciliata).
4. Most are heterotrophic, but others are photosynthetic, saprophytic, or parasitic.
5. Photosynthetic forms have chlorophylls *a*, c_1, and c_2. Thylakoids in stacks of three; four membranes surrounding the chloroplast with the outermost membrane continuing around nucleus. Yellow and brown xanthophylls give them a brownish green color that has earned them the common name "golden algae."
6. Food reserves stored as liquid polysaccharide (usually aminarin) or oils
7. Mitochondria with short tubular cristae
8. With single vesicular nucleus
9. Nuclear division occurs by open peuromitosis without centrioles.
10. Asexual reproduction by binary fission
11. Sexual reproduction usually gametic; gametes usually sogametous (not the case for many diatoms and brown algae)

Diatoms (e.g., *Chaetoceros, Thalassiosira*) are key components of marine ecosystems and, along with dinoflagellates and coccolithophores, contribute greatly to oceanic primary productivity. In today's ocean, diatoms might be responsible for up to 40% of the net primary production (and upward of 50% of the organic carbon exported to oceanic ecosystems). When conditions are right, oceanic diatoms can multiply at astonishing rates, creating "blooms" that are sometimes toxic. It has been estimated that diatoms produce 19 billion tons of organic carbon annually (giving them a key roll in processing CO_2 into solid matter to mitigate climate warming). Recent estimates suggest diatoms alone account for up to 20% of global carbon fixation. Some species of diatoms can form extensive blooms. Because their shells (**frustules**) are composed of silica, they are also extremely important for the biogeochemical cycling of silicon.

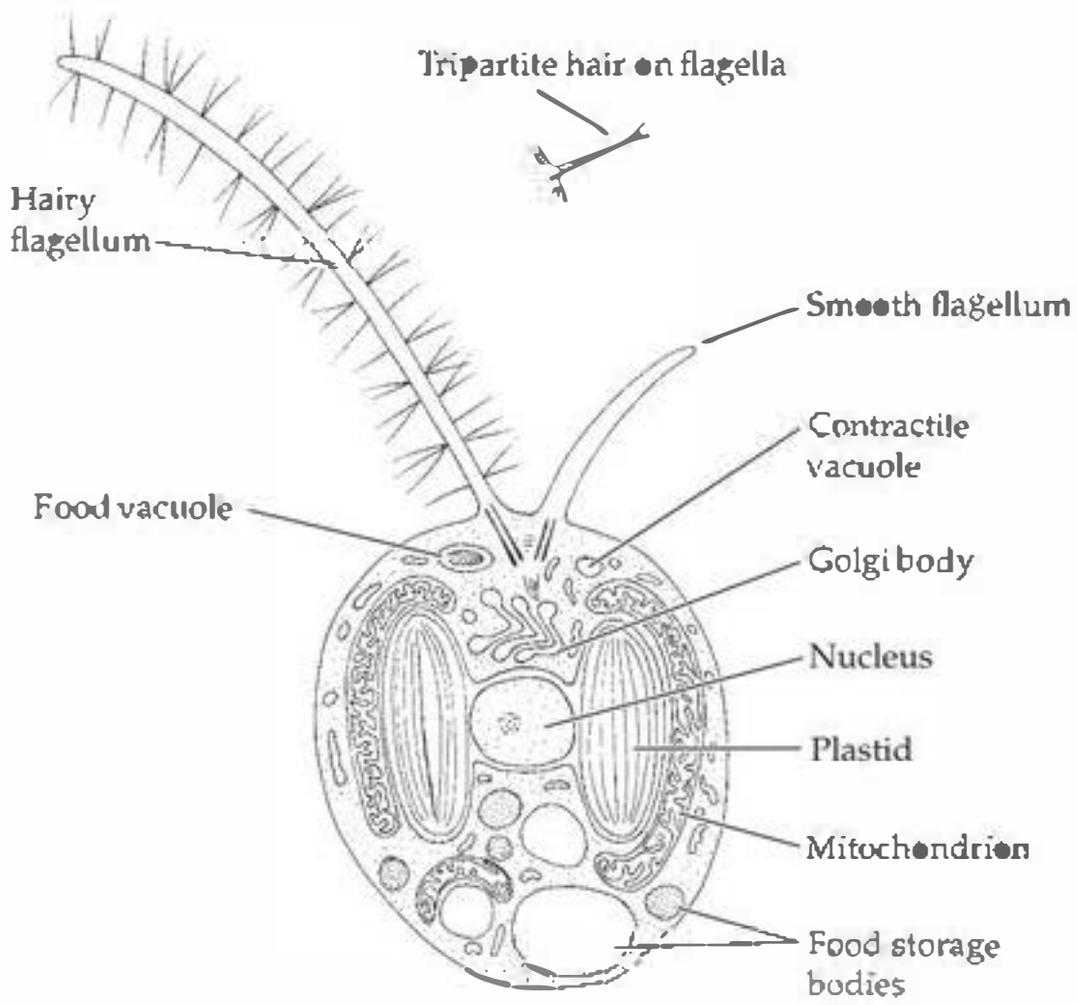

Figure 3.29 Phylum Stramenopila. Generalized anatomy (*Ochromonas*). Note the tripartite hairs on the flagellum.

A few marine diatoms produce toxins similar in potency to those seen in some dinoflagellates. Of particular concern are increasing occurrences of *Pseudonitzschia australis* blooms. In southern California, blooms of this diatom have caused deaths of sea lions, seabirds, fish and shellfish. Diatoms in the genus *Pseudonitzschia* produce **domoic acid** that accumulates in the food chain. In humans, domoic acid poisoning causes severe symptoms, including gastrointestinal disorders and memory loss (amnesic shellfish poisoning, or ASP), and it can be fatal. Cases of ASP have been reported with increasing frequency worldwide since its discovery late in the twentieth century.

The photosynthetic, freshwater diatom *Didymosphenia geminata*, native to cool oligotrophic waters of northern Asia, Europe and North America, has recently become an invasive species, both within its range and elsewhere in the world (e.g., New Zealand, Chile). Individuals attach to the bottom by a stalk, and colonies of the diatom can from thick brown mats in lakes and rivers that smother benthic communities and deplete bottom oxygen as they decompose. The flowing "tails" from these brownish mats look like tissue paper or cotton waving in the water, resulting in the common name of "rock snot." Massive blooms of this diatom have had a major negative impact on freshwater ecosystems since the mid-1980s. It isn't known why populations of this species have become invasive, although reduced stream flow is one important factor (the diatom cannot withstand rapid water flow).

Unlike dinoflagellates and coccolithophores, pelagic (mostly centric) diatoms have a large nutrient storage vacuole that occupies about 40% of the cell volume. This storage organelle allows diatoms to take advantage of short-term pulses of environmental nutrients, storing reserves for rapid reproduction or to survive periods of nutrient depletion. Their nutrient storage capacity also adapts diatoms for fluctuating environments. In addition, the vacuole in pelagic species aids in buoyancy due to its light osmolite content.

The siliceous cell walls (frustules) of diatoms do not preserve well in deep marine sediments because the silica dissolves. Although the earliest certain fossils are Mesozoic, molecular clock estimates suggest that they originated near the Permian-Triassic boundary. The fossil record indicates diatoms experienced two major bursts of radiation during the Cenozoic era, one at the Eocene/Oligocene boundary, and one through the middle and late Miocene. It has been suggested that the rise of diatoms in the Cenozoic stems from their unique, absolute requirement for a large supply of silica in the world's oceans. The theory suggests that the rise of land plants, especially grasses and the grazing ungulates that consume them, led to greatly increased removal of silica from soils and it's eventual transport to the sea, setting the stage for diatoms to radiate and flourish.

Brown seaweeds form an integral base to many coastal food webs, especially on temperate coasts. **Algin**, extracted from certain brown algae (kelp), is used as an emulsifier in everything from paint to baby food to cosmetics. This material has many industrial uses (e.g., in paint as a spreader; as filtration material in food production and water purification). Silicon deposits produced by diatoms and other stramenopiles are used in geology and limnology as markers of different stratigraphic layers of the Earth. Benthic deposits of the siliceous shells of dead marine diatoms can, over geologic time, result in massive uplifted land formations that are mined as diatomaceous earth.

Most Stramenopila are heterotrophic, but a few are serious parasites or agents of disease. Because some secrete fishy-smelling aldehydes, they may become a nuisance when they occur in great quantities, but stramenopiles only rarely cause fish kills or foul drinking water. However, the Oomyceta contain many plant parasites, including many that attack domestic crops. The devastating Irish (European, actually) potato blight disease and resulting famine of the nineteenth century was caused by an oomycete, *Phytophthora infestans*.

Chrysophytes, or "golden algae," are very common in fresh water; more than 1,000 species have been described. Most are photosynthetic, but some species are colorless and strictly heterotrophic. In fact, most of the autotrophic species will become facultatively heterotrophic in the absence of adequate light, or in

the presence of plentiful food. When this occurs, the chloroplasts (called chrysoplasts in this group) atrophy and the algae may turn into predators, feeding on bacteria or other protists, including diatoms. The photosynthetic species are important primary producers in lakes. Although most are unicellular, there are also filamentous and colonial forms In the well known *Dinobryon* (a freshwater genus), the individual cells are surrounded by vase-shaped loricae, composed of chitin fibrils and other polysaccharides. The colonies grow as branched or unbranched chains. Species of *Synura* form spherical colonies covered by silica scales. The oldest known Chrysophytes are from Cretaceous deposits, and the group has a fairly complete fossil record because of the siliceous resting cysts that freshwater species tend to form.

The enigmatic group Blastocystida includes *Blastocystis*, a highly prevalent, fecal-transmitted parasite that infects the gastrointestinal tract of humans and other animals, including many vertebrates and a few insects (e.g., cockroaches). Infection with *Blastocystis*, blastocystosis, causes abdominal pain, constipation and/or diarrhea. Most of the species found in mammals and birds are also able to cause infections in humans. These protists were first classified as yeasts, later as sporozoans, and then shown by molecular analyses to be stramenopiles

Support and Locomotion

Stramenopile support structures are highly varied. In addition to their cell membrane, many also possess shells, tests, and other support structures, resulting in many different shapes and appearances. Like most protists, they rarely have chitin in the cell wall (further distinguishing them from true fungi, or Eumycota, which rely heavily on chitin for support). Some chrysophytes produce small discs of calcite, protein, or even silicon in their cells. These are then packaged in endoplasmic reticulum vesicles and secreted onto the surface of the cell to form a layer of distinctive scales much the same mechanism seen in other scaly protists, including Haptophyta. In some stramenopiles, these can be quite elaborate and beautiful (Figure 3 30). The silicoflagellates have a distinctive internal skeleton of tubular pieces of silica associated with a central nucleus, and a complex lobed body that contains many chloroplasts

Diatoms also secrete silica in the form of an external test, or frustule, which consists of two parts, called valves. Beneath the test is the cell membrane, enclosing the nucleus, chloroplasts, and the rest of the cytoplasm. There are two different diatom forms: **centric diatoms** have radially symmetrical frustules, and since one valve is slightly larger than the other, they resemble a petri dish (Figures 3.30A and 3.28); **pennate diatoms** are bilaterally symmetrical and often have longitudinal grooves on the valves (Figure 3.30B).

Stramenopiles generally exhibit heterokont flagellation. That is, they possess two flagella, one directed anteriorly, the other usually extended posteriorly. The anteriorly directed flagellum has a bilateral array of tripartite, tubular hairs, while the posterior is either smooth or has a row of fine, filamentous hairs (see Figure 3.29). The tripartite, tubular hairs are stiff and reverse the direction of the thrust of the flagellum so that, even though the flagellum is beating in front of the cell, the cell is still drawn forward.

Labyrinthulids are commonly called "slime nets," and because of their unique lifestyle and locomotion, in the past they have been classified as a distinct phylum. However, because they can produce cells with two heterokont flagella they are now classified as Stramenopila. The nonflagellated stage of the labyrinthulid's life cycle forms complex organisms consisting of numerous spindle shaped bodies, each containing a nucleus, which glide rapidly within a common membrane bound ectoplasmic network. This network contains a calcium-dependent contractile system of actinlike proteins that is responsible for shuttling the cells through the net. The net spreads out over decaying material, or acts as a pathogen of living plants. They are associated in particular with marine and brackish habitats.

Nutrition

As you have no doubt already guessed, stramenopiles exhibit a wide variety of nutritional habits. Some are photosynthetic, others are ingesting heterotrophs, and still others are saprophytic. Those forms that are photosynthetic have: chlorophylls *a*, c_1, and c_2; thylakoids in stacks of three; and four membranes surrounding the chloroplast (as in haptophytes and cryptomonads, the outermost membrane is often continuous with the nuclear envelope) (see Figure 3.3). Yellow and brown accessory pigments (primarily xanthophylls such as fucoxanthin, but carotenoids are present as well) give many of them a brownishgreen color that has earned them the common name "golden algae." There is usually an eyespot associated with the region of the chloroplast near the basal bodies.

Many of the heterotrophic stramenopiles use the anteriorly directed flagellum with tripartite hairs to capture food particles, which are engulfed by small pseudopodia or a hoopshaped cytostome near the base of the flagella. Other heterotrophic forms feed saprophytically by excreting enzymes that digest food items outside the cell and then absorbing nutrients through small pores on the cell surface. This mode of nutrition is similar to that of true fungi (Eumycota), and it is the reason that the labyrinthulids, oomycetes ("water molds"), and hyphochytridiomycetes were once classified as fungi. However, the presence of a heterokont flagella stage in these organisms makes it clear that they are stramenopiles. The oomycetes produce hyphae that absorb nutrients much like fungi, and are mostly coenocytic. Included among the oomycetes are the water molds, white rusts, and downy mildews.

Reproduction

Mitosis in most stramenopiles is characterized as open pleuromitosis. During division, the basal bodies of the two flagella separate and a spindle forms adjacent to them or adjacent to the striated root at the base of each. In those forms with scales, the scaly armor appears to be added to the surface of the daughter cells as division proceeds. In diatoms, each daughter cell gets one of the silica valves and makes a new second valve to complete the frustule.

Sexual reproduction is poorly studied in most forms but appears to almost always occur by the production of haploid gametes, which fuse to form a zygote. In many, the gametes are undifferentiated, but in a few (such as diatoms), one of the gametes is flagellated and motile, and the other is stationary. Many of the brown algae (Phaeophyta) have alternation of generations.

The opalinids, once classified as "protociliates," then as zooflagellates, then as a separate phylum of uncertain relationship, is included here in the Stramenopila based primarily on analyses of DNA sequence data. Their numerous oblique rows of cilia clearly differ from the rows in ciliates in that they lack the kinetidal system. During asexual reproduction, the fission plane parallels the oblique ciliary rows; thus it is longitudinal (as it is in flagellates) rather than transverse (as it is in ciliates). Some opalinids are binucleate, others multinucleate, but all are homokaryotic (i.e., the nuclei are all identical). There are about 150 species of opalinids, in several genera, almost all being endosymbiotic in the hindgut of anurans (frogs and toads) where they ingest dissolved material anywhere on their body surface. Sexual reproduction is by syngamy and asexual reproduction is by binary fission and plasmotomy, the latter involving cytoplasmic divisions that produce multinucleate offspring *Opalina* and *Protopalina* are two genera commonly encountered (Figure 3 31). Opalinids are often found in routine dissections of frogs in the classroom; their large size and graceful movements through the frog's rectum make them a pleasant discovery for students.

Phylum Haptophyta: Coccolithophores

Haptophyta (also known as Prymnesiophyta) comprise a group of single-celled, phytoplanktonic protists most of which are known as coccolithophores (or coccolithophorids) (Figure 3.32). Haptophytes are distinguished by their possession of two normal flagella plus a third flagellum-like, or peglike structure called a

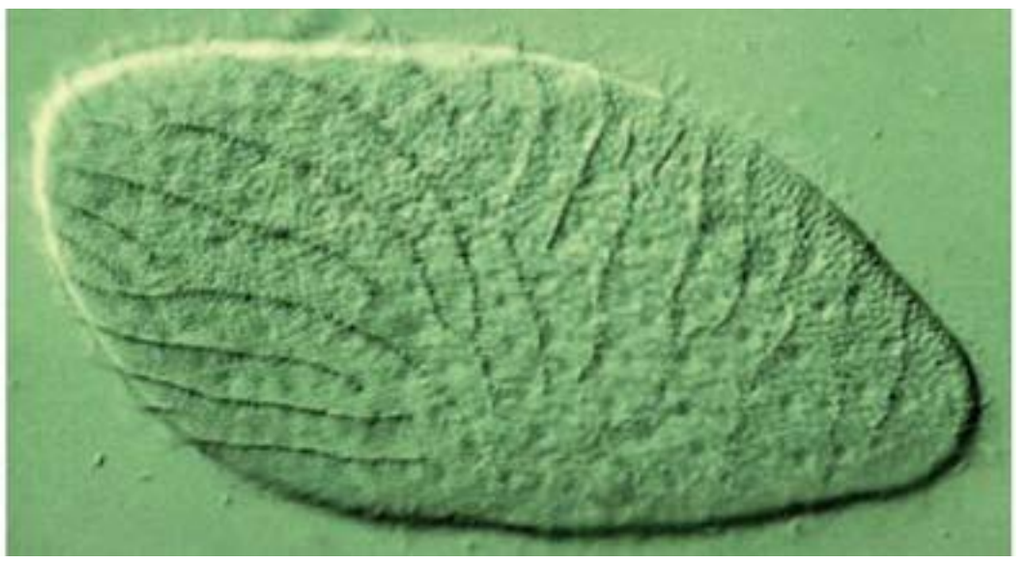

Figure 3.31 The enigmatic *Opalina*, once classified in its own phylum, now generally regarded as a member of the phylum Stramenopila.

haptonema. The haptonema is generally coiled, and it differs from the flagella proper in its internal structure, basal attachment, and function. During the nonmotile phase of the life cycle, the flagella disappear, but the haptonema often remains. Its primary function is not entirely clear and may vary from species to species. It is used as a food collection device in at least some species, but otherwise it appears to have attachment and/or mechanosensory functions. The cell itself contains a nucleus and two golden brown chloroplasts that carry the yellow-brown accessory pigments diadinoxanthin and fucoxanthin The cells are usually covered by scales, either small scales made of carbohydrate, or, in the case of some or all life stages of coccolithophores, small or large scales--coccoliths--composed predominantly of calcium carbonate (see below). Some may have siliceous scales. The scales show a broad variety and complexity of shape—they can resemble buckets, donuts, muffins, pentagons, or even be trumpetlike (Box 3J).

Although almost exclusively marine, there are a few reported freshwater and "terrestrial" species. Coccolithophores live in huge numbers throughout the photic zone of the world's oceans, and they are one of the main primary producers in this environment. One of the most abundant species in the world's oceans is *Emiliania huxleyi* (Figure 3.32). The secreted plates, or coccoliths, are held in place on the surface of the cell by an organic coating, the coccosphere. The coccoliths are usually composed of calcium carbonate ($CaCO_3$), but unmineralized (carbohydrate compounds) and even siliceous plates are also known from a few species. The function of the coccosphere is presumably either protection or buoyancy. A single coccolithophore will be covered by 10 to over 100 coccoliths, and these vary wildly in shape between species. As might be expected, coccoliths play a central role in haptophyte taxonomy.

It is estimated that coccolithophores produce several million tons of calcite annually. Most of this ends up on the sea floor as calcareous ooze that eventually contributes to the Earth's sedimentary record. In fact, these "calcareous nannofossils" (generally less than 30 μm in diameter) have become the preferred tool for quick accurate stratigraphic age determination in post Paleozoic calcareous sequences. The earliest uncontested calcareous nannofossils are from the Late Triassic, thought to correspond to the

Figure 3.32 Phylum Haptophyta Colorized SEM of the coccolithophore *Emiliania huxleyi*.

BOX 3J Characteristics of the Phylum Haptophyta

1. A small group of phytoplanktonic protists, almost exclusively marine, most of which are known as coccolithophores
2. Distinguished by two normal flagella, plus a third flagellum-like, or peglike haptonema. The haptonema is usually coiled and differs completely from the true flagella.
3. With two golden-brown chloroplasts that have diadinoxanthin and fucoxanthin accessory pigments
4. Cells usually covered by scales (coccoliths) composed of carbohydrates, calcium carbonate, or silicon
5. Reproduction is poorly understood for this group, but evidence suggests that both asexual and sexual methods occur.

first time open-ocean planktonic organisms utilized calcareous skeletons and exported calcium carbonate to the deep oceans. Fossilizable Haptophytes reached their greatest abundance in the Late Cretaceous, experiencing a mass extinction at the end of the Cretaceous (two-thirds of the ~50 known genera disappeared). Many new groups appear in the Paleocene fossil record. Exposed ancient calcareous coccolithophore sediments are recognized as limestone, or "chalk," mostly Mesozoic in age. The White Cliffs of Dover (England) is one of the more well known coccolithophore formed limestone exposures

The life history of coccolithophores is only partly understood, but the existence of both haploid and diploid phases is inferred by DNA studies, with mitotic reproduction occurring in both stages. In at least some species, such as *Emiliania huxleyi*, the coccosphere-bearing phase is diploid and capable of asexual reproduction, allowing for rapid population growth during periods of optimum conditions when "coccolithophore blooms" may occur. Some of these blooms, especially those of *Emiliania huxleyi*, have been measured at densities of 1.5 million cells per liter! Motile naked haploid gametes may be produced by meiosis, and nonmotile benthic stages also are known to be produced. Syngamy has not been observed but is assumed to occur. Both single and double fission occur, sometimes accompanied by a swarm spore stage. Large blooms can be problematic because of the mucilage surrounding the cells that can clog fish gills or render them permeable to dissolved toxins.

Phylum Cryptomonada: Cryptomonads

Cryptomonads include several genera of photosynthetic, and sometimes heterotrophic flagellates that occur in marine and freshwater habitats. One heterotrophic form, previously called *Chilomonas* but now classified in *Cryptomonas*, is a commonly used research tool in biological laboratories. Cryptomonads are biflagellated cells with a large flagellar pocket, a semirigid cell surface supported by proteinaceous plates (called the **periplast**), and a single large mitochondrion with cristae that appear to be flattened tubes. The plastids of cryptomonads are surrounded by four membranes and contain chlorophylls *a* and *c*. As with chlorarachniophytes, the plastid of cryptomonads includes a small pocket of cytoplasm between the inner and outer pair of membranes, and also contains ribosomes and a **nucleomorph**—the highly reduced nucleus of the eukaryotic, photosynthetic endosymbiont that became the plastid (Figure 3.33). Unlike chlorarachniophytes, however, the cryptomonad plastid is of red algal origin (rather than green algal origin), and starch is synthesized and stored within the plastid's cytoplasmic compartment. Thus cryptomonads and chlorarachniophytes stem from two independent and unrelated endosymbiotic events. The nucleomorph of cryptomonads consists of three small chromosomes that primarily encode only those genes necessary for the maintenance of the nucleomorph itself. This "enslaved" and reduced algal nucleus now encodes only around 20 of the proteins necessary for the maintenance of the plastid, and extensive lateral gene transfer has moved most of the essential algal genes to the host nucleus. The cryptomonad "model organism" *Bigelowiella natans* has a nucleomorph genome of only 373,000 base pairs, one of the smallest eukaryotic genomes known (Box 3K).

Figure 3.33 Phylum Cryptomonada. *Cryptomonas*.

BOX 3K Characteristics of the Phylum Cryptomonada

1. A small group of primarily photosynthetic flagellates that occurs in marine and freshwater habitats
2. Cells biflagellate; with semirigid cell surface supported by proteinaceous plates (the periplast)
3. Single large mitochondrion with cristae that appear as flattened tubes
4. Plastids surrounded by four membranes that contain chlorophylls *a* and *c*. Plastid has small pocket of cytoplasm between inner and outer pair of membranes, and also contains ribosomes and a nucleomorph (the nucleomorph is a highly reduced nucleus of the red alga symbiont that became the plastid).
5. Starch is synthesized and stored within the plastid's cytoplasmic compartment.

Figure 3.34 Two rare rhizarian phyla, Chlorarachniophyta (A) and Haplosporidia (B). (A) *Chlorarachnion reptans*; the green algal endosymbionts are visible within the cell, each retaining its own nucleus. (B) *Haplosporidium nelsoni*, the causative disease agent in MSX, in the Pacific oyster (*Crassostrea gigas*). The vascular spaces between the digestive gland tubules contain numerous hemocytes, or blood cells, elevated in number as a response to the infection. Note the extensive sporulation within the epithelial cells of the digestive gland tubules, as well as multinucleate plasmodial stages and hemocyte infiltration within the vascular spaces of the digestive gland. Host nuclei are dark purple/blue, cytoplasm and cell membranes are pink. H: hemocytes; S: sporulation/spores; P: plasmodia stages. (5 μm-section stained with haematoxylin and eosin)

BOX 3L Characteristics of the Phylum Chlorarachniophyta

1. A small group of uncommon protists in tropical and subtropical seas
2. Normally small, unicellular, and ameboid with branching cytoplasmic extensions (pseudopodia) that sometimes connect several cells together in netlike fashion
3. Some form uniflagellated zoospores, and coccoid cells (thought to be cysts).
4. Mixotrophic, feeding on bacteria and other protists, or photosynthesizing with green chloroplasts containing chlorophylls *a* and *b* (and a prominent projecting pyrenoid). Chloroplasts with four envelope membranes and a prominent pyrenoid (food storage structure)
5. With nucleomorph (reduced nucleus of the endosymbiotic green algal cell that became the chloroplast) present in space between second and third envelope membranes of each chloroplast
6. Thylakoids often loosely stacked in threes
7. Mitochondrial cristae tubular
8. Asexual reproduction by normal mitotic cell division or zoospore formation. Sexual reproduction apparently rare, but both anisogamy and isogamy have been reported

GROUP 3: RHIZARIA

Phylum Chlorarachniophyta: Chlorarachniophyte Algae

The Chlorarachniophyta (or Chlorarachniophytes) comprise a recently recognized, small, and fascinating group of single-celled algae that have become a major focus of evolutionary biologists (Figure 3.34A). They occur, apparently with rarity, in tropical and subtropical seas. The species are typically mixotrophic, ingesting bacteria and smaller protists as well as conducting photosynthesis. They have green chloroplasts but have a cell structure completely different from that of green algae (phylum Chlorophyta). Normally they have the form of small amebas, with branching cytoplasmic extensions (reticulopods) that capture prey and sometimes connect several cells together in a netlike fashion. They may also form flagellated zoospores, which characteristically have a single subapical flagellum that spirals backwards around the cell body. Some species also form walled coccoid cells (thought to be cysts) (Box 3L).

Chlorarachniophytes are distinguished by the following characteristics: always unicellular, although cells may anastomose their pseudopodia to form "nets"; photosynthetic, with green chloroplasts, with four envelope membranes, and that contain chlorophylls *a* and *b* and a prominent projecting pyrenoid[7]; nucleomorph present in space between the second and third envelope membranes of each chloroplast; thylakoids often loosely stacked in threes; mitochondrial

[7]Pyrenoids are protein-rich structures found inside some types of chloroplasts. They are thought to function in the carbon concentration/carbon fixation portions of photosynthesis, and are often closely associated with accumulations of storage materials, such as starch.

cristae tubular, fundamentally amoeboid cells with long, thin (filose) pseudopodia. Species that have coccoid stages in their life history have been found from coastal areas, while those with flagellated stages (zoospores) tend to occur in oceanic waters (as picoplankton). The patterns of the life cycle vary among species Coccoid cells tend to be regarded as cysts. Asexual reproduction is carried out by either normal mitotic cell division or zoospore formation. Sexual reproduction has been reported from two species: *Chlorarachnion reptans* and *Cryptochlora perforans*. In the former, two different types of cells, amoeboid and coccoid, fuse to form a zygote (anisogamy), while in *C. perforans* the fusion occurs between two amoeboid cells (isogamy).

The chlorarachniophytes are one of several protist groups that acquired their chloroplasts via secondary endosymbiosis, in which a nonphotosynthetic eukaryote engulfed a eukaryotic alga and coopted it as a symbiont, which over evolutionary time was reduced to a photosynthetic organelle. In at least two cases of secondary endosymbiosis, Chlorarachniophyta and Cryptomonada, nuclear material (and a small amount of cytoplasm) has been retained from the assimilated photosynthetic endosymbiont (a green and a red alga, respectively), along with the plastid to the present day by the "host" lineage. In both of these phyla the symbiont's nuclei are greatly reduced and termed nucleomorphs. The nucleomorphs, and particularly the genes they contain, have been a key to understanding the phenomenon of secondary endosymbiosis.

The nucleomorph in chlorarachniophytes is the vestigial nucleus of the eukaryotic green algal endosymbiont that gave rise to the chloroplast itself In the one species studied to date, the nucleomorph genome is just 380 kb—one of the smallest eukaryotic genomes known. The genome consists of three linear chromosomes that encode about 300 genes arranged in a highly compacted manner. Genes encoded by the nucleomorph genome are mostly "housekeeping genes," genes for maintaining its own replication and expression systems. Only a few chloroplast targeted proteins are encoded by the nucleomorph, suggesting that the majority of nuclear-encoded chloroplast genes have been co-opted by the host's nuclear genome.

Like other DNA containing organelles, the nucleomorph is semiautonomous. Nucleomorph division takes place just before chloroplast division by the sequential infolding of the inner and outer membranes of the nucleomorph envelope. No spindle formation has been observed during the division. How the chromosomes are correctly segregated into two daughter nucleomorphs is not clear.

Despite the striking similarity in structure and genome organization between the chlorarachniophytes and the cryptomonads, their origins are clearly different. Cryptomonad nucleomorphs originated from a red algal endosymbiont, whereas the chlorarachniophytes nucleomorphs came from a green algal endosymbiont. Nucleomorphs are thus an excellent example of convergent evolution through endosymbiosis (see phylogeny section below). Molecular phylogenetic studies suggest that the "host" clade of Chlorarachniophyta is monophyletic, and that its ancestry lies in a heterotrophic protist that we would place within the clade Cercozoa.

Phylum Granuloreticulosa: Foraminiferans and Their Kin

The phylum Granuloreticulosa contains about 40,000 described living and fossil species (Box 3M). Members of this phylum are nearly ubiquitous in all aquatic habitats from the poles to the equator, and at all depths in the world's oceans The phylum consists of two major groups: the Athalamida and Foraminifera (including the monothalamids). Athalamids are found in fresh water, soil, and marine environments and are distinguished from the forams in that they lack a test and the pseudopodia can emerge any place on the body.

The Foraminifera (e.g., *Globigerina*), also called Foraminiferida or forams, are the most common and well-known members of the Granuloreticulosa (Figures 3 35 and 3.36; see also Figure 3.1J). They are

BOX 3M Characteristics of the Phylum Granuloreticulosa

1. Common protists, ubiquitous in all aquatic habitats and all depths
2. Cell surrounded by plasma membrane, which may by supported by organic, agglutinated, or calcareous test; test situated outside plasma membrane
3. Locomotion and feeding involves long thin pseudopodia called reticulopodia, which branch and fuse to form a network.
4. Heterotrophic and without plastids. However, many species host symbiotic, photoautotrophic protists within their cell (e.g., diatoms, dinoflagellates, red algae, green algae).
5. Mitochondria with tubular cristae
6. Nuclei either ovular or vesicular; many are multinucleate; some exhibit nuclear dualism
7. Nuclear division by closed intranuclear pleuromitosis
8. Asexual reproduction by budding and/or multiple fission
9. Sexual reproduction known in most. The life cycle is usually complex, involving alternation of an asexual form (agamont) and a sexual form (gamont).

Figure 3 35 Phylum Granuloreticulosa. (A) Foram niferan shells from the Red Sea. (B) The foraminiferan *Spirolina* sp., with ts extended reticulopodia.

most frequently found in marine and brackish water and are characterized by the presence of a test with one to multiple chambers and distinctive reticulopodia long, thin pseudopodia (supported by microtubules) that branch and anastomose, and house a rapid bidirectional intracellular transport mechanism. Most forams are benthic and have flattened tests. A small number, however, are pelagic and may have calcareous spines that have been implicated in prey capture (e g., *Globigerinella;* see Figure 3.1J). Foraminiferans (noncalcareous species) have even been found living in the deepest ocean trenches, such as the Challenger Deep (10,896 m). Trench and abyssal forams primarily are simple, single chambered species belonging to ancient lineages that long ago gave rise to the more complex multichambered groups that dominate shallower seas.

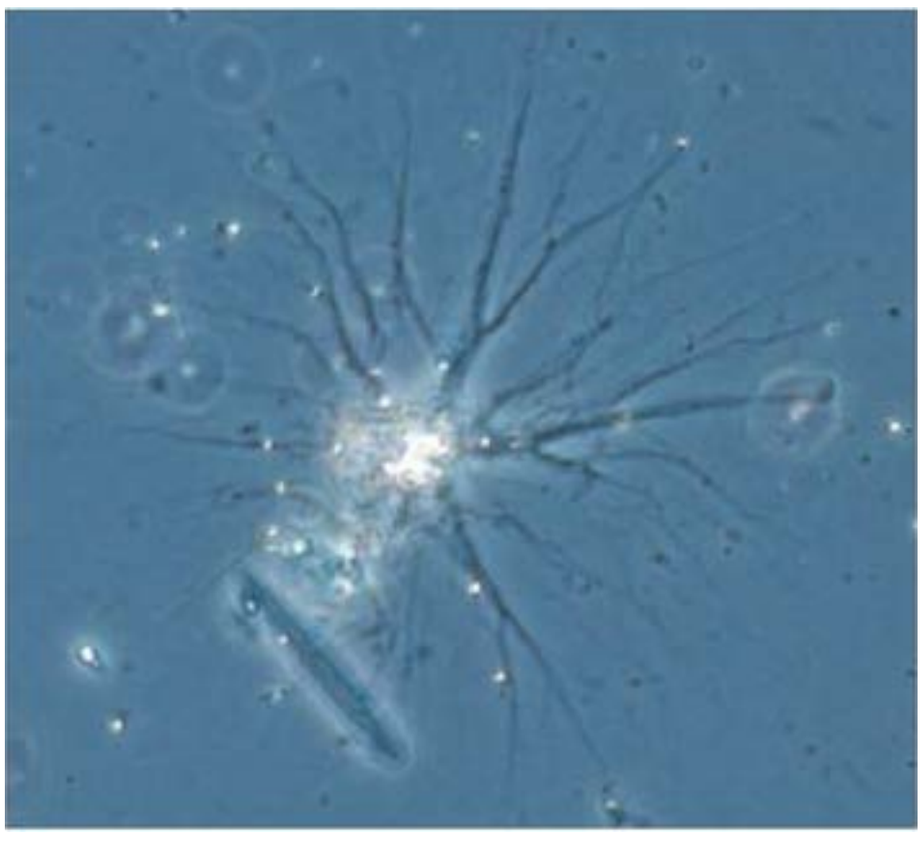

Figure 3 36 Phylum Granuloreticulosa. An unidentified athalamid with reticulopodia.

Members of these single-chambered lineages are also the only forams to have invaded freshwater and ter restrial habitats. Thus the great ocean depths and ter restrial ecosystems serve as refugia for ancient foram lineages

The tests of forams have left an excellent fossil record dating back to at least the Lower Cambrian, and perhaps the Precambrian. The tests of planktonic forams are used by geologists as paleoecological and biostratigraphic indicators, and deposits of benthic foram tests are often used by petroleum geologists in their search for oil. The tests of some species are surprisingly durable. On the island of Bali, the tests of one species are mined and used as gravel in walks and roads! Much of the world's chalk, limestone, and marble is composed largely of foraminiferan tests or the residual calcareous material derived from the tests. Most of the stones used to build the great pyramids of Egypt are foraminiferan in origin (it's engaging and instructive to think of the great pyramids as being built of protist skeletons). Before they get buried on the sea floor, the tests of foraminiferans function as homes and egg-laying sites for many minute metazoan species, such as small sipunculans, polychaetes, nematodes, copepods, isopods, and others

Support and Locomotion

Although little is known about locomotion in the Granuloreticulosa, the reticulopodia are involved (see Figure 3.36). Most species have tests covering their plasma (cell) membrane. However, the Althalamida lack a test and instead are covered by a thin, fibrous envelope. The tests of forams are usually constructed as a series of inter connected chambers of increasing size, with main openings, or apertures, in the largest chamber from which the reticulopodia emerge. The connecting pores between the chambers are called foramina (hence the group's name) and they actually constitute the former apertures. There may be one large aperture, or several smaller ones in the largest (youngest) cham-

ber. Cytoplasm emerging from the aperture(s) forms the reticulopodial network and also often forms a layer covering the outside of the test.

There are three types of tests in the Foraminifera: (1) organic, (2) agglutinated, and (3) calcareous. The nature of the test is a taxonomic feature used to clas sify forams. Organic tests are composed of complexes of proteins and mucopolysaccharides. These tests are flexible and allow the organisms that secrete them (e g , *Allogramia*) to change shape rapidly.

Agglutinated tests are composed of materials gathered from the environment (e.g, sand grains, sponge spicules, diatoms, etc.) that are embedded in a layer of mucopolysaccharide secreted by the cell. The test may be made rigid by calcareous and iron salts. Some forams that have agglutinated tests are highly selec tive about the building materials used to build their tests (e.g., *Technitella*), while others are not (e.g., *Astrorhiza*).

Calcareous tests are composed of an organic layer reinforced with calcite ($CaCO_3$) secreted by the forams themselves. The arrangement of calcite crystals gives the tests a characteristic appearance, and three major categories of calcareous tests are recognized: (1) porcelaneous, (2) hyaline, and (3) microgranular. Porcelaneous tests appear shiny and white, and these are probably the most familiar to students (see Figure 3.35). These tests generally lack perforations and the reticulopodia emerge from a single aperture. Hyaline tests have a glasslike appearance in reflected light and often are perforated with tiny holes. Microgranular tests have a sugary (granular) appearance in reflected light. Planktonic foraminiferans can occur in such high numbers that the calcareous tests of dead individuals constitute a major portion of the sediments of ocean basins. In some parts of the world, these sediments called foraminiferan ooze—are hundreds of meters thick. Such sediments are restricted to depths shallower than 3,000 to 4,000 m, however, because $CaCO_3$ dissolves under high pressure.

Nutrition

All Granuloreticulosa are heterotrophic and feed by phagocytosis. The prey varies depending on the species. Some are herbivores, other carnivores, and still others are omnivores or detritivores. The life cycles of many herbivorous planktonic species are tuned to the bloom of certain algae, such as diatoms or chloro phytes, and they graze heavily on the phytoplankton at those times. All species probably use their ret culopodia to trap food. Vesicles at the tip of the reticulopodia secrete a sticky substance to which prey adhere upon contact. Benthic species trap prey by spreading their reticulopodia out on the lake or ocean bottom. The prey are eventually transported to the cell's plasma mem brane where they are engulfed in food vacuoles

Shallowwater benthic and planktonic forams living near the water's surface often harbor endosymbiotic algae such as diatoms, dinoflagellates, or red or green algae, which can migrate along the reticulopodia to expose themselves to more sunlight. These forams are particularly abundant in warm tropical seas. Studies suggest that nutrient and mineral recycling occurs between the forams and their algal symbionts. Furthermore, it has been shown that the symbionts may enhance the test building capacities of forams and that their presence often allows their hosts to grow to very large sizes (e.g., the Eocene foram *Nummulites gizehensis* reached 12 cm in diameter), even in nutrient-poor waters. "Giant" forams, such as *Nummulites*, are much more common in fossil deposits than they are today.

Reproduction and Some Life Cycles

The life cycles of granuloreticulosans are frequently complex, and most are incompletely understood. These cycles often involve an alternation of sexual and asexual phases (Figure 3.37). However, some smaller species apparently only reproduce asexually, by bud ding and/or multiple fission. Nuclear division in both sexually and asexually reproducing species occurs by intranuclear pleuromitosis. In those that reproduce sexually, it is not uncommon to find individuals of the same foraminiferan species differing greatly in size and shape at different phases of the life cycle. The size difference is generally determined by the size of the initial shell chamber (the **proloculum**), produced following a particular life cycle event. Often the proloculum that is formed following asexual processes is significantly larger than one formed after syngamy. Individuals with large prolocula are called the **macro-** or **megaspheric generation**; individuals with small prolocula are the **microspheric generation**.

During the sexual phase of the life cycle, the haploid individuals (gamonts) undergo repeated divisions to produce and release bi- or triflagellated isogametes, which pair and fuse to form the asexual individuals. Asexual, diploid individuals (called agamonts) under go meiosis and produce haploid gamonts—the sexual individuals. The means of return to the diploid condition varies. In many foraminiferans (*Elphidium*, *Iridia*, *Tretomphalus*, and others), flagellated gametes are produced and released; fertilization occurs freely in the seawater to produce a young agamont. In others, such as *Glabratella*, two or more gamonts come together and temporarily attach to one another The gametes, which may be flagellate or amoeboid, fuse within the chambers of the paired tests. The shells eventually separate, releasing the newly formed agamonts. True autogamy occurs in *Rotalella*: each gamont produces gametes that pair and fuse within a single test, and the zygote is then released as an agamont.

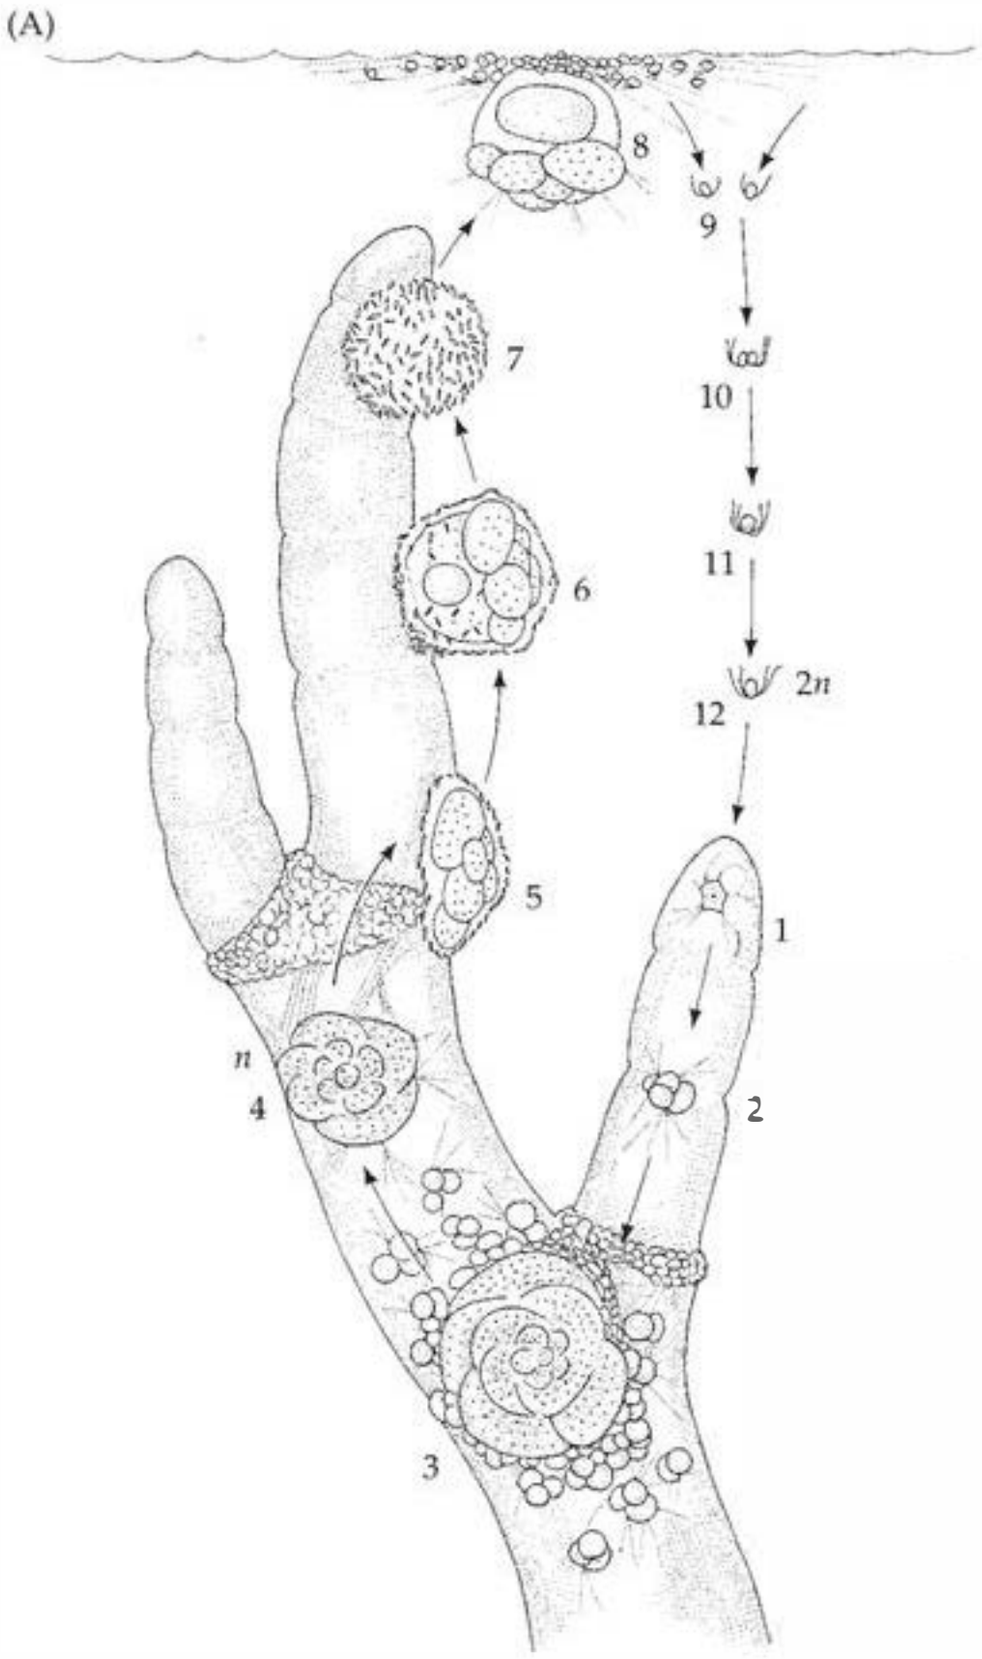

Figure 3.37 Phylum Granuloreticulosa. (A) Life cycle of the foraminiferan *Tretomphalus bulloides*. (1) The shell-less, ameboid zygote settles on the surface of an alga or sea grass (e.g., *Thalassia testudinum*). (2) The cell grows and matures as an agamont, which (3) asexually produces young gamonts. Each mature gamont (4) accumulates particles of detritus (5–6) to produce a flotation chamber (7). (8) The gamont floats to the surface and produces and releases gametes (9), which fuse to produce a swimming zygote (10–12). (B) A common habitat for *Tretomphalus bulloides* in the Caribbean is sea grass beds (*Thalassia testudinum*).

BOX 3N Characteristics of the Phylum Radiolaria

1. Common marine planktonic protists in the world's oceans; most common in the tropics
2. Cytoplasm divided into two regions, endoplasm and ectoplasm (=calymma), separated by a capsular wall composed (usually) of muceprotein. Cell surrounded by plasma membrane, which may be supported by skeleton secreted by the cell and usually internal; skeletons of variable composition
3. Locomotion mostly passive; some movement can be accomplished with axopods
4. Mitochondria with tubular cristae (in most)
5. Heterotrophic, capturing prey with axopods and extrusomes. Although without plastids, some species harbor symbiotic, photoautotrophic protists (e.g., chlorophytes, dinoflagellates).
6. Most with single vesicular nucleus; some have single ovular nucleus; some have multiple nuclei
7. Nuclear division occurs by closed intranuclear pleuromitosis. Electron-dense plaques act as organizers for mitotic spindle; pair of centrioles are located outside nucleus and situated near plaques. Amorphous structures called polar caps located in cytoplasm act as mitotic spindle organizers.
8. Asexual reproduction by binary fission, multiple fission, or budding
9. Meiosis involves two divisions prior to formation of gametes.

Phylum Radiolaria: Radiolarians

The phylum Radiolaria comprises about 2,500 described species whose threadlike pseudopodia appear to ally them with chlorarachniophytes and many heliozoans—the three forming a clade known as the Cercozoa (Box 3N). Three groups are typically classified in the Radiolaria: Polycystina, Acantharia, and Phaeodaria, although it is likely that none of these represents a monophyletic group (Figure 3.38). Most have internal siliceous (SiO_2) skeletons that preserve well as fossils, although acantharians have a skeleton of strontium sulfate (celestite, $SrSO_4$) that is more water soluble and less frequently found in the fossil record. Radiolarians are all planktonic; they are found exclusively in marine habitats and are most abundant in warm waters (26°–37°C).

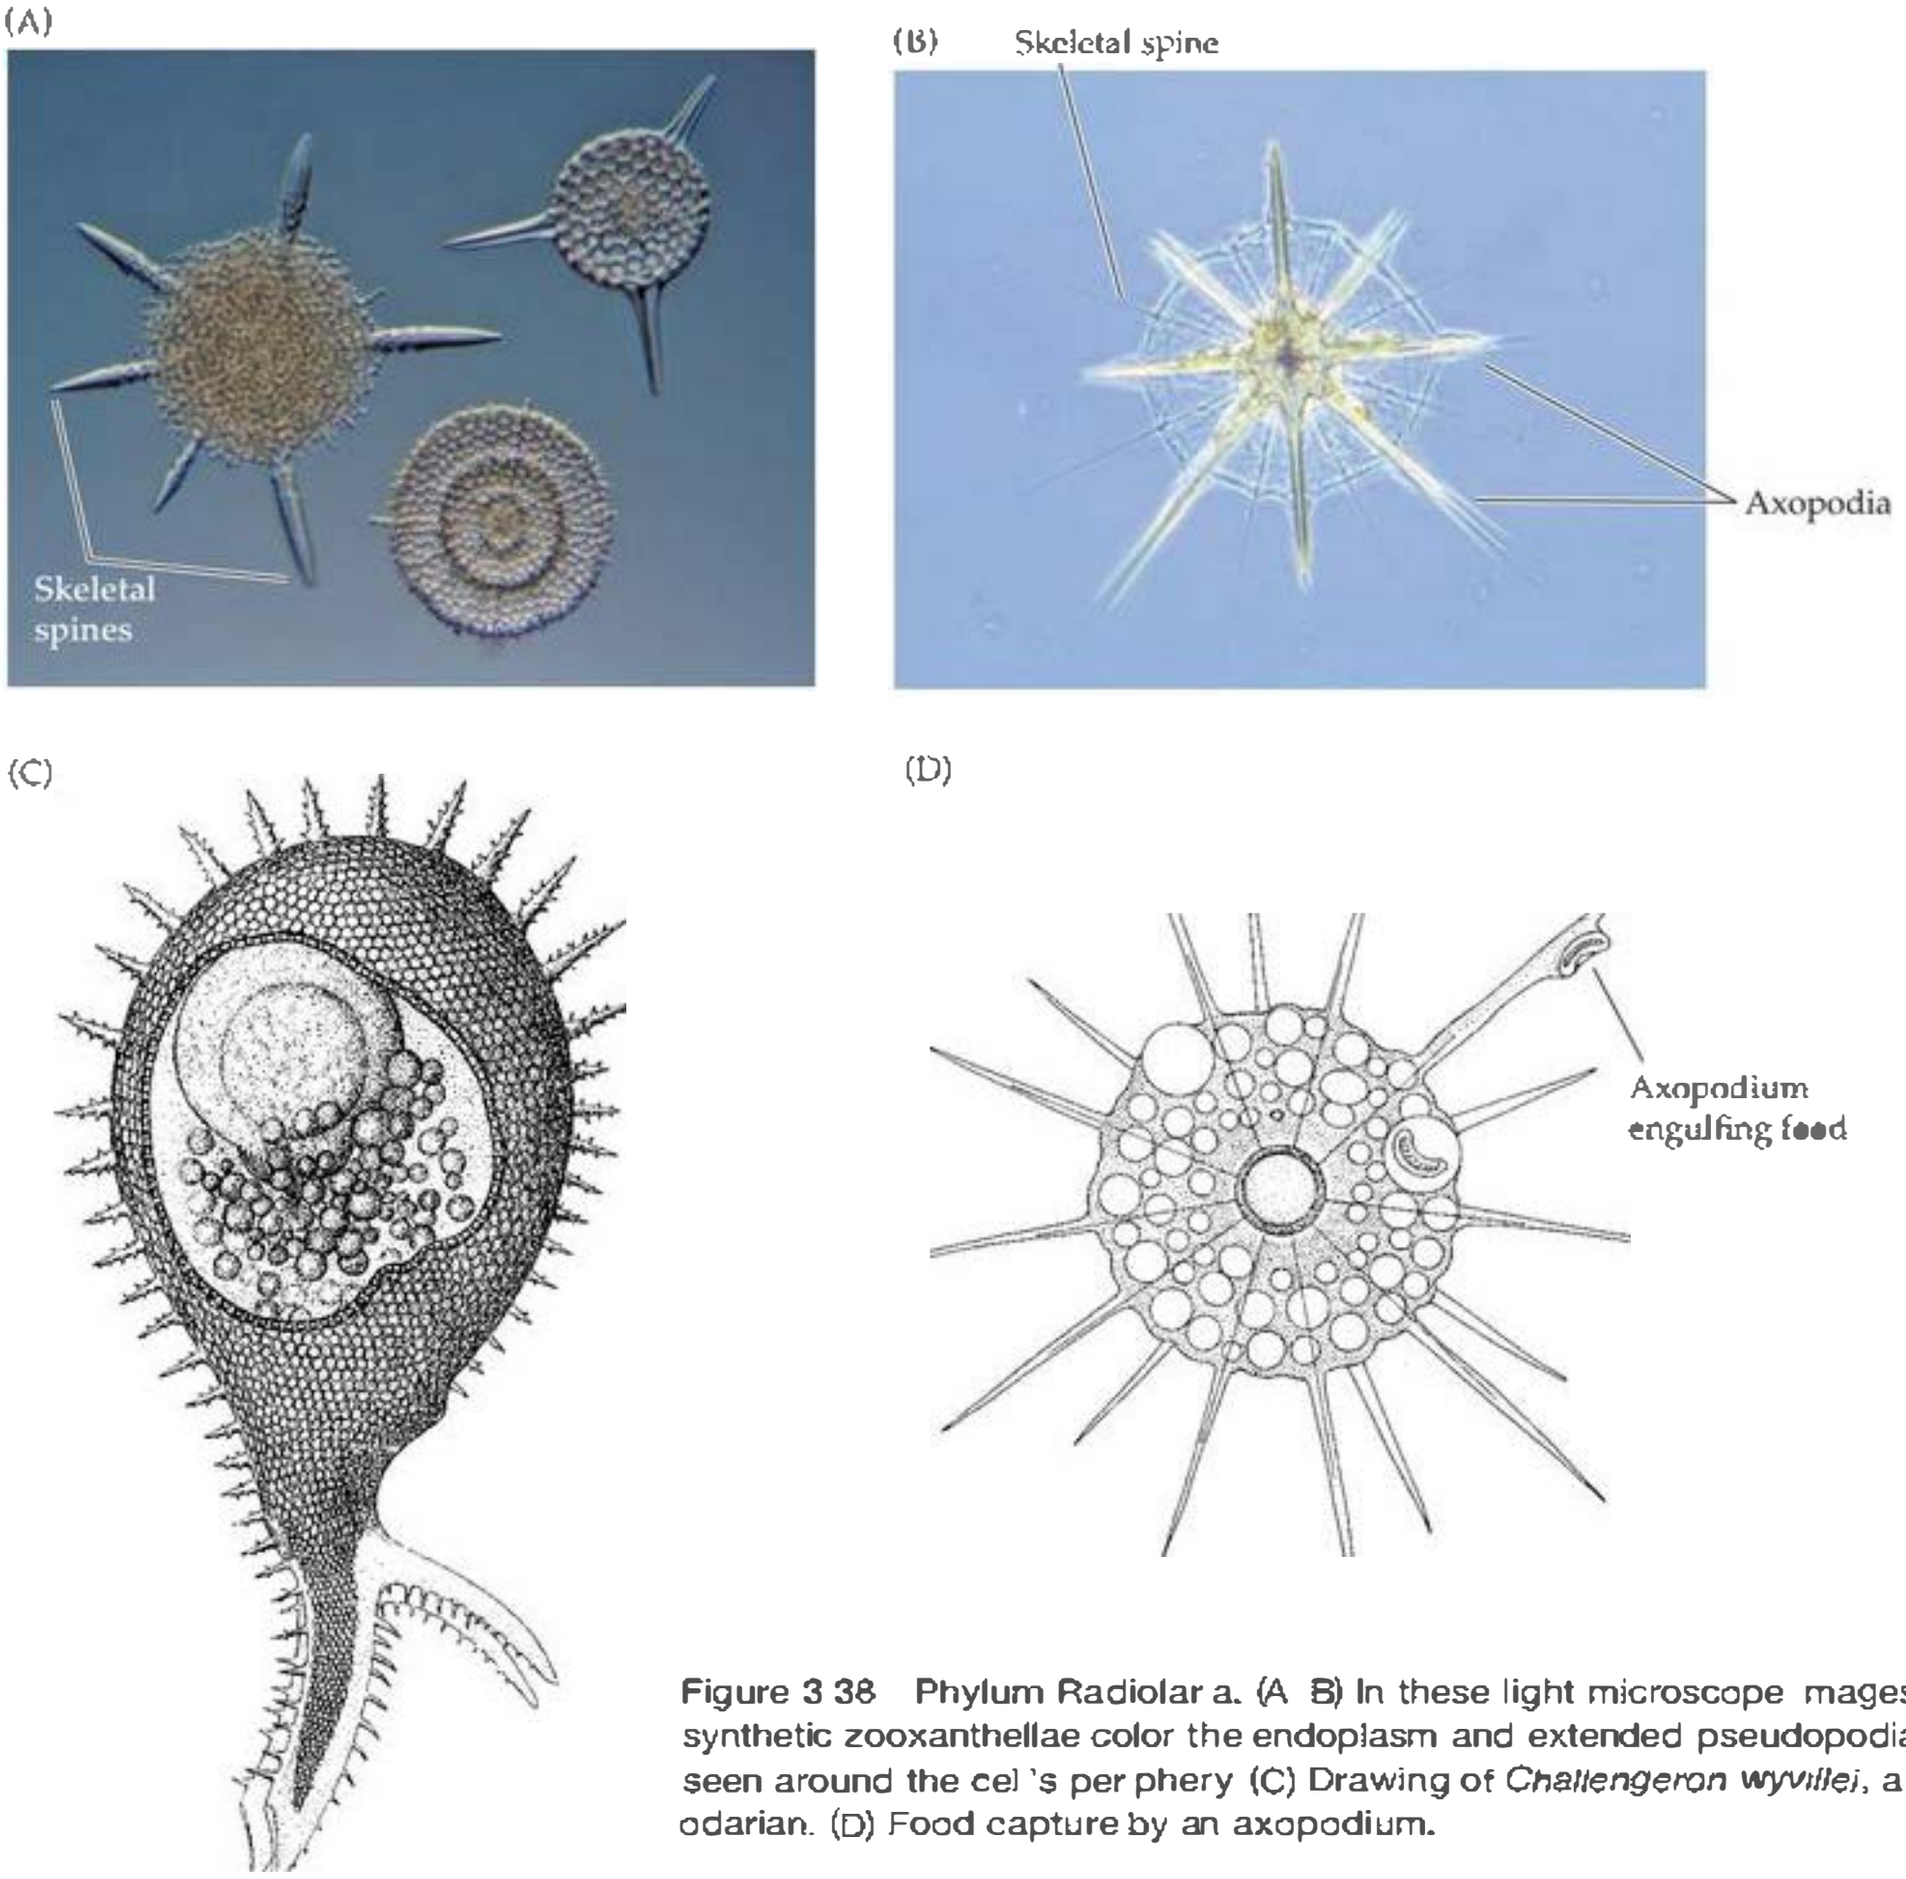

Figure 3 38 Phylum Radiolar a. (A B) In these light microscope mages, photosynthetic zooxanthellae color the endoplasm and extended pseudopodia can be seen around the cel 's per phery (C) Drawing of *Challengeron wyvillei*, a phae odarian. (D) Food capture by an axopodium.

The axopods, which radiate from the bodies of these beautiful protists, are slender pseudopodia supported by an inner core of microtubules. In many groups, the axopods extend from a central region of the cell called the **axoplast** (Figure 3.39). The pattern of the microtubule arrangement within the axopods varies and is an important taxonomic feature. Axopods function primarily in feeding and, in some cases, locomotion. The cytoplasm exhibits a characteristic bidirectional movement (like the Granuloreticulosa), circulating substances in the cytoplasm between the pseudopodia and the main body of the cell. One of the most useful aspects of radiolarians for humans is related to the nature of their skeletons—the strontium sulfate skeletons of acanthar ians have been used by scientists to measure amounts of natural or anthropogenic radioactivity in marine environments. The siliceous skeletons of polycystines and phaeodarians do not dissolve under great pressure and therefore accumulate, along with diatom tests, as deposits called siliceous ooze on the floors of deep ocean basins (3,500–10,000 m deep). These skeletons date back to the Cambrian and have been used as paleoenvironmental indicators

Support and Locomotion

The cytoplasm of radiolarians is divided into two regions, the endoplasm and the ectoplasm, which are separated by a capsular wall that is composed (usually) of mucoprotein. The central endoplasm is granular and dense, and contains most of the organelles: nucleus, mitochondria, Golgi apparatus, pigmented granules, digestive vacuoles, crystals, and the axoplast. Axopods emerge from the axoplast in the endoplasm through pores in the capsule wall. The pore pattern is

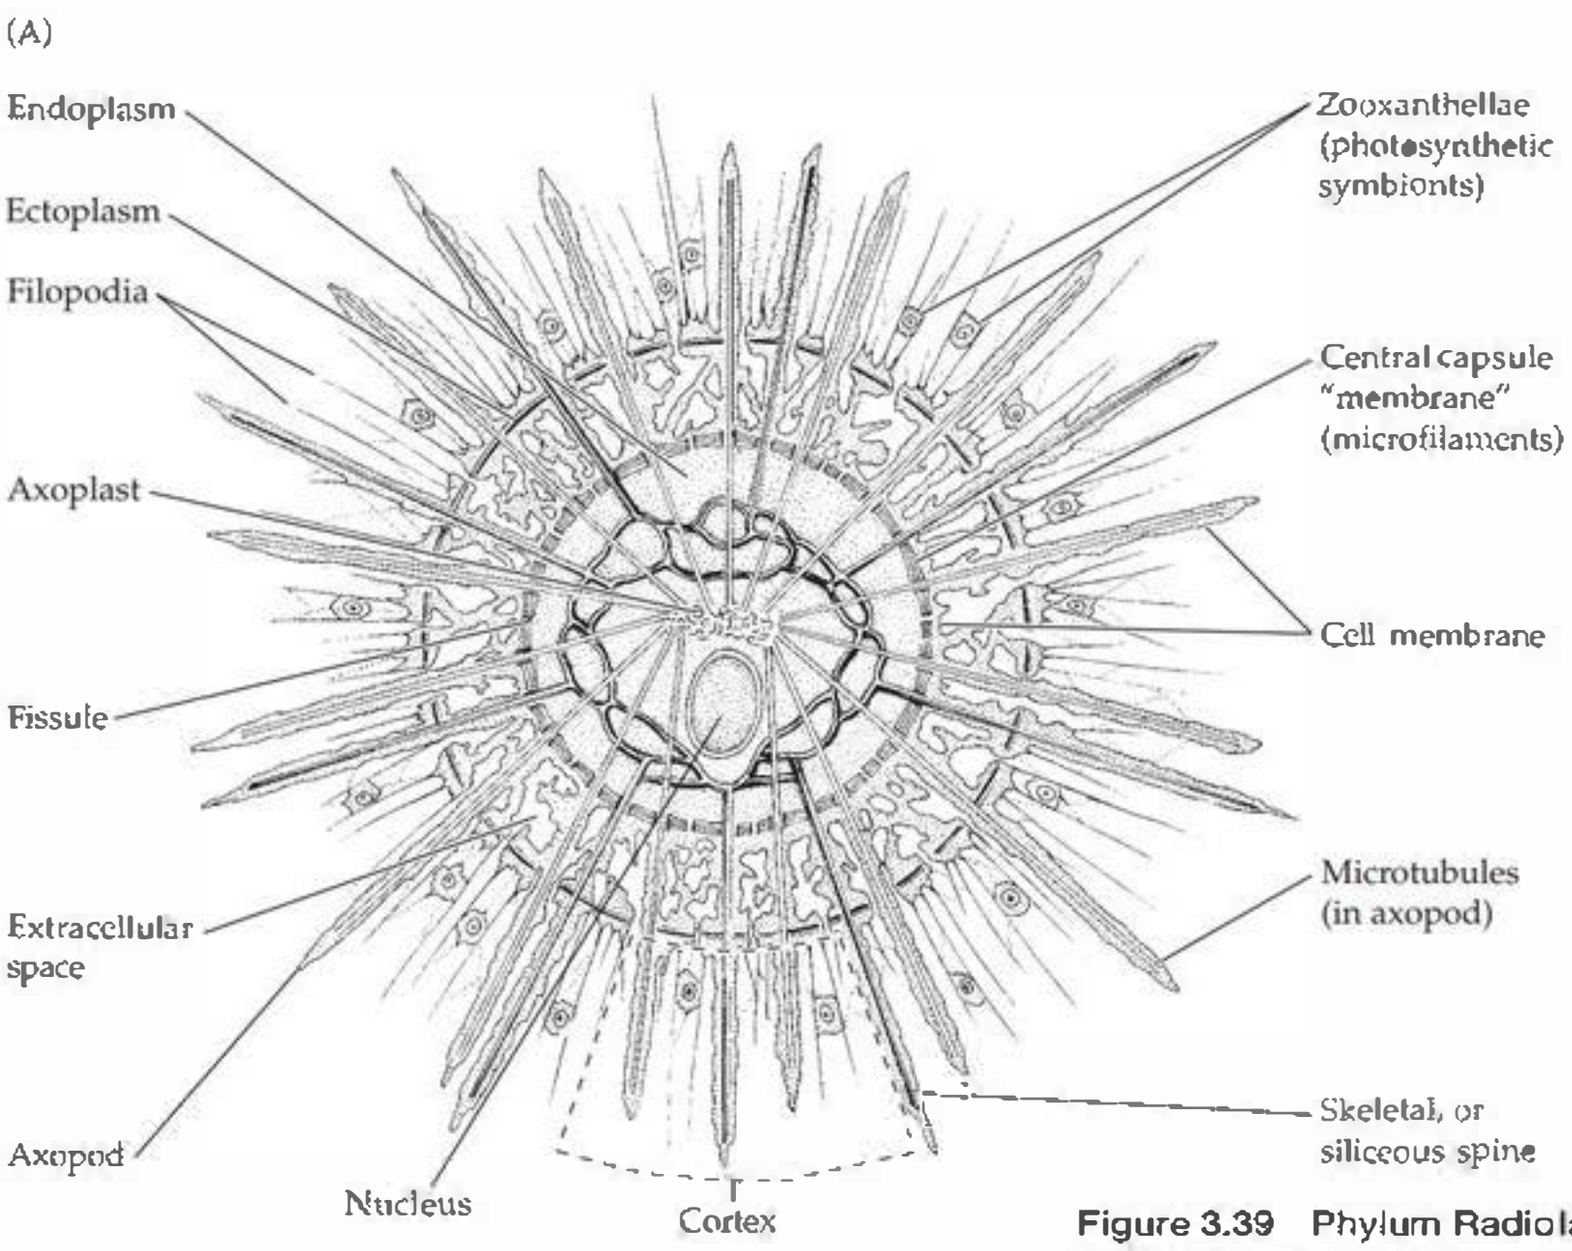

Figure 3.39 Phylum Radiolaria. (A) General anatomy of a radiolarian, showing the axopods (radiating spines that aid in flotation) and other structures. (B) Cross section (TEM) through axopodium of *Actinosphaerium*.

variable. In polycystines, for example, there are many pores in the capsule wall, all of which are associated with collarlike structures called **fusules**. In phaeodarians, there are only three pores in the capsule wall. The largest pore, the **astropyle**, is associated with fusules. Axopods emerge from the two smaller pores, the **parapyles**, which are not associated with fusules.

Most radiolarians have skeletons for support. The skeleton is formed and housed within the endoplasm and is therefore internal. In Polycystina and Phaeodaria, the skeleton is composed primarily of siliceous elements that are solid in polycystines and hollow in phaeodarians. In acantharians, the skeleton is composed of strontium sulfate embedded in a proteinaceous matrix. These skeletons vary greatly in construction and ornamentation, and frequently bear radiating spines that aid in flotation. In the Acantharia, there is a strict arrangement of 20 radial spicules, which is a diagnostic feature of this group.

The ectoplasm, often called the **calymma**, lies outside the capsule wall and contains mitochondria, large digestive vacuoles, extrusomes, and (in some) algal symbionts. The calymma has a rather foamy appearance due to the presence of a large number of vacuoles (see Figures 3.38 and 3.39). The vacuoles, some of which house oil droplets and other low-density fluids, aid in flotation in free-living species. When surface water conditions become rough and potentially dangerous to these delicate protists, the calymma expels some of its contents and the creature sinks to calmer depths. Eventually the cell replaces the oils and other fluids, and the organism rises toward the surface again. Unique to the ectoplasm of phaeodarians are balls of waste products called **phaeodium**, after which this group was named. The ectoplasm of acantharians is covered with a netlike cortex that is anchored to the apex of the spicules by contractile myonemes. Both the cortex and the presence of myonemes in association with the skeletal spicules are distinctive features of the acantharians.

Locomotion in radiolarians is limited. Most radiolarians drift passively in the water column using the axopods, skeletal spines (if present), and ectoplasmic

vacuoles as flotation devices. In some cases, however, the axopods and spines play a more active role in locomotion. For example, the axopods may also help these organisms maintain their position in the water column by the expansion and contraction of vacuoles between the axopods This has been suggested because it has been observed in polycystines that when the ectoplasm and axopods are lost during cell division, the organisms sink. In at least one genus, *Sticholonche*, the axopods appear to be used as tiny oars. In acantharians, it is thought that contraction of the myonemes that are attached to the spicules may somehow regulate buoyancy.

All radiolarians are heterotrophic, obtaining food by phagocytosis, and many are voracious predators. Prey items include bacteria, other protists (e.g., ciliates, diatoms, flagellates), and even small invertebrates (e g., copepods). Radiolarians use their axopods as traps for prey. The Radiolaria are usually equipped with extrusomes such as mucus-producing mucocysts, and kinetocysts, which eject barbed, threadlike structures. Prey items adhere to mucus (discharged by mucocysts) that covers the extended axopods, or they become attached to the axopods by the discharged kinetocysts.

The size and motility of the prey determines the particular feeding mechanism used. Small prey are engulfed in food vacuoles directly, whereas large prey may be partially digested extracellularly by the action of secretory lysosomes in the mucous coat or broken into pieces by the action of large pseudopodia. The extracellular food is drawn toward the cell body by cytoplasmic streaming, eventually enclosed within food vacuoles, and completely digested in the central portion of the cell. In polycystines, it has been observed that when fast-moving or large prey (especially those with skeletons, such as diatoms) contact the axopods, the axopods actually collapse, drawing the prey into the cell body where it is engulfed by thin filopodia and then enclosed in a food vacuole (see Figure 3.38D). The collapse of the axopods is thought to involve microtubule disassembly.

An interesting feeding arrangement is found in the phaeodarians. As mentioned earlier, they have only three openings in the capsule wall: two parapyles and the single astropyle. Prey become trapped on the axopods. Then a large pseudopod, formed from the astropyle, engulfs the prey item into a food vacuole where it is digested in the ectoplasm. Because of this behavior, some workers have referred to the astropyle as a cytostome.

Many polycystines and acantharians live near the water's surface. These protists often have algal symbionts, including chlorophytes and dinoflagellates, which presumably provide them with additional nutrients. Phaeodarians do not have algal symbionts, which is not surprising since they tend to be found in water depths unsuitable for photosynthesis.

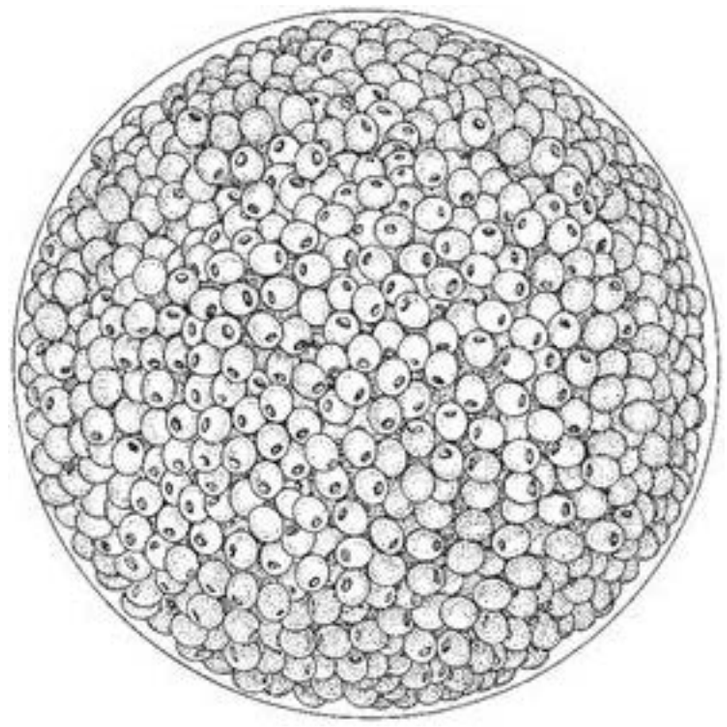

Figure 3.40 Phylum Radiolaria. Mass of swarmers produced by multiple fission within the central capsule of the radiolarian *Thalassophysa*.

Reproduction

Asexual reproduction occurs by binary fission, multiple fission, or budding. In the Polycystina and various shelled forms, however, division occurs along planes predetermined by body symmetry and skeletal arrangement. The same basic mode of multiple fission is seen in all groups. A polyploid nucleus results from numerous mitotic divisions. The nucleus fragments, producing many biflagellate individuals called swarmers, which eventually lose their flagella and develop into adults (Figure 3.40). In polycystines, swarmers have a crystal of strontium sulfate in their cytoplasm. In most polycystine and acantharian species, multiple fission is the only mode of asexual reproduction.

Sexual reproduction is poorly documented in radiolarians. Autogamy is usually triggered by either a lack of food or, conversely, it follows heavy feeding. First the cell encysts and undergoes a mitotic division to produce two gamonts. Each gamont nucleus divides by meiosis without cytokinesis. All but two of the nuclei disintegrate The two surviving haploid nuclei fuse while still inside the cyst, forming a diploid zygote that later emerges from the cyst when environmental conditions become more favorable.

Nuclear division occurs by closed intranuclear pleuromitosis. Electrondense plaques, located on the inner surface of the nuclear envelope, act as organizers for the mitotic spindle. A pair of centrioles, located outside of the nucleus is found near the plaques.

Phylum Haplosporidia: Haplosporidians

The haplosporidians comprise a small phylum of parasitic protists that typically (though not always, e.g., *Bonamia*) form uninucleate spores without polar

capsules or polar filaments; the spore wall has an orifice at one pole (see Figure 3.34B). In *Urosporidium*, the orifice is "closed" by an internal diaphragm; in the other genera there is an external hinged operculum. Tubular, filamentous, or ribbon-like strands of material have often been observed on the external spore surface, but this ornamentation is structurally diverse and not well understood. There is, in fact, no single ultrastructural feature that characterizes haplosporidians, and they are usually recognized on the basis of a combination of features: a uninucleate stage, usually with a central nucleus, which develops to a diplokaryotic stage. In the later stage, two nuclei lie close and in contact with one another after division, with further nuclear division producing multinucleate plasmodia, from which operculate spores may develop. Haplosporidians are exclusively intracellular parasites of certain invertebrates, including flatworms (Turbellaria), annelids, crustaceans, and especially molluscs. They occur worldwide, primarily in marine environments and to a lesser extent in freshwater habitats. Causative agents of MSX disease, haplosporidians (*Haplosporidium* and *Bonamia*) have been known to decimate coastal oyster populations. We have little knowledge of haplosporidian life histories, and species are characterized on the basis of spore structure and gene sequencing.

The largest genus in the phylum, *Haplosporidium*, contains about two dozen species, most of which are parasites on bivalve molluscs, although some species infest commercially important crabs and shrimps (e.g., *H. littoralis* infects the common European shore crab *Carcinus maenas*).

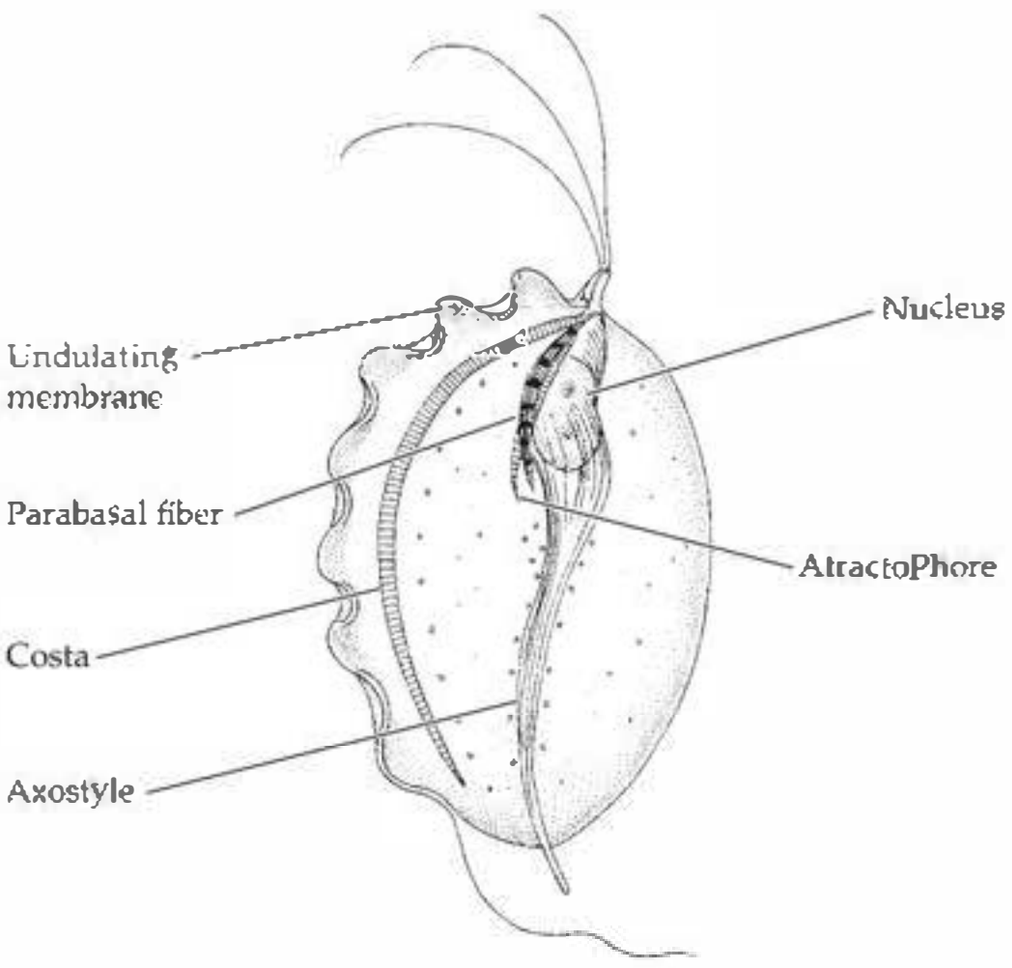

Figure 3.41 Phylum Parabasalida. *Trichomonas murius*, a trichomonad inhabiting the large intestine of mice.

Haplosporidians have been a troublesome group for taxonomists. Historically, the taxon was treated as a catchall for any spore-forming parasites with multinucleated naked cells (plasmodia) in their life cycles that could not be easily classified elsewhere. The Haplosporidia were first erected (in 1899) as an order of the phylum Sporozoa. In 1979 the Haplosporidia (and the Paramyxea) were separated from the "other Sporozoa" and placed in a new phylum called Ascetospora, not all of which have a spore stage in their life history. Recently, the Ascetospora was abandoned and the Haplosporidia and Paramyxea were each elevated to phylum rank. The phylum Paramyxea also contains several important parasites of oysters and other bivalves, including species of *Marteilia* from the Indo-Pacific region. Molecular phylogeneticists have begun trying to unravel the relationships of these groups, but so far with little success. Some protistologists now regard haplosporidians as an order within a recently erected phylum called Retaria, while others place them in a phylum called Cercozoa.

GROUP 4: EXCAVATA

Phylum Parabasalida: Trichomonads, Hypermastigotes, and Their Kin

The phylum Parabasalida contains about 300 species of heterotrophic flagellate protists, all of which are endosymbionts (mostly parasites) of animals (Figure 3.41). There are two major subgroups of parabasalids: the trichomonads and the hypermastigotes (Box 30). The hypermastigotes (e.g., *Trichonympha*) are obligate mutualists in the digestive tracts of wood-eating insects such as termites and wood roaches. The obligate mutualism between hypermastigotes and termites and wood roaches is well studied. Although these insects eat wood, they lack the enzymes necessary to break it down. The hypermastigotes produce the enzyme cellulase, which breaks the cellulose in wood down to a form that the insect can metabolize.

Trichomonads are symbionts in the digestive, reproductive, and respiratory tracts of vertebrates, including humans. There are four species of trichomonads found in humans, three that are normally harmless commensals (*Dientamoeba fragilis*, *Pentatrichomonas hominis*, *Trichomonas tenax*), and one that is an extremely prevalent, sexually transmitted pathogen (*T. vaginalis*). *Pentatrichomonas hominis* is found in the gut of humans, other primates, dogs, and cats. It is generally present in less than 2% of the population, although in many developing countries the prevalence is much higher (e.g., 32% in Mexico). It is directly associated with poor hygiene since the parasite is transmitted by the oral-fecal route via contaminated food, water, and filth insects such as flies and roaches.

BOX 30 Characteristics of the Phylum Parabasalida

1. Small phylum of heterotrophic flagellates, without plastids, all of which are endosymbionts (mostly parasites) of animals. Hypermastigotes are obligate mutualists in the digestive tracts of wood-eating insects. Trichomonads are symbionts in the digestive, reproductive, and respiratory tracts of vertebrates.
2. Body surrounded only by plasma membrane; some rigidity provided by cytoskeleton, associated with the flagella
3. With flagella for locomotion (almost always); number of flagella can vary between one to thousands; fibrous roots (parabasal fiber, atractophore) and microtubular structures (axostyle, pelta) associated with basal bodies of the flagella
4. Highly modified mitochondria present in the form of hydrogenosomes (lacking many normal mitochondrial features, including DNA and oxidative phosphorylation)
5. Hypermastigotes possess either a single chromosomal or vesicular nucleus with a prominent nucleolus. Trichomonads possess a single vesicular nucleus with a minute nucleolus.
6. Nuclear division occurs by closed extranuclear pleuromitosis without centrioles.
7. Asexual cell division by longitudinal binary fission
8. Sexual reproduction occurs in some hypermastigotes, but is unknown in trichomonads. In hypermastigotes, sexual reproduction varies, occurs by gametogamy, gamontogamy, or autogamy.

The parabasalids get their name from a fiber, the parabasal fiber, which extends from the basal bodies to the Golgi apparatus. Several other unusual cytoskeletal fibers, basically rodlike or sheetlike bundles of microtubules, are associated with the basal bodies (an atractophore, an axostyle, and a pelta) and their presence, along with the parabasal fiber, is a diagnostic feature of this group. Most species also have an undulating membrane. Parabasalids have highly modified mitochondria called hydrogenosomes. These generate energy (ATP) in the absence of oxygen, releasing hydrogen gas as one of the waste products. Similar organelles are found in some other protists that live in oxygen-poor environments (e.g., many ciliates).

Trichomonads have been the focus of much research because there are four species found as symbionts in humans and several species that parasitize domestic stock and fowl. *Trichomonas vaginalis* is a cosmopolitan species found in the vagina and urethra of women, and in the prostate, seminal vesicles, and urethra of men. It is transmitted primarily by sexual intercourse, although it has been found in newborn infants. Its occasional presence in very young children suggests that the infection can also be contracted from shared washcloths, towels, or clothing. Most strains of *T. vaginalis* are of such low pathogenicity that the victim is virtually asymptomatic, although urethritis and prostatitis are not uncommon. However, other strains cause intense inflammation with itching and a copious greenish-white discharge (leukorrhea) that is swarming with the parasite. *Trichomonas vaginalis* is basically a highly voracious and indiscriminant predator, feeding on bacteria, vaginal epithelial cells, erythrocytes and leukocytes, and cell exudates. An estimated 170 million new cases of *T. vaginalis* occur annually.

O. F. Müller discovered *Trichomonas tenax* in 1773, when he examined a culture of tartar from his own teeth. *T. tenax* is generally regarded as a harmless commensal of the human mouth, its prevalence ranging from 4% to 53% of the population. However, a rare, but serious disease known as pulmonary trichomoniasis can be contracted by aspirating *T. tenax*. *Dientamoeba fragilis* is a fairly common parasite of human intestinal tracts, where it lives in the large intestine and feeds mainly on debris. Although traditionally considered a harmless commensal, recent studies suggest that infections by this protist routinely result in abdominal stress (e.g., diarrhea, abdominal pain). *Tritrichomonas foetus* is a parasite in cattle and other large mammals and is one of the leading causes of abortion in these animals; it is common in the United States and Europe. *Histomonas meleagridis* is a cosmopolitan parasite of gallinaceous fowl (i.e., domestic poultry and game birds of the order Galliformes). Histomoniasis in chickens and turkeys causes over a million dollars in losses annually.

Trichomonads are members of the parabasalid lineage that lacks "normal" mitochondria and peroxisomes, but contains hydrogenosomes. Analogous organelles have been identified in ciliates and some other eukaryotes. *Trichomonas vaginalis* is known to use carbohydrate as a main energy source via fermentative metabolism under aerobic and anaerobic conditions.

Support and Locomotion

In parabasalids, the cell body is surrounded only by plasma membrane, but some rigidity is provided by a system of supporting fibers and microtubules that are associated with the kinetosomes. There are two striated fibrous roots (a parabasal fiber and an atractophore) and two microtubular roots (an axostyle and a pelta) (Figure 3.41). The number of parabasal fibers is variable. In small trichomonads, there are only a few, whereas in hypermastigotes, such as *Trichonympha*, there can be over a dozen. The atractophore extends toward the nucleus from the basal bodies. The axostyle is a rodlike bundle of microtubules that originates near the basal bodies and curves around the nucleus as it extends to the posterior region of the cell. The pelta is

a sheet of microtubules that encloses the flagellar bases. In trichomonads, an additional striated fiber called the costa is present. This fiber originates at the bases of the flagella and extends posteriorly beneath the undulating membrane. These fibers, along with the flagella and the nucleus, comprise the karyomastigont system (similar to those found in diplomonads). Trichomonads are characterized by protoplasmic plasticity, so that various shapes may be assumed. However, they are usually pear-shaped and possess 3 to 5 anterior flagella, with a recurrent anterior flagellum attached to the body as an undulating membrane.

Locomotion is accomplished by the beats of flagella. In *Trichomonas vaginalis*, for example, four free flagella form a tuft in the anterior region of the cell. The fifth flagellum is attached to the cell body at regular attachment sites so that when it beats, the cell membrane in that region of the body is pulled up into a fold, forming an undulating membrane. As in trypanosome kinetoplastids, the flagellum-undulating membrane complex seems to be efficient in moving the organism through viscous media. Hypermastigotes usually have dozens or even hundreds of flagella occurring all over the body. In these protists, the basal bodies of the flagella are arranged in parallel rows and are connected by microfibrils. The beat of the flagella is synchronized (as in ciliates, the synchronization is imposed by hydrodynamic effects), forming metachronal waves.

Some trichomonads (e.g., *Dientamoeba fragilis*, *Histomonas meleagridis*, *Trichomonas vaginalis*) also form pseudopodia. These pseudopodia function primarily in phagocytizing food particles, but they can also aid in locomotion.

Nutrition

All parabasalids are heterotrophic but lack a distinct cytostome (although claims have been made for the presence of a rudimentary, anteriorly positioned cytostome). In some trichomonads (e.g., *Tritrichomonas*), fluid is taken up by pinocytosis in depressions on the cell surface. Trichomonads also form pseudopodia that engulf bacteria, cellular debris, and leukocytes. Most parabasalids, however, take in particulate matter by phagocytosis. In hypermastigotes, pseudopodia formed in a sensitive region at the posterior end of the cell engulf wood particles. The chloroplasts of phototrophic euglenids originated through a secondary endosymbiotic relationship between eukaryovorous euglenids and green algae.

Reproduction

Asexual reproduction is by longitudinal binary fission (Figure 3.42A). Nuclear division occurs by closed extranuclear pleuromitosis with an external spindle. The atractophores are thought to act as microtubular organizing centers.

Sexual reproduction is unknown for the trichomonads but it occurs in some hypermastigotes, where it is well understood. A variety of sexual processes are exhibited by hypermastigotes, including **allogamy**, or cross-fertilization (e.g., union of two single-celled gametes to form a zygote) and **autogamy**, or self-fertilization (the fusion of two nuclei originating from a single cell). Hypermastigotes spend most of their lives as haploids in the digestive tract of wood-eating insects, dividing asexually by mitosis. Sexual reproduction is stimulated when the host insect molts and produces ecdysone, the molting hormone.

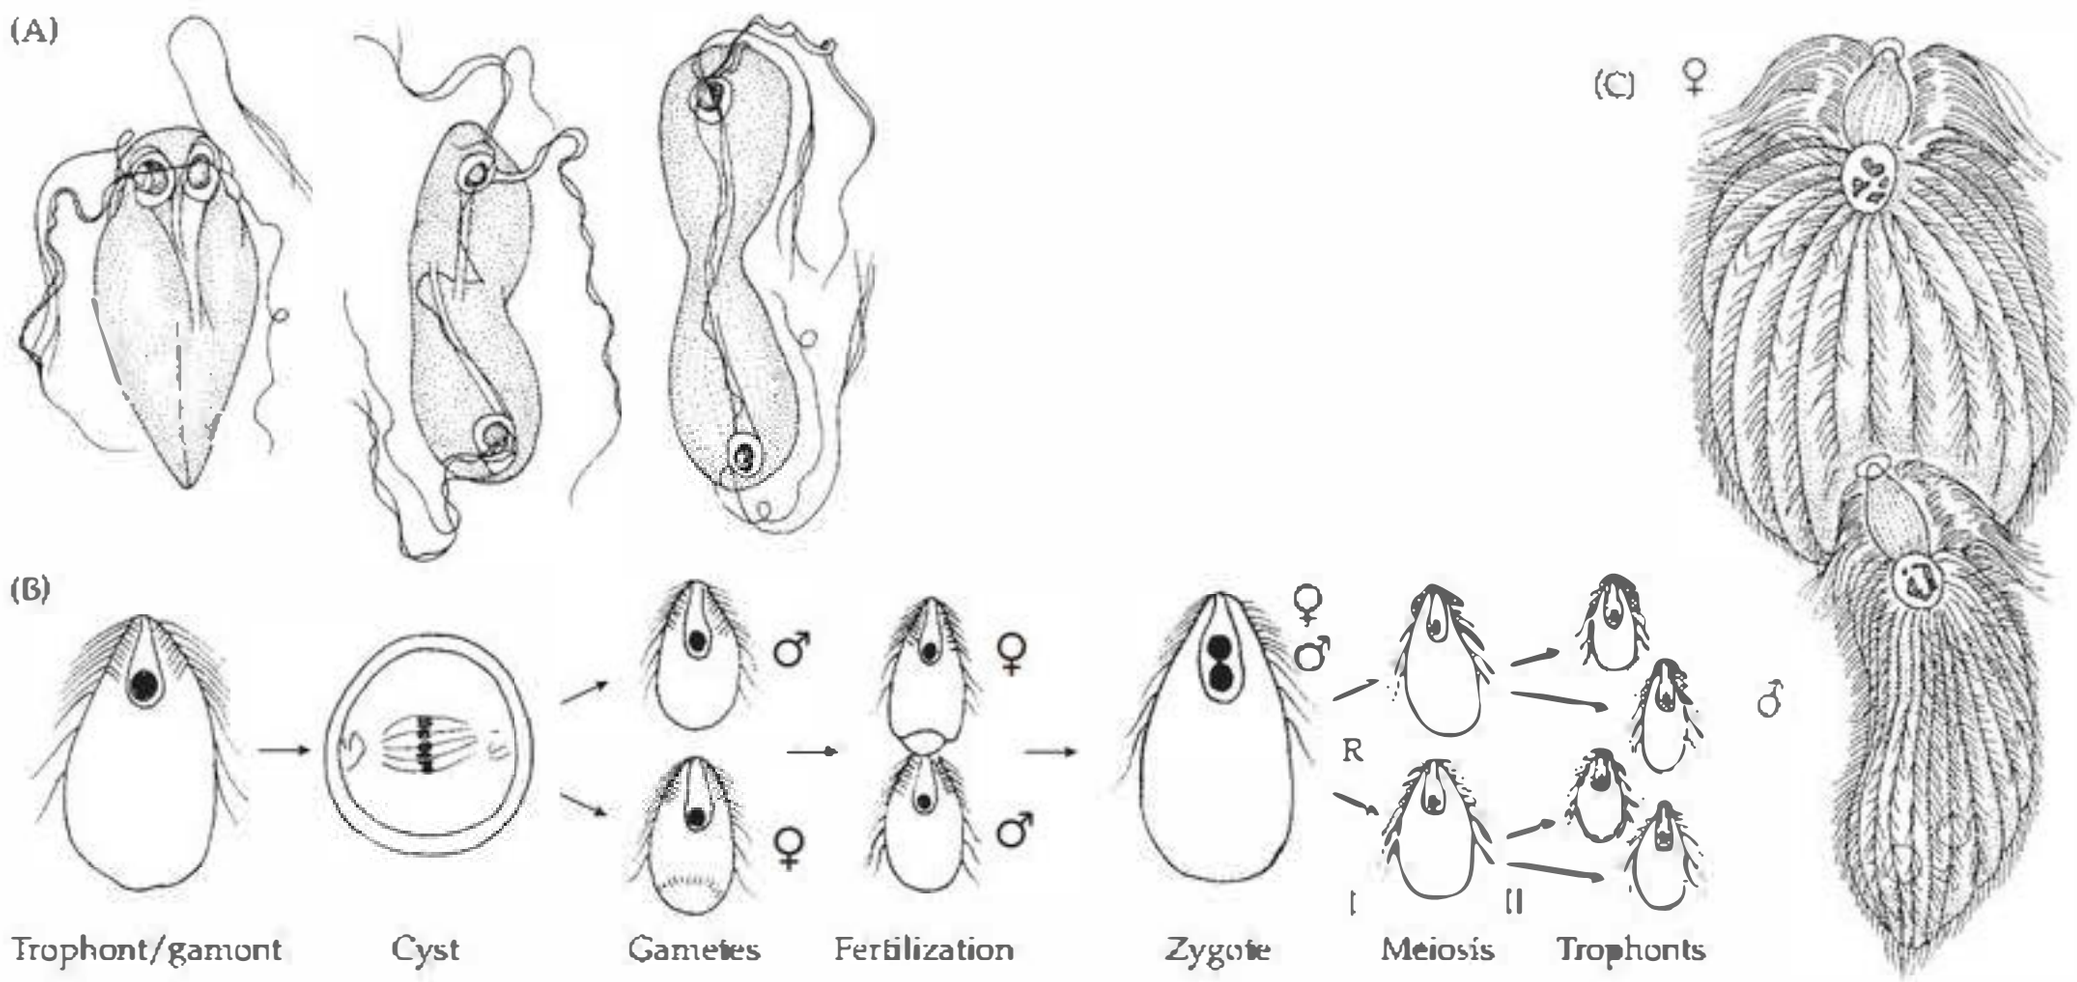

Figure 3.42 Phylum Parabasilida. Reproduction in parabasalids. (A) Longitudinal binary (asexual) fission in the trichomonad *Devescovina*. (B) Sexual reproduction in *Trichonympha* (a hypermastigote). (C) Mating activity (fertilization) in *Eucomonympha* (a hypermastigote), in which individuals act as gametes.

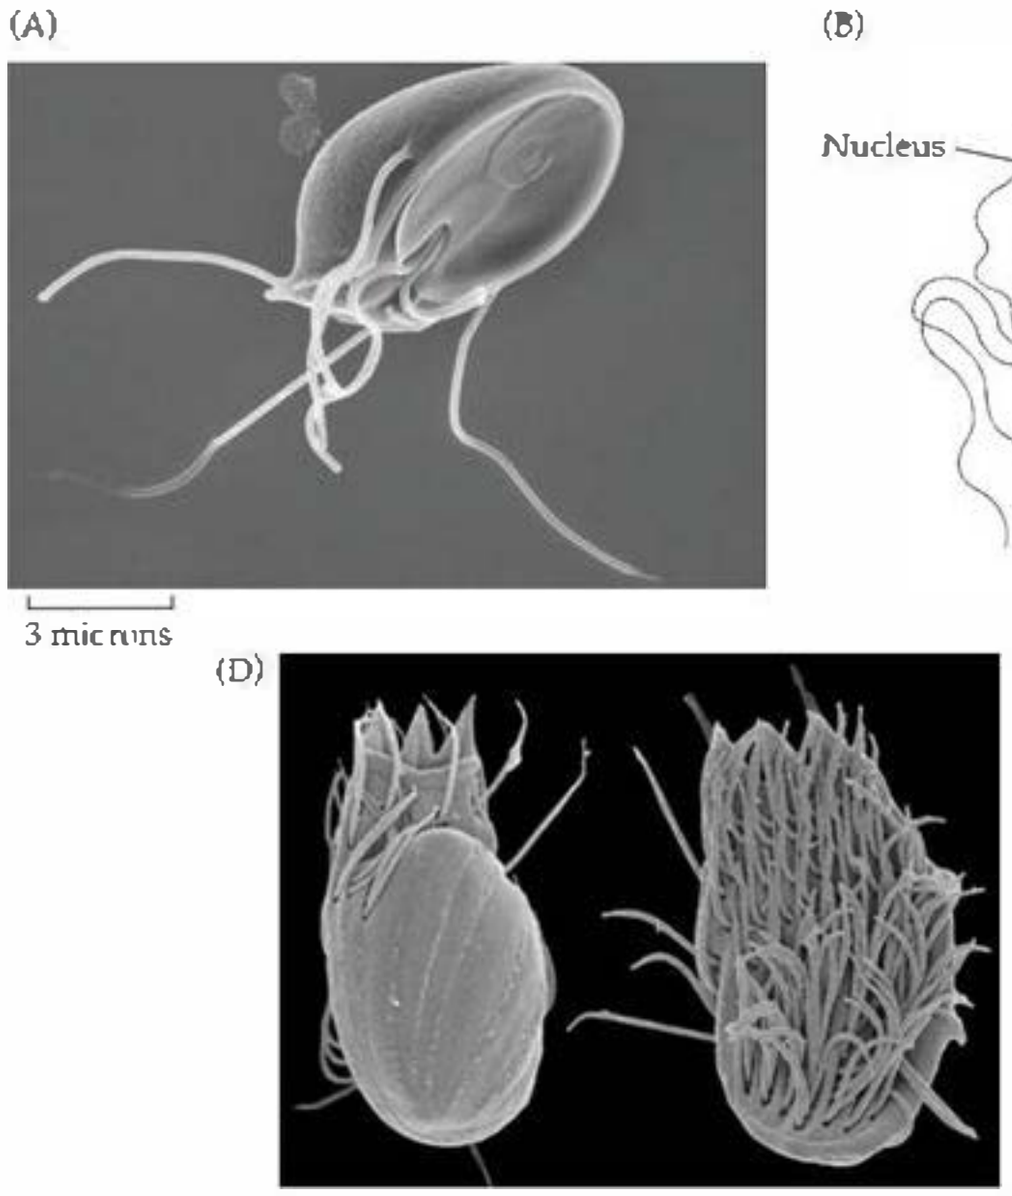

Figure 3.43 Phyla Diplomonadida and Heterolobosea. (A) *Giardia muris* can occur in the intestine of various vertebrates, although it appears to be a relatively benign parasite. The ventral adhesive disk and four pairs of flagella can be seen in this SEM photograph. Schematic drawings of *Giardia* (B) and *Hexamita* (C), illustrating the paired nuclei and numerous flagella. (D) Two views (SEMs) of *Stephanopogon minuta* (Heterolobosea), which has 8 rows of flagella on one side.

An example of a life cycle involving gametogamy is seen in *Trichonympha* (Figure 3.42B). In this group, the gametes are anisogametous, the male gamete being smaller than the female gamete. In some other species that undergo gametogamy, the gametes are isogametous. The haploid individual encysts and transforms into a gamont. While still encysted, the gamont divides by mitosis to produce a pair of flagellated gametes, one male and one female, which escape from the cyst. The posterior end of the female gamete is modified to form a fertilization cone through which the male gamete enters the cell. Once the male gamete enters, it is entirely absorbed by the female gamete, and nuclear fusion produces a diploid zygote. Within a few hours, the zygote undergoes meiosis, resulting in four haploid cells. Because *Trichonympha* are obligate anaerobes in the guts of insects, encysting prior to host molting may allow the insects to maintain their protist symbionts.

Phylum Diplomonadida: Diplomonads

The diplomonads were one of the first protist groups ever to be observed. Antony van Leeuwenhoek described a diplomonad protist, now known as *Giardia intestinalis* (=*G. lamblia*), from his own diarrheic stool as early as 1681 (Figure 3.43A). About 100 species of diplomonads are known today (Box 3P). This is a group of predominantly symbiotic flagellates, but a few free-living genera are known. Free-living species tend to be found in organically rich, oxygen-poor waters or sediments. Most diplomonads live as harmless commensals within the digestive tracts of animals, but a few are serious pathogens.

BOX 3P Characteristics of the Phylum Diplomonadida

1. Predominantly symbiotic flagellates, most of which are harmless commensals in the guts of animals (some are serious pathogens)
2. Heterotrophic; without plastids
3. Body surrounded only by plasma membrane; some rigidity provided by up to three microtubular roots associated with the flagella
4. With flagella for locomotion. Number of flagella varies (typically eight); usually divided into two equal clusters; one flagellum from each cluster usually directed posteriorly
5. Most possess two vesicular nuclei (one associated with each vesicular cluster) with minute nucleoli.
6. Mitochondria represented by highly aberrant organelles called mitosomes (which stem from an ancient endosymbiotic event)
7. Nuclear division occurs by semi-open orthomitosis, synchronous between the two nuclei. Replicated basal bodies (rather than separate centrioles) act as organizing centers for the mitotic spindle.
8. Asexual cell division by longitudinal binary fission
9. Meiosis and sexual reproduction unknown

The diplomonads are so-named because the first species described from this group had a two fold symmetry defined by a pair of karyomastigont systems (Figure 3.43B). It was later discovered that some genera (the enteromonads) have only one system. Each "karyomastigont" consists of a nucleus and a set of flagella connected to it, plus a system that consists of fibers (mostly microtubular) that originate at the basal bodies of the flagella. The pair of anteriorly located nuclei (one from each karyomastigont), along with their nucleoli, makes the protist seem to have eyes that peer up at the observer (these are the eyes van Leeuwenhoek saw looking at him in 1681). The mitochondria are highly unusual; for a long time they were thought to be completely absent, but in 2003 tiny organelles called mitosomes were identified as probable mitochondrial homologues. The mitosomes stem from the endosymbiotic event that gave rise to ancestral mitochondria, but they are now highly reduced and no longer function in cellular energy production. They are, however, known to function in at least one biosynthetic pathway.

As noted above, some diplomonads are pathogenic. *Hexamita salmonis*, a parasite of fish, causes many deaths in salmon and trout hatcheries. *Giardia intestinalis* is a common and nearly ubiquitous intestinal parasite in humans that causes diarrhea, dehydration, and intestinal pain. Although it is not fatal if treated promptly, giardiasis is one of the top ten most common parasite diseases in the world today. There are literally hundreds of millions of *Giardia* infections each year, mostly in the developing world, resulting mainly from sewage contamination of drinking water. In the United States, *G. intestinalis* is the most prevalent parasitic protist, with an incidence possibly as high as 0.7% of the national population (Box 3Q).

Most of the genome of *Giardia intestinalis* was recently sequenced. Unusual features of this enigmatic protist include the presence of two diploid nuclei and the absence of mitochondria. The two nuclei, present in the trophozoite stage, both seem to be fully functional and essentially indistinguishable, containing evidential copies of the genome. The absence of typical mitochondria have led some biologists to speculate that this genus is an ancient clade that evolved prior to the endosymbiotic event that first generated mitochondria in eukaryotes. Analysis of sequence data from the

BOX 3Q *Giardia*

The genus *Giardia* is notable among human parasites in lacking mitochondria, conspicuous Golgi bodies, and lysosomes. For many years, these had been interpreted as primitive traits that placed *Giardia* and other diplomonads near the point of divergence between prokaryotes and eukaryotes (hence the genus has been referred to as a "missing link"). However, recent studies suggest that the absence of mitochondria represents a secondary loss. There are probably five valid species in the intensely studied genus *Giardia*: *G. lamblia* (= *G. intestinalis*, = *G. duodenalis*) and *G. muris* from mammals, *G. ardeae* and *G. psittaci* from birds, and *G. agilis* from amphibians. The closely related genus *Hexamita* has no human parasites, but *H. meleagridis* is a common parasite of the guts of young gallform birds (e.g., turkey, quail, pheasant), and it causes millions of dollars in losses to the U.S. turkey industry annually. The genus *Spironucleus* includes species that cause serious diseases in fishes, including farmed salmon.

Giardia lamblia is a cosmopolitan species that occurs most commonly in developing countries. It is the most common flagellated protist of the human digestive tract—there are hundreds of millions of infections in the developing world each year, thanks to human-to-human transmission and sewage contamination of drinking water. However, it is also present in natural water bodies, including in North America, and it can be contracted by drinking nonpurified, or poorly purified water while camping and hiking. Over 30,000 cases of giardiasis are reported annually in the United States, where animal reservoirs of *G. lamblia* include beavers, dogs, cats, and sheep. Treatment with quinacrine or metronidazole ("Flagyl") usually effects complete cure within a few days.

Giardia lamblia is a teardrop-shaped organism, dorsoventrally flattened with the ventral surface bearing a concave bilobed adhesive disc with which the cell adheres to the host tissue. Eight flagella arise from kinetosomes located between the anterior portions of the two nuclei. The flagella facilitate rapid swimming. Members of this genus also possess a unique pair of large, curved, dark staining median bodies lying posterior to the adhesive discs; their function is unknown. In severe infections, the free surface of nearly every cell in the infected portion of the gut is covered by parasites. A single diarrheic stool can contain up to 14 billion parasites, facilitating the rapid spread of this very common protist. Some infections show no evidence of disease, whereas others cause severe gastritis and associated symptoms, no doubt due to differences in host susceptibility and strains of the parasite. The dense coating of these protists on the intestinal epithelium interferes with absorption of fats and other nutrients. Stools are fatty, but never contain blood. The parasite does not lyse host cells, but appears to feed on mucous secretions. Some protective immunity can apparently be acquired.

Lacking mitochondria, the tricarboxylic acid cycle and cytochrome system are absent in *Giardia*, but the organisms avidly consume oxygen when it is present. Glucose is apparently the primary substratum for respiration, and the parasites store glycogen. However, they also multiply when glucose is absent. Trophozoites divide by binary fission. As with trypanosomes and *Plasmodium*, *G. lamblia* exhibits antigenic variation, with up to 150 different antigens being expressed over 6 to 12 generations.

ribosomal RNA and elongation factor genes tend to place *Giardia* as a basal eukaryote, whereas other genes position it well within the diplomonads as one of many eukaryotic lineages that diverged nearly simultaneously with the opisthokonts and plants. However, genomic analysis has revealed the presence of a mitochondrion-like *cpn60* gene and a mitosome, which implies that the absence of typical (respiring) mitochondria in *Giardia* may reflect adaptation to a microaerophilic lifestyle, rather than divergence before the endosymbiotic event with the mitochondrial ancestor. The genome of *G. intestinalis* is small, compact, and distributed on just five chromosomes. DNA synthesis, transcription, RNA processing, and cell cycle machinery are also highly simplified. In fact, *Giardia* has fewer nucleotide sugar transporters than any other known eukaryotic genome. There are essentially no homologues for Krebs cycle enzymes and, except for scavenging pathways, no evidence of vestigial genes associated with purine and pyrimidine biosynthesis. The genome contains a single actin gene, but does not encode other classical microfilament proteins. It lacks myosins (as does the closely related genus *Trichomonas*), suggesting that either unknown novel proteins or altered cytoskeletal dynamics must be present. When attached to the surface of the intestinal mucosa, *Giardia* trophozoites have ample opportunity to pick up genes from bacteria and to scavenge products of host and bacterial metabolism. Hence, it is not surprising that, like both *Trichomonas* and *Entamoeba*, *Giardia*'s genome contains many genes that appear to have been gained secondarily via lateral gene transfer. In fact, one reason is has been so difficult to resolve *Giardia*'s evolutionary history is probably because so many genes may have been derived from horizontal transfer.

Support and Locomotion

The cell is surrounded by a plasma membrane, but some rigidity is provided by three microtubular roots that are associated with the basal bodies. These roots include a supranuclear fiber that passes over or in front of the nuclei, an infranuclear fiber that extends beneath or behind the nuclei, and a band of microtubules that parallels the posteriorly directed flagellum. Some genera have additional fibrous structures that are associated with the basal bodies. For example, the genus *Giardia* attaches to the host's intestinal epithelium with an adhesive disc that is constructed in part from the microtubular bands of the cytoskeleton. The disc is delimited by a ridge or lateral crest that is composed of actin and is used to "bite" into the host's tissue. The contractile proteins myosin, actin, and tropomyosin have all been reported around the periphery of the disc and may be involved with attaching to the host. The supranuclear fiber in *Giardia* is composed of a single ribbon of microtubules that connects to the plasma membrane of the disc. Each microtubule of the supranuclear fiber is associated with a ribbon of protein that extends into the cytoplasm.

Each karyomastigont system typically has four flagella. The flagella are of at least two kinds, although in *Giardia* each of the four flagella that form each karyomastigont has a distinct appearance. Locomotion is accomplished by the coordinated actions of the eight flagella (although not all play a direct locomotory role in all species). It has been suggested that the flagella may also be involved with creating a suction force beneath the adhesive disc in *Giardia*, enabling it to attach to its host.

Nutrition

Most diplomonads are phagotrophic and feed on bacteria. These forms have a cytostome through which bacteria are engulfed via endocytosis. In some (e.g., *Spironucleus, Hexamita*) the two intracellular channels in which the posterior flagella lie function as cytostomes. Other genera such as *Giardia* and *Octomitis* lack cytostomes and are saprozoic, feeding upon mucus secretions of the host's intestinal tissue through simple pinocytosis.

Reproduction

Asexual reproduction is the only reproductive mode known to occur in diplomonads, and division occurs along the longitudinal plane. Nuclear division involves semiopen orthomitosis and is synchronous between the two nuclei (if there are two). Replicated basal bodies act as organizing centers for the mitotic spindle. Most symbiotic diplomonads form cysts at some point during their life cycle, thus alternating between a motile trophozoite form and a dormant encysted form. *Giardia intestinalis*, for example, will form a thick protective covering that resists desiccation as it passes from the host's small intestine into the large intestine, where it is prone to dehydration. Once it leaves the digestive system through the anus, it must be swallowed by another host, where it will travel through the digestive system until it reaches the duodenum of the small intestine and excyst.

Phylum Heterolobosea: Heterolobosids

The Heterolobosea comprise a small and enigmatic protist group, first described in 1985, that seems to be most closely related to the phyla Euglenida and Jakobida. Many heterolobosids can transform between amoeboid, flagellate, or cyst forms, although the amoeboid stage is most frequently seen. Flagellate stages typically have 2 or 4 flagella and possess the typical Excavata feeding groove. The ameboid stage does not form true pseudopods. Instead, they move with "eruptive waves" which bulge from one end of the cell. All have mitochondria. Ameboid stages seem to be mainly

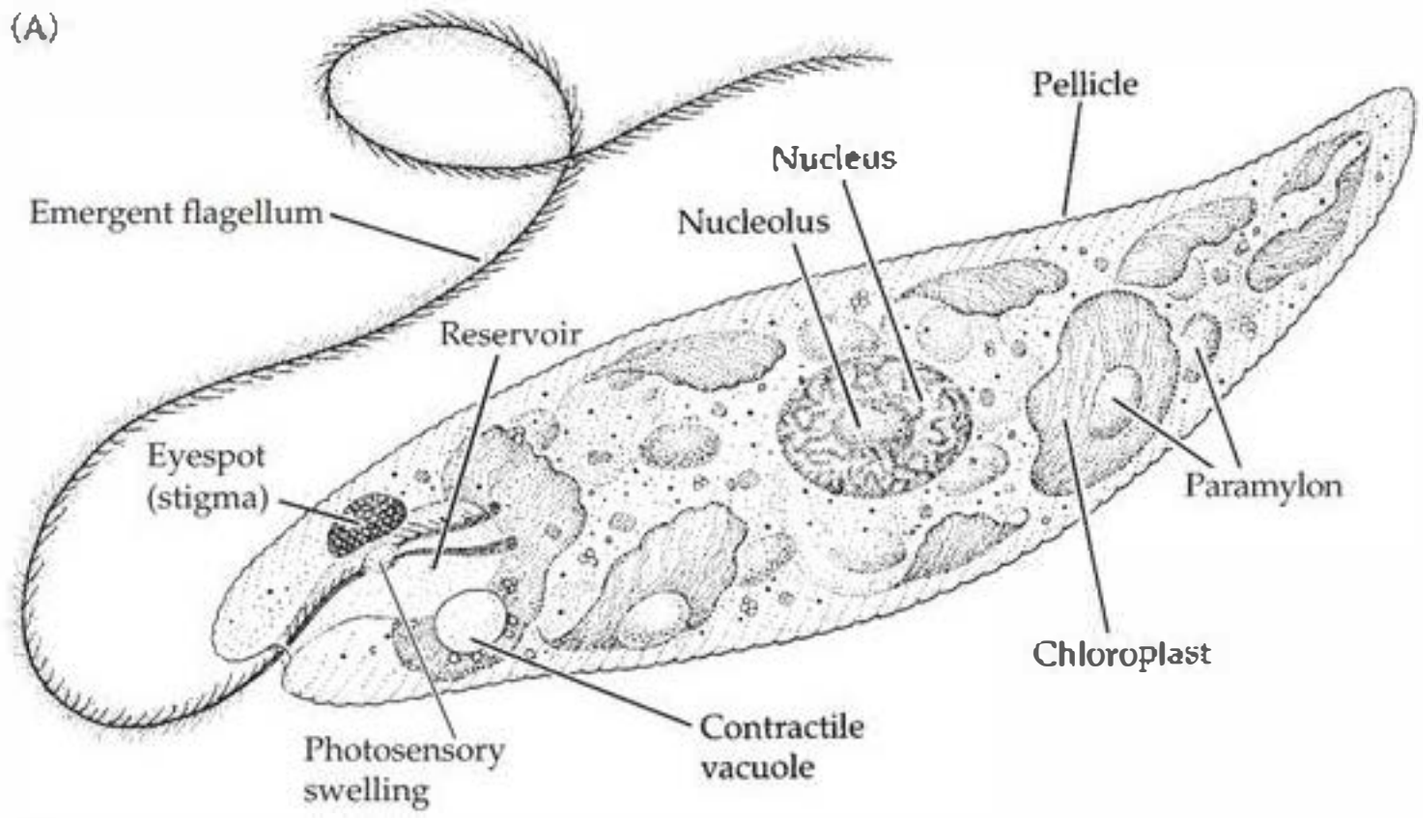

Figure 3.44 Phylum Euglenida. (A) Anatomy of *Euglena*. (B) *Entosiphon*. (C) A variety of *Euglena* species and body shapes.

feeding; flagellate stages, many locomotory. Most heterolobosids live as bacteriovores in soil, but they are also found in freshwater and organic waste (including feces). A few species are marine and some species are parasitic, including *Naegleria fowleri*, which can become pathogenic in humans and is mostly fatal.

Phylum Euglenida: Euglenids

The Euglenida include about 1,000 described species, mostly from fresh water but marine and brackish-water species are also common. Most are noncolonial, but some colonial forms exist (e.g., *Colacium*). Euglenids come in a wide variety of shapes (e.g., elongate, spherical, ovoid, peltate) (Figures 3.44 and 3.1F). The familiar genus *Euglena* has been used extensively in research

BOX 3R Characteristics of the Phylum Euglenida

1. Mostly marine, although the majority of the described species are freshwater
2. Shape of cell maintained by pellicle, formed by interlocking strips of protein beneath the cell membrane that are associated with linked microtubules arranged in regular pattern (also beneath the cell membrane). Some species secrete a mucous lorica.
3. With two flagella of unequal length for locomotion, supported by paraxonemal rods (one of the flagella may be greatly reduced); each flagellum usually with hairs; one or both flagella arise from an anterior pocket, the reservoir
4. Single mitochondrion has discoidal cristae
5. With single chromosomal nucleus
6. Heterotrophic or autotrophic. Photosynthetic forms have chlorophylls a and *b*; usually appear grass-green in color. Thylakoid membranes arranged in stacks of three; three membranes surround the chloroplast; outermost membrane not continuous with nuclear membrane
7. Food reserves stored in cytoplasm as the unique starchlike carbohydrate, paramylon
8. Nuclear division occurs by closed intranuclear pleuromitosis without centrioles; organizing center for mitotic spindle is not obvious
9. Asexual reproduction by longitudinal binary fission
10. May be strictly asexual—neither meiosis nor sexual reproduction has been confirmed

laboratories for decades, and it is commonly studied in introductory biology and invertebrate zoology courses (Box 3R).

The phyla Euglenida and Kinetoplastida are closely related, even though some euglenids are photosynthetic and some kinetoplastids (see below) are parasitic heterotrophs. Shared morphological features include: linked microtubules underlying the cell membrane; discoidal mitochondrial cristae; flagella containing a latticelike, spiral, or crystalline supportive rod (the paraxonemal rod); an anterior pocket from which the two flagella arise; and a similar pattern of mitosis. Molecular studies have also corroborated the close relationship of these two groups. Most recently, the odd, low-oxygen, deepsea genus *Calkinsia* has also been shown to belong to the Euglenozoa clade, sharing the same paraxonemal rods, microtubular root system, and extrusomes seen in Euglenida and Kinetoplastida.

Euglenids are commonly found in bodies of water rich in decaying organic matter. As such, some of them are useful indicator organisms of water quality (e.g., *Leocinclis, Phacus, Trachelomonas*). Some species of *Euglena* have been used in experiments for wastewater treatment and have been reported to extract heavy metals such as magnesium, iron, and zinc from sludge. Other euglenids, however, are environmental pests, and some have been shown to produce toxic substances associated with diseases in trout fry. Still others are responsible for toxic blooms, which have caused destruction of fishes and molluscs in Japan. Many species are phagotrophic, hunting particulate food items such as other small protists and bacteria.

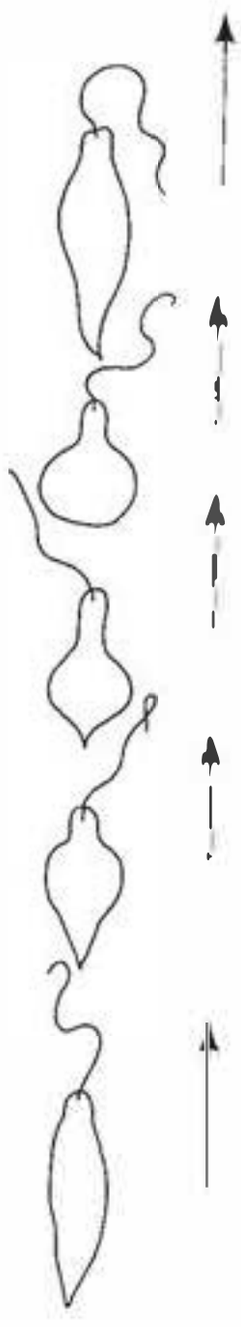

Figure 3.45 Phylum Euglenida. Euglenoid movement in *Euglena*.

Support and Locomotion

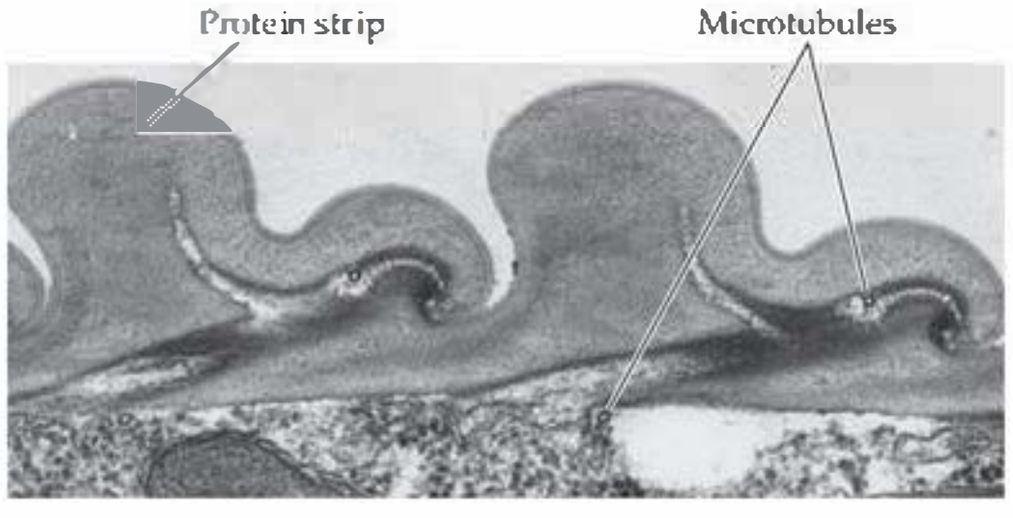
The shape of euglenids is maintained by a pellicle consisting of interlocking longitudinally or helically arranged strips of protein that articulate along their lateral margins. The stripes that can sometimes be seen on a euglenid are the seams between the long protein strips winding around the cell. The pellicle is also supported by regularly arranged microtubules lying just underneath each strip. The rigidity of the pellicle is variable. Some (e.g., *Menodium, Rhobdomonas*) have protein strips that are fused together into a rigid pellicle, while others (e.g., *Euglena*) have protein strips that are articulated to produce a flexible pellicle. Those euglenids with a flexible pellicle undergo euglenoid movement, or **metaboly**, in which the cell undulates as it rapidly extends and contracts (Figures 3.44 and 3.45). Although this type of movement is not fully understood, it is accomplished by the microtubular-driven sliding of adjacent protein strips against one another (Figure 3.46).

A few euglenids (e.g., *Ascoglena, Colacium, Strombomonas, Trachelomonas*) secrete a lorica, or envelope, exterior to the cell membrane. The lorica is formed by the mucus secretions of small vesicles called mucocysts, which are located under the cell membrane along the seams between the protein strips of the pellicle. Secretions of mucocysts are also used to form protective coverings when environmental conditions become unfavorable.

Locomotion in euglenids is primarily by flagella. They have two flagella, but one may be very short or represented by just a kinetosome. The flagella originate in an invagination at the anterior end of the cell, called a reservoir (= flagellar pocket). In photosynthetic species, the longer, anteriorly directed flagellum (the emergent flagellum) propels the cell through the water or across surfaces. The shorter flagellum either trails behind or does not emerge from the reservoir at all. In many heterotrophs (e.g., *Entosiphon*), the posterior flagellum is actually the longer of the two and is involved in gliding locomotion, while the anterior flagellum is probably primarily for food detection and other tactile functions. Both flagella have a single row of hairs on their surface and a latticelike supporting rod, called the paraxonemal rod, lying adjacent to the microtubules within the shaft. In phagotrophic euglenids, the flagella (with associated paraxonemal rods and hairs) are used to glide along substrates.

Nutrition

Euglenids are quite variable in their nutrition. About one-third of the Euglenids have chloroplasts and are photoautotrophic. These species are positively phototactic and have a swelling near the base of the anterior



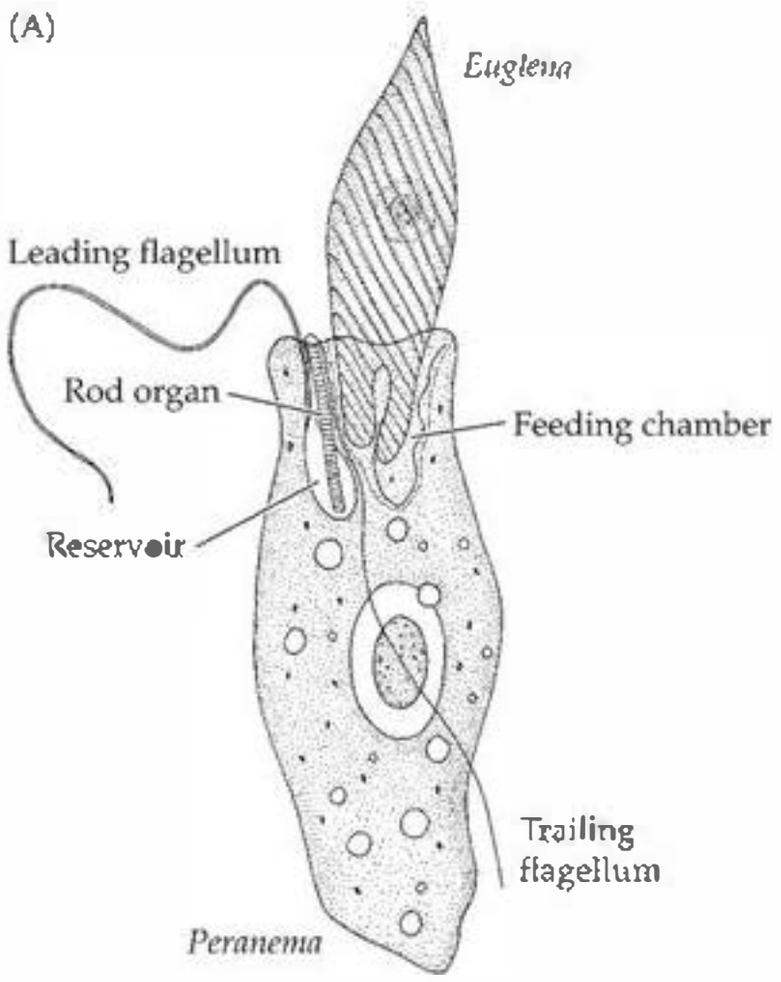


Figure 3.46 Phylum Euglenida. Cross section (TEM) through the pellicle of *Euglena* showing the protein strips and microtubules.

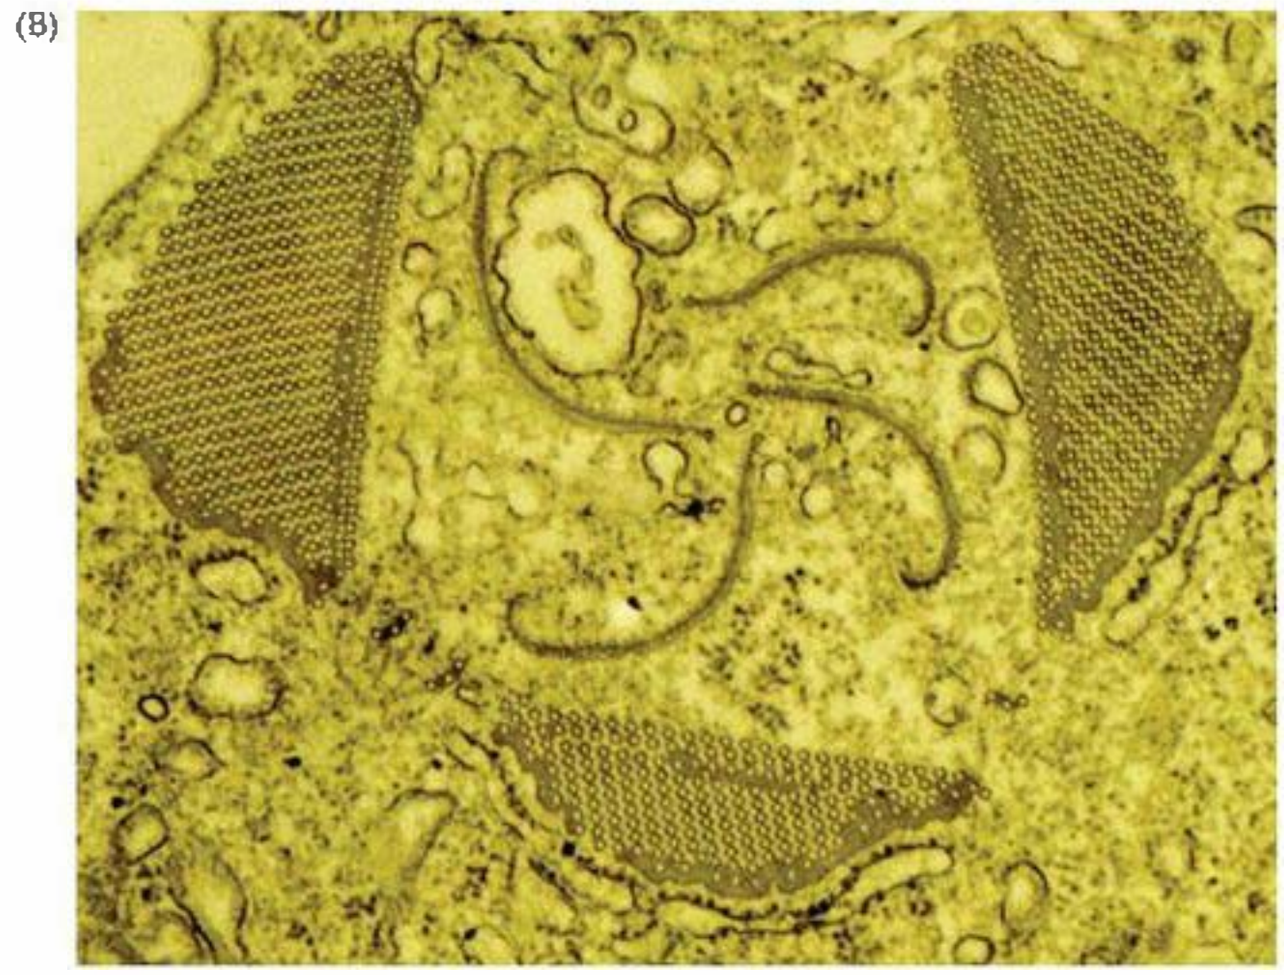

Figure 3.47 **Phylum Euglenida.** (A) *Paranema* feeding on *Euglena*. *Paranema* possesses an expandable feeding pocket separate from the reservoir in which the flagella arise. The rod organ can be extended to pierce prey and either pull it into the feeding apparatus or hold it while the contents are sucked out. (B) TEM through the cytopharyngeal rods and vanes of the euglenid *Entosiphon*.

flagellum that acts as a photoreceptor. The chloroplast is surrounded by three membranes and has thylakoids that are arranged in stacks of three (see Figure 3.2). The photosynthetic pigments include: chlorophylls *a* and *b*, phycobilins, β-carotene, and the xanthophylls neoxanthin and diadinoanthin.

Approximately two-thirds of the described species of euglenids lack chloroplasts and are thus obligate heterotrophs, and even phototrophic forms can lose their chloroplasts and switch to heterotrophy. A few parasitic species have been reported in invertebrates and frog tadpoles, but these reports remain questionable. Most euglenids also take in dissolved organic nutrients by saprotrophy, and this is generally restricted to parts of the cell not covered by the pellicle (e.g., the reservoir). Some euglenids also ingest particulate food items by phagocytosis of relatively large (sometimes comparatively huge) food materials. These have a cytostome located near the base of the flagella where food vacuoles form (e.g., *Peranema*; Figure 3.47A). The cytostome typically leads to a tube (the "cytopharynx") that extends deep into the cytoplasm. The walls of the cytopharynx are often reinforced by highly organized bundles of microtubules (e.g., *Entosiphon*, *Peranema*) (Figure 3.47B). Extrusomes are often found near the cytostome and presumably aid in prey capture. Euglenids typically store food reserves in the form of starches and a unique molecule called paramylon, which is a starchlike carbohydrate.

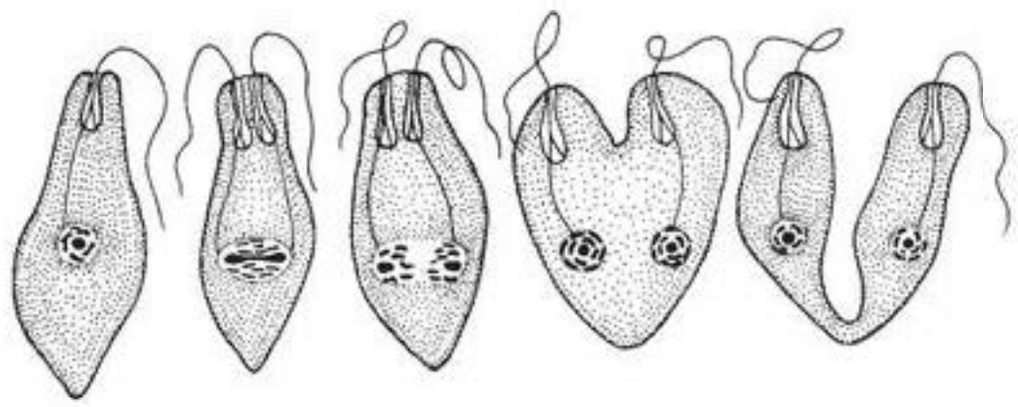

Figure 3.48 **Phylum Euglenida.** Asexual reproduction. Longitudinal fission in *Euglena*, in which the flagella and reservoir duplicate prior to cell division.

Reproduction

Asexual reproduction in euglenids primarily is by longitudinal cell division (Figure 3.48). Nuclear division occurs by closed intranuclear pleuromitosis. During mitosis, the nucleolus remains distinct and no obvious microtubular organizing center is evident. Sexual reproduction has been reported in one species, but this has not been confirmed.

Phylum Kinetoplastida: Trypanosomes, Bodonids, and Their Kin

There are about 600 described species of kinetoplastids. The phylum includes two major groups: the bodonids and the trypanosomes (*Trypanosoma*, *Leptomonas*, *Leishmania*, etc.) (Figures 3.49 and 3.1F). The bodonids are primarily free living in marine and freshwater en-

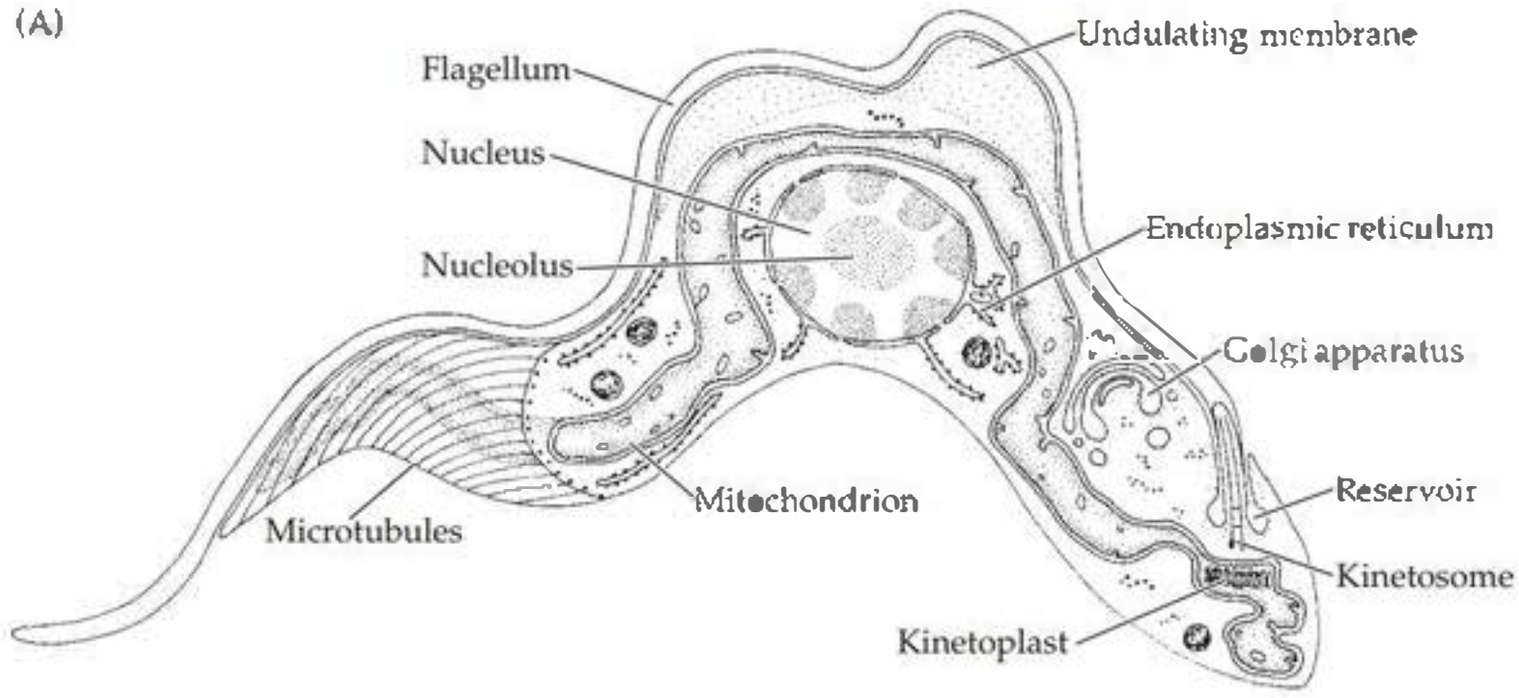

Figure 3.49 Phylum Kinetoplastida. (A) *Trypanosoma brucei*, a bloodstream parasite. (B) *Bodo caudatus*, a free-living kinetoplastid. (C) Electron micrograph of a trypanosome.

vironments, especially those rich in organic material. Like phagotrophic euglenids, they are often associated with surfaces, but generally being smaller they tend to take smaller prey and consequently are important consumers of bacteria in these habitats. Because bodonids have strict oxygen preferences they often aggregate at a particular distance from the water surface. The trypanosomes (or trypanosomatids) are exclusively parasitic, and they occur in the digestive tracts of invertebrates, phloem vessels of certain plant species, and the blood of vertebrates. *Leptomonas* exhibits the simplest life cycle, in which an insect is the sole host and transmission occurs by way of an ingested cyst. In humans, *Leishmania* and *Trypanosoma* cause several debilitating and often fatal diseases. There are no vaccines for diseases caused by these protists, and the few drugs that are used are inadequate because of toxicity and resistance. However, these human parasites are very closely related, sharing a conserved core proteome of about 6,200 genes, suggesting that a genetic-based scientific attack on these protists might be possible as we come to better understand their gene expression patterns (Box 3S).

Kinetoplastids are best known as agents of disease in humans and domestic animals. Species of *Leishmania* cause a variety of ailments collectively called leishmaniasis, and these include kala-azar (a visceral infection that particularly affects the spleen), oriental sore, and "Baghdad boil" (characterized by open, slow-healing, sometimes disfiguring skin boils; parasites that spread to internal organs and can cause death if left untreated), and several other skin and mucous membrane

BOX 3S Characteristics of the Phylum Kinetoplastida

1. Bodonids are primarily free-living heterotrophs in marine and freshwater environments; trypanosomes are strictly parasitic in the digestive tracts of invertebrates.
2. Shape of cell maintained by a pellicle, consisting of the cell membrane and a corset of microtubules beneath it.
3. With one (trypanosomes) or two (bodonids) flagella for locomotion. Flagella contain a paraxonemal rod and arise from an anterior pocket. Flagellum of trypanosomes usually forms an undulating membrane.
4. Single, large, elongate mitochondrion has discoidal cristae and conspicuous discoidal concentration of mDNA (the kinetoplast). Shape of cristae can change as organism progresses through life cycle, but predominantly discoidal.
5. With single vesicular nucleus; prominent nucleolus typically evident.
6. Nuclear division occurs by closed intranuclear pleuromitosis without centrioles. Plaques on inside of nuclear envelope may act as organizing centers for mitotic spindle.
7. Asexual reproduction by longitudinal binary fission.
8. Neither meiosis nor sexual reproduction has been confirmed, although indirect evidence suggests sex might occur in at least some kinetoplastids.
9. Without plastids.
10. Mitochondrial DNA forms aggregates, collectively known as the kinetoplast, readily seen with the light microscope.

infections. Leishmaniasis strikes over one million humans annually but due to effective treatment, it only kills about 1,000 people each year (although many survivors are badly scarred). Leishmaniasis occurs in the tropics and subtropics, and it is transmitted almost exclusively by the bite of sand flies (Diptera: Psychodidae: Phlebotominae). The Neotropical species *Leishmania mexicana* first appeared in the United States (in Texas) in 2007—one of many tropical parasites that are beginning to show up in the United States as climates warm. Both *Trypanosoma* and *Leishmania* were long thought to be asexual and clonal, but in the 1980s solid evidence began to appear that they were also capable of genetic exchange (Box 3T).

More serious diseases are caused by members of the genus *Trypanosoma*, all of which are parasites of vertebrates. *Trypanosoma brucei* is a debilitating parasite that lives in the bloodstream of African hoofed animals, in which it causes a disease called nagana (which kills about three million farm animals annually). It also attacks domestic livestock, including horses, sheep, and cattle; in the latter case it is often fatal, making it impossible to raise livestock on more than 4.5 million square miles of the African continent (an area larger than the United States). Two other African species (sometimes considered subspecies of *T. brucei*) are *T. gambiense* and *T. rhodesiense*, both of which cause sleeping sickness in humans. These parasites are introduced into the blood of humans from the salivary glands of the blood-sucking tsetse fly (*Glossina*). From the blood, trypanosomes can enter the lymphatic system and ultimately the cerebrospinal fluid. It is estimated that 300,000 to 500,000 people annually contract sleeping sickness, and once it enters the brain it is invariably fatal if untreated (it kills about 100,000 people annually). Tsetse flies have been called "vampires of the insect world," because of their voracious appetite for blood. Whereas only female mosquitoes sip blood, among tsetse flies both sexes will drink nearly their own weight in blood with each meal. Infected flies are known to drink more frequently, favoring transmission of the trypanosome parasite to more vertebrate hosts.

Chagas disease (common in Central and South America, and Mexico) is caused by *Trypanosoma cruzi* and is transmitted to humans by cone-nosed hemipteran bugs (also known as assassin or kissing bugs; family Reduviidae, subfamily Triatominae). These bugs feed on blood and often bite sleeping humans. They commonly bite around the mouth, hence the vernacular name. After feeding they leave behind feces that contain the infective stage, which invades through mucous

BOX 3T Leishmaniasis

Species of *Leishmania* are difficult to differentiate morphologically, and their taxonomy is unsettled (although now being unraveled by molecular genetics). Most widespread are *Leishmania infantum* and *L. major*, which occur in Africa and southern Asia and are transmitted by species of the sand fly genus *Phlebotomus* (Psychodidae). These species produce the cutaneous ulcers variously known as oriental sore, cutaneous leishmaniasis, Jericho boil, Aleppo boil, and Delhi boil. *Leishmania donovani* is endemic to southern Asia but also occurs in low levels in Latin America and the Mediterranean region; it is the etiological agent of Dum-Dum fever or kala-azar. Kala-azar can result in extreme and even grotesque skin deformations. *Leishmania braziliensis* is endemic to Brazil, where it causes espundia, or uta, which often leads to such severe destruction of the skin and associated tissues that complete erosion of the lips and gums ensues. *Leishmania mexicana* occurs in northern Central America, Mexico, Texas, and probably some Caribbean islands, where it mostly affects agricultural or forest laborers. Infections of *L. mexicana* cause a cutaneous disease called chicle ulcer, because it is so common in "chicleros," men who harvest the gum of chicle trees.

membranes or the wound caused by the insect's bite. Occasionally the bugs bite around the eyes of the sleeping victims, and subsequent rubbing leads to conjunctivitis and swelling of a particular lymph node, a symptom known as Romaña's Sign. The parasites migrate to the bloodstream, where they circulate and invade other tissues. In chronic human infections, *T. cruzi* can cause severe tissue destruction, including the enlargement and thinning of walls of the heart In Central and South America the incidence of Chagas disease is high, and an estimated 15 to 20 million persons are infected at any given time with an annual death rate recognized at ~21,000 people. A study in Brazil attributed a 30% mortality rate to Chagas disease. In the United States, at least 14 species of mammals may serve as reservoirs for *Trypanosoma cruzi* (including dogs, cats, opossums, armadillos, and wood rats). However, the U.S. strain of *T cruzi* is less pathogenic than the Mexican and Central and South American strains, and the species of *Triatoma* in the U.S. tend not to defecate when they bite, thus leading to a lower incidence of the disease north of Mexico. In recent decades, *T cruzi* has also been found to spread by way of blood and organ donations.

The Kinetoplastida have a single, large, elongate mitochondrion with a uniquely conspicuous dark-staining concentration of mitochondrial DNA (mDNA) called the **kinetoplast** (hence the phylum name). Generally the kinetoplast is found in the part of the mitochondrion lying close to the kinetosomes, although there is no known relationship between these two structures. The size, shape, and position of the kinetoplast are important in the taxonomy of trypanosomes and bodonids, and it is used in distinguishing between different stages in the life cycle. Kinetoplast DNA (kDNA) in trypanosomes is organized into a network of linked circles, quite unlike the DNA in mitochondria of other organisms. Kinetoplastids share many ultrastructural and molecular features with the euglenids, their putative sister group (see Euglenida, above).

Support and Locomotion

The shape of the cells is maintained by a pellicle consisting of the cell membrane and a supporting layer of microtubules. In some smaller bodonids, the pellicular microtubules consist of three microtubular bands, whereas in other bodonids, and in trypanosomes the pellicular microtubules are evenly spaced and form a more-or-less complete corset that envelops the entire body. In trypanosomes, a layer of glycoprotein (12 to 15 μm thick) coats the outside of the cell and acts as a protective barrier against the host's immune system. The composition of the glycoprotein coat is changed cyclically; as a result, the trypanosome is able to avoid the host's immune system. This has been well studied in pathogenic trypanosomes such as *Trypanosoma brucei* (the causative agent of African sleeping sickness). When the trypanosome enters the host's body, the immune system recognizes the glycoprotein as foreign (an antigen) and specific antibodies are made against it. Although most of the trypanosome population is destroyed, a few cells are able to evade the immune system by changing their glycoprotein coat so that the new coat is unrecognizable to the host's antibodies. Once a new antibody is produced by the host, another new glycoprotein is produced by the trypanosome, and so on. About 1,000 genes contain information that encodes surface glycoproteins, although it appears that only one of these genes is expressed at a time. The ability of trypanosomes to change their glycoprotein coat makes treatment of trypanosome infections difficult.

Both bodonids and trypanosomes move using flagella, which, like those of euglenids, usually emerge from an inpocketing and contain a paraxonemal rod. Trypanosomes have two kinetosomes, but only one has a flagellum. In many forms this flagellum lies against the side of the cell and its outer membrane is attached to the cell body's membrane. When the flagellum beats, the membrane of the cell is pulled up into a fold and looks like a waving or undulating membrane (see Figure 3.49). This arrangement appears to be relatively efficient in moving the cell through viscous media (e.g., blood). Although trypanosomes can change the direction of flagellar beat in response to chemical or physical stimuli, usually the beat begins at the tip of the flagellum and proceeds toward the kinetosome. This is the reverse of the way the flagella of other eukaryotes beat (from base to tip). Bodonids usually have two flagella: one is extended anteriorly while the other trails behind and may be partially attached to the body in some species (e.g., *Dimastigella, Procryptobia*). Although most bodonids swim, they also employ various mechanisms to move efficiently across surfaces, including a gliding type of locomotion.

Nutrition

All kinetoplastids are heterotrophic. Free-living bodonids capture particulate food, primarily bacteria, with the aid of their anterior flagellum and ingest through a permanent cytostome. Most are raptorial feeders, ingesting prey items (especially attached bacteria) one at a time. The cytostome leads to a cytopharynx, which is supported by microtubules. At the base of the cytopharynx, food is enclosed in food vacuoles by endocytosis

Little is known about feeding mechanisms in trypanosomes, all of which are parasitic. Some trypanosomes have a cytostome cytopharyngeal complex through which proteins are ingested. The proteins are taken into food vacuoles by pinocytosis at the base of the cytopharynx. It has also been reported that some trypanosomes can take in proteins by pinocytosis from the membrane lining the flagellar pocket or by some sort of cell membrane-mediated mechanism.

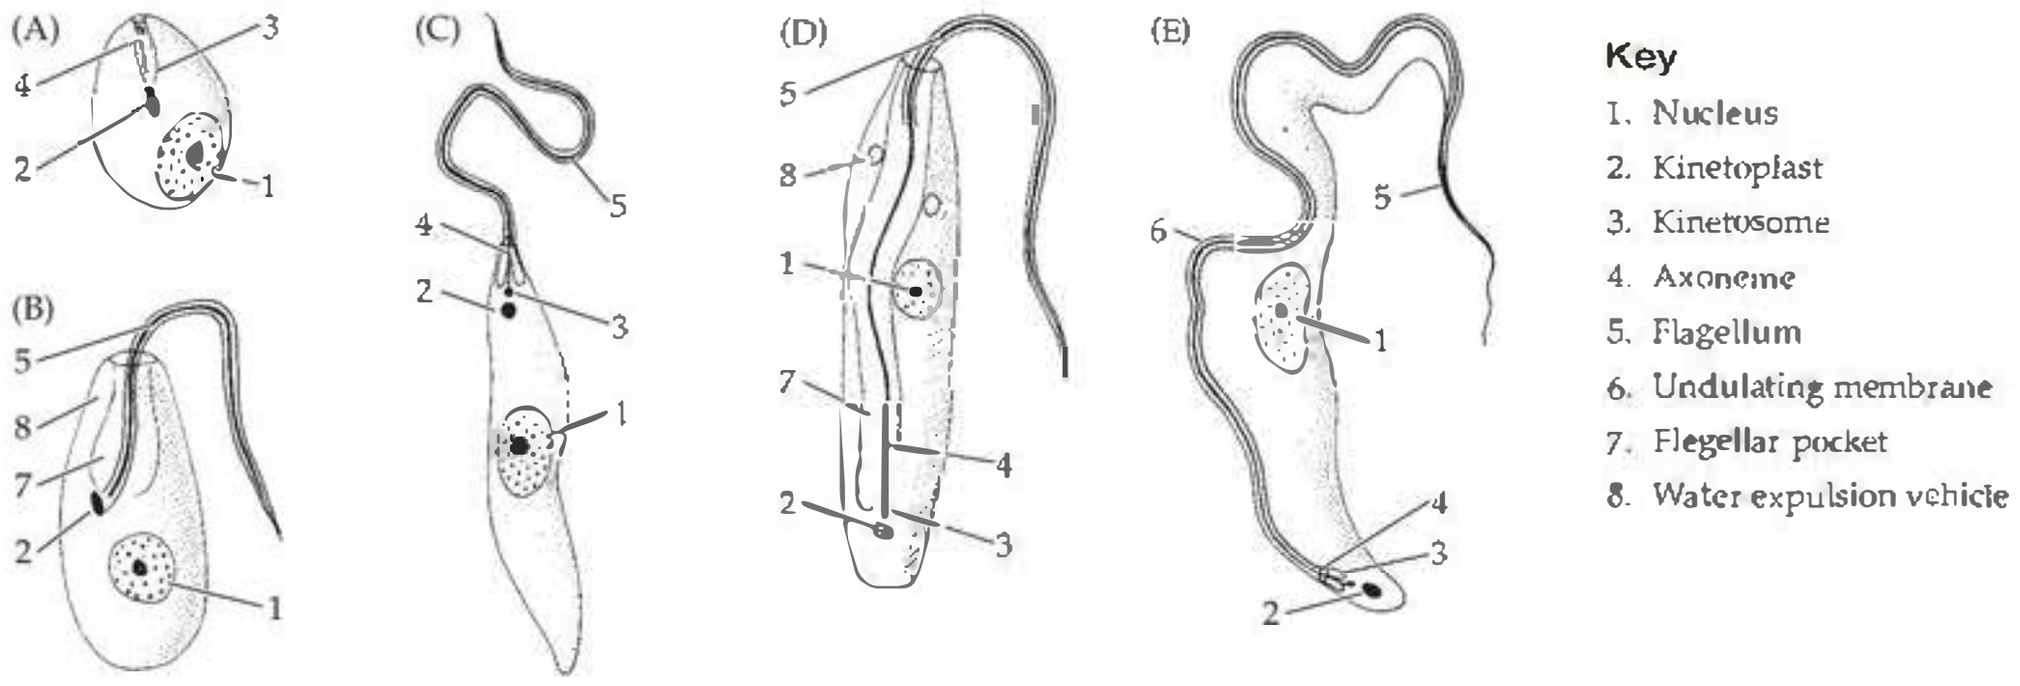

Figure 3.50 Phylum Kinetoplastida. Body plans of various trypanosomes. (A) *Leishmania* (amastigote form). (B) *Crithidia* (choanomastigote form). (C) *Leptomonas* (promastigote form). (D) *Herpetomonas* (opisthomastigote form). (E) *Trypanosoma* (trypomastigote form).

Reproduction and Life Cycles

Although sexual reproduction has never been observed in kinetoplastids, there is indirect genetic evidence that it occurs. Asexual reproduction occurs by longitudinal binary fission, as in *Euglena*. Nuclear division is by closed intranuclear pleuromitosis. During pleuromitotic mitosis, the nucleolus remains distinct and plaques on the inside of the nuclear envelope appear to organize the spindle (centrioles are absent). An unusual feature of kinetoplastid mitosis is that condensed chromosomes cannot be identified when the nucleus is dividing, even though they are typically conspicuous during interphase.

The life cycles of trypanosomes are complex and involve at least one host, but usually more. Monoxenous trypanosomes (those with one host) usually are found infecting the digestive tracts of arthropods or annelids. Most heteroxenous forms (those with more than one host) live part of their life cycle in the blood or organs of vertebrates and the remaining part of their life cycle in the digestive tracts of bloodsucking invertebrates, usually insects, sometimes leeches. As a trypanosome progresses through its life cycle, the shape of the cell undergoes different body form changes, depending on the phase of the cycle and the host it is parasitizing. Not all of these forms (Figure 3.50) occur in all genera. Body forms can differ in shape, position of the kinetosome and kinetoplast, and in the development of the flagellum.

GROUP 5: OPISTHOKONTA

Phylum Choanoflagellata (Choanoflagellates)

The choanoflagellates are stalked, sessile cells existing singly or in colonies (Figure 3.51). They are distinctive in that they are seemingly identical to choanocytes, the flagellated feeding cells of sponges. Like choanocytes, they have a single flagellum that is encircled by a basketlike transparent collar of retractile microvilli that contain actin filaments. The microvilli are sometimes called "collar tentacles"—perhaps to differentiate them from microvilli that are not retractile and lack a special cytoskeleton of microtubules connected to the basal body of the cilium. The central flagellum has a pair of basal, lateral vanes, just as in sponge choanocytes. Also, in both choanoflagellates and sponges a true ciliary rootlet is absent.[3] The collar acts as a food-catching net; feeding is accomplished when food particles are swept into the collar by the beating of the flagellum, pressed down against the cell surface, and engulfed by small pseudopodia. The choanoflagellates have long been viewed as a transitional link between flagellated protists and the sponges, or more specifically, as the actual ancestors of the Porifera, and thus the Metazoa. In addition to the structure of the collar itself, some choanoflagellates secrete a skeleton of siliceous pieces

[3]Rootlets do occur in monociliated cells of sponge larvae and in most metazoan monociliated cells.

Figure 3.51 Phylum Choanoflagellata. The choanoflagellate *Salpingoeca*.

similar to sponge spicules. DNA data support this hypothesis, although extant choanoflagellates appear to be a monophyletic group and thus sister to Metazoa. On the other hand, some protozoologists in the past have suggested the possibility that, because they are not obviously related to any other protist group, choanoflagellates might actually be highly reduced sponges!

About 150 species of choanoflagellates, in three families, have been described. Most are marine, but a few freshwater species are also known. Codosigidae (=Monosigidae) are naked cells, or cells with thin organic vestments (e.g., *Codonosiga, Sphaeroeca*). Salpingoecidae have cellulose theca (e.g., *Salpingoeca, Stelexomonas*). Acanthoecidae produce extracellular loricae made of tiny strips of silica, usually forming an open basketlike structure (e.g., *Bicosta, Stephanoeca*). The lorica of acanthoecids may be several times larger than the cell. Salpingoecids and acanthoecids are restricted to marine and brackish waters and are mostly planktonic. They are present in huge numbers in the world's oceans, and are thought to be among the most important groups of bacteria-consuming organisms in marine systems, and therefore of major ecological significance

Protist Phylogeny

The Origin of the Protista

We can do no more than touch upon the myriad questions and interesting ideas concerning the origin and evolution of the protists. Beyond the fast moving field of protist phylogeny, we are faced here with questions about the very origin of eukaryotic life, as well as the ancestry of the multicellular eukaryotic kingdoms—Plantae, Metazoa, and Fungi. The origin of the Protista (and the Eukaryota) probably took place 2.0 to 2.5 billion years ago. Although there are over 30,000 known fossil species of protists, they are of little use in establishing the origin or subsequent evolution of the various protist lineages. Only those with hard parts have left us much of a fossil record, and only the foraminiferans and radiolarians have substantial records in Precambrian rocks. However, there are some deposits inferred to be testate amoebae in ~750 million year old rocks, and there are also some isolated "algal" fossils scattered between 750 to 1,200 million year old period (these are probably red algae/Rhodophyta). The origin of the eukaryotic condition was, of course, a pivotal event in the biological history of our planet, for it enabled life to escape from the severe limitations of the prokaryotic body plan by providing the various subcellular units that have formed the basis of specialization among the protists as well as the tissue forming multicellular kingdoms of life. In addition to the eukaryotic cellular condition, the origin of the protists also ushered in the origin of sex, enabling related cells to fuse and pool their genetic resources in new and creative ways. Prevailing consensus is that the eukaryotic condition evolved only once, making the Eukaryota monophyletic, and protists paraphyletic.

It is now broadly agreed that the origin of modern eukaryotic diversity involved a series of endosymbiotic events, described as the serial endosymbiotic theory (or SET for short). The SET theory is one of the most fascinating ideas in biology, and a quick historical review is worthwhile. By the late nineteenth century workers had observed that both chloroplasts and mitochondria behave like independent, autonomous organisms that grow in number by division, and that mitochondria had the same staining properties as bacteria. In 1905, the brilliant Russian biologist C. Mereschkowsky hypothesized that this independent behavior of chloroplasts is because they are the evolutionary descendants of endosymbiotic Cyanobacteria-like organisms. And, in 1927, I. Wallin hypothesized that mitochondria also evolved from once free living bacteria. Thus was born the SET theory. However, the theory remained controversial and sidelined until it was revived by Lynn Margulis in 1970 (it was Margulis who actually first used the phrase "serial endosymbiosis theory," in 1979).

The premise in SET theory is that eukaryotes arose first through an intimate symbiotic relationship between two prokaryotic cells in which one came to live inside the other in a type of permanent endosymbiosis (Figure 3.52). Over time, the symbiont became dependent upon (and integrated with) its host until it eventually became no longer obviously recognizable as a separate organism. It appeared, to all intents and purposes, to be an organelle of the host cell—an organelle we now call the mitochondrion. A second, later event involving a different prokaryotic symbiont (a photosynthetic cyanobacterium) gave rise to the first chloroplast organelle. This "horizontal" mode of origin of an organelle is called symbiogenesis (as distinct from "autogenesis," or origin by vertical descent with modification).

Unlike prokaryotic cells, all eukaryotic cells contain several kinds of membrane-bounded organelles that harbor distinct genetic systems. The membranes of these organelles are there *because* the organelles originated as membranebound, freeliving, prokaryotic cells (e.g., the two membranes that surround chloroplasts are derived from the inner and outer membranes of the original gram-negative cyanobacterium). Hence, we are faced with the fascinating proposition that the functions now performed by these various eukaryotic organelles must have evolved long before the eukaryotic cell itself evolved. We are also faced with the reality that evolution has proceeded not only by the splitting and divergence of lineages (as classically depicted on phylogenetic trees), but also by merging of distantly related lineages into evolutionary chimaeric cells.

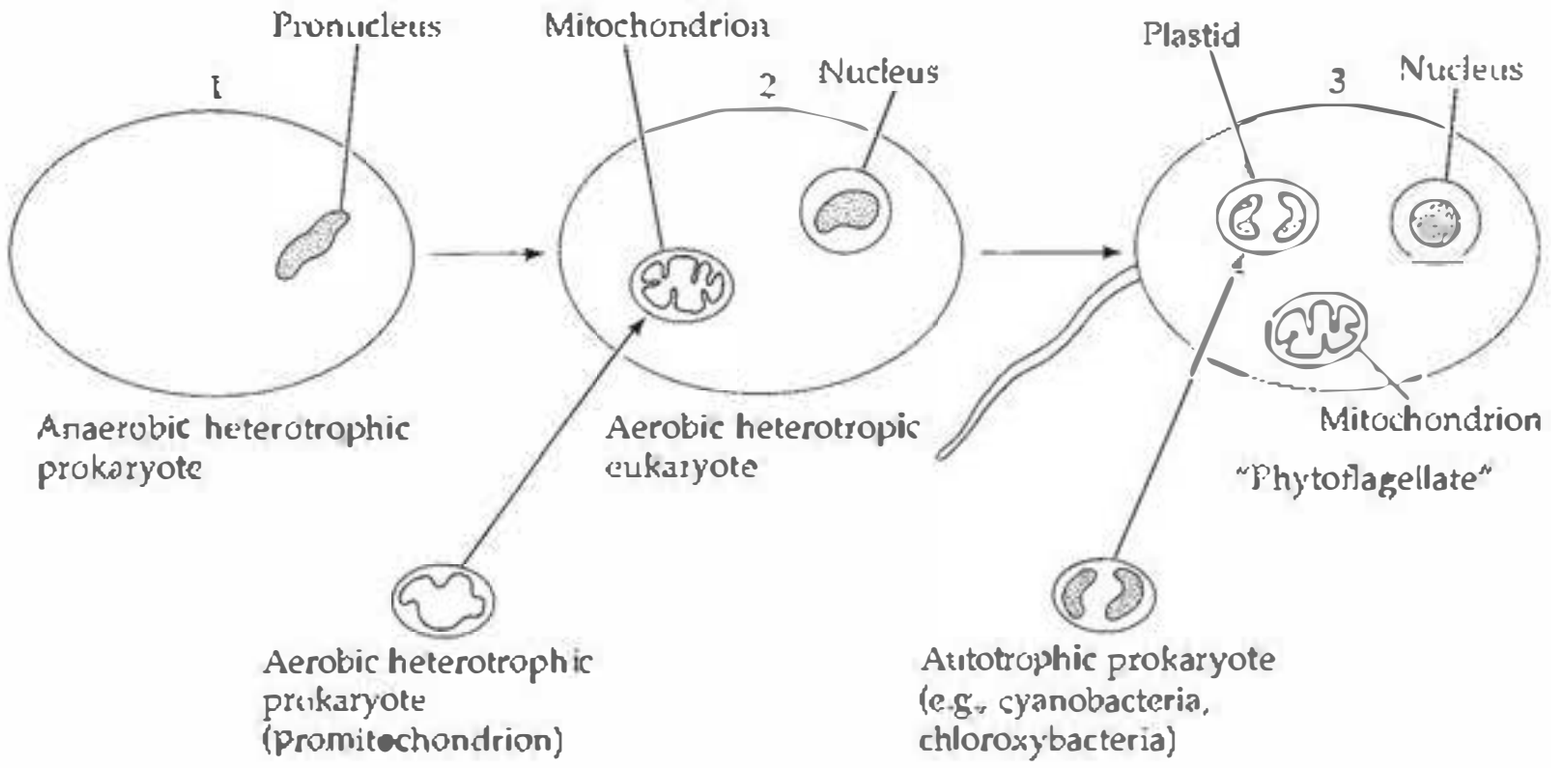

Figure 3.52 A simple model of the origin of eukaryotic cells by symbiosis (the serial endosymbiotic theory). The major events depicted are: acquisition of an aerobic heterotrophic prokaryote (origin of mitochondrion) and acquisition of an autotrophic prokaryote (origin of plastid).

Both ultrastructural and molecular genomic (DNA) evidence suggest that the eukaryotic mitochondrion evolved by way of a symbiotic relationship with a prokaryote that was similar (if not identical) to modern α-proteobacteria. This event is estimated to have transpired between 2 and 2.5 billion years ago. This particular association provided a means for early eukaryotic cells, previously limited to anaerobic metabolism, to carry out aerobic respiration. Once oxygen could be used as a terminal electron acceptor, the energy derived from ingested food increased by a factor of almost 20.

DNA data also indicate that, later in eukaryotic history, one lineage of heterotrophic eukaryotes acquired a photosynthetic cyanobacterium symbiont that then evolved into plastids (e.g., chloroplasts), thus setting the stage for the origin of red and green algae, perhaps between 1.2 and 1.5 billion years ago. Even today, the DNA of plastid genes in red and green algae closely resembles the DNA of Cyanobacteria. Thus the two membranes that surround the plastids in red and green algae correspond to the inner and outer membranes of the original gram-negative Cyanobacteria endosymbionts.

Plastids and mitochondria, which have retained large fractions of their prokaryotic biochemistry, contain only a few remnants of the protein-coding genes that their ancestors possessed. Studies have shown that most of their genes have been lost or have been transferred from the organelles to the nucleus of the eukaryotic "host cell." Today, more than 90% of the proteins required for the operation of any mitochondrion or plastid are encoded by the nuclear genome, rather than the organellar genome.

Support for the SET theory also comes from evidence of eukaryote–eukaryote secondary endosymbiosis in numerous photoautotrophic protist clades. It seems that plastids from both red algae and green algae have been secondarily co-opted by various heterotrophic protists to secondarily incorporate photosynthesis as an option in their nutritional arsenal. This process appears to have taken place many times, and most of the important groups of algae in the modern ocean are actually the products of these secondary symbiotic events. For example, diatoms (Stramenopiles), coccolithophores (Haptophytes), peridinin-containing dinoflagellates, and cryptomonads all probably acquired their chloroplasts from red algae, while chlorarachniophytes and euglenids obtained their chloroplasts from two different green algal species. Perhaps the most unusual group to have acquired a plastid from another protist is the parasitic apicomplexans, whose bizarre apicoplast is apparently a vestigial plastid from a photosynthetic ancestor with a red algal, secondary endosymbiont. In most cases little remains of the engulfed alga apart from the plastids themselves, but in two groups, the cryptomonads and chlorarachniophytes, a small remnant nucleus (and a bit of cytoplasm) of the once-engulfed alga remains to this day. These tiny nuclei, called nucleomorphs, are the smallest and most compact eukaryotic genomes known. These kinds of chimeric organisms complicate but make more exciting the study of protists.

Interestingly, endosymbiosis is not restricted to protists, but is also fairly common among animals. The hydrothermal vent clam *Calyptogena magnifica*, for example, harbors a sulfur-oxidizing proteobacterium in specialized cells of its gills. The clam depends on these symbiotic bacteria for its nutrition, and the bacteria are transmitted, like mitochondria, via the eggs of the animal. And, the bacteria have apparently lost their ability to live freely in the marine environment. Many, well-known examples of endosymbiosis are seen among the insects. One of the best examples is the bacterium *Buchnera amphidicola*, a mutualist with aphids. Aphids suck phloem sap that is rich in many nutrients but

deficient in amino acids that are provided by *Buchnera*, which are intracellular and restricted to the cytoplasm of one aphid cell type. These endosymbionts are maternally inherited via the aphid ovary. Thus the relationship is mutualistic and obligatory. Molecular phylogenetic studies indicate that the *Buchnera*-aphid relationship is hundreds of millions of years old and is extraordinarily fine-tuned and successful. The intracellular *Buchnera* have a highly reduced genome and resemble endosymbiotic bacteria at the proto-organelle grade of evolution.

Another fascinating invertebrate example of endosymbiosis occurs in certain green sea slugs. These animals feed by evacuating the cellular contents of siphonaceous green algae (e.g., *Vaucheria*) and transferring the metabolically active chloroplasts into their bodies. The chloroplasts are then distributed throughout the slug's body and become lodged only one cell layer beneath the epidermis, where light can reach them. By this means, the animals are capable of photoautotrophic CO_2 fixation. The chloroplasts remain active for a limited amount of time and eventually new ones must be acquired by the sea slug. Analogous processes are common in certain protists (e.g., see the section on ciliates).

In addition to secondary endosymbiosis, many protists maintain close commensalistic relationships with other, photoautotrophic protists. Many species of foraminiferans, for example, harbor symbiotic diatoms, dinoflagellates, or red or green algae. These cases exemplify potential early stages of secondary endosymbiotic evolutionary events.

Relationships among the Protists

We are still a ways from understanding how all protists are interrelated and how they should be classified. However, there are a number of emerging, higher-level protistan clades, identified by combinations of molecular genetics and ultrastructural/biochemical studies. Most of these identified clades aren't given (and might never be given) standard categorical rankings, although some workers refer to them as kingdoms, groups, superphyla and such. Below, we briefly describe the six, major, well-supported clades. Taxonomic summaries and descriptions of these groups were provided earlier in this chapter. One current view of their relatedness is shown in Figure 3.53.

The clade Amoebozoa is well supported by molecular phylogenetic analyses, although there have been no unique ultrastructural synapomorphies identified to distinguish this group. All species (at least primitively) have lobose pseudopodia, although lobopods are not unique to Amoebozoa.

The clade Chromalveolata is one of the most diverse protist assemblages, and it includes dinoflagellates, apicomplexans, ciliates, stramenopiles, and some other small groups—perhaps also Haptophyta and Cryptomonada. With the exception of the last two groups, the clade is fairly strongly supported by molecular data, and in addition, photosynthetic species in these groups share the feature of plastids containing chlorophyll *c*, as well as chlorophyll *a*. Mounting evidence supports the hypothesis that all chromalveolatans are descended from one secondary endosymbiotic event, probably involving a red algal symbiont (the "chromalveolate hypothesis"). Three phyla—Dinoflagellata, Apicomplexa, Ciliata—comprise a well-supported subclade called the Alveolata, and molecular analyses suggest these phyla may be part of a larger monophyletic group that also includes the phylum Stramenopila. The alveolates are uniquely characterized by the presence of alveoli beneath the outer cell membrane. The Stramenopila (treated as a phylum in this text) was first identified through

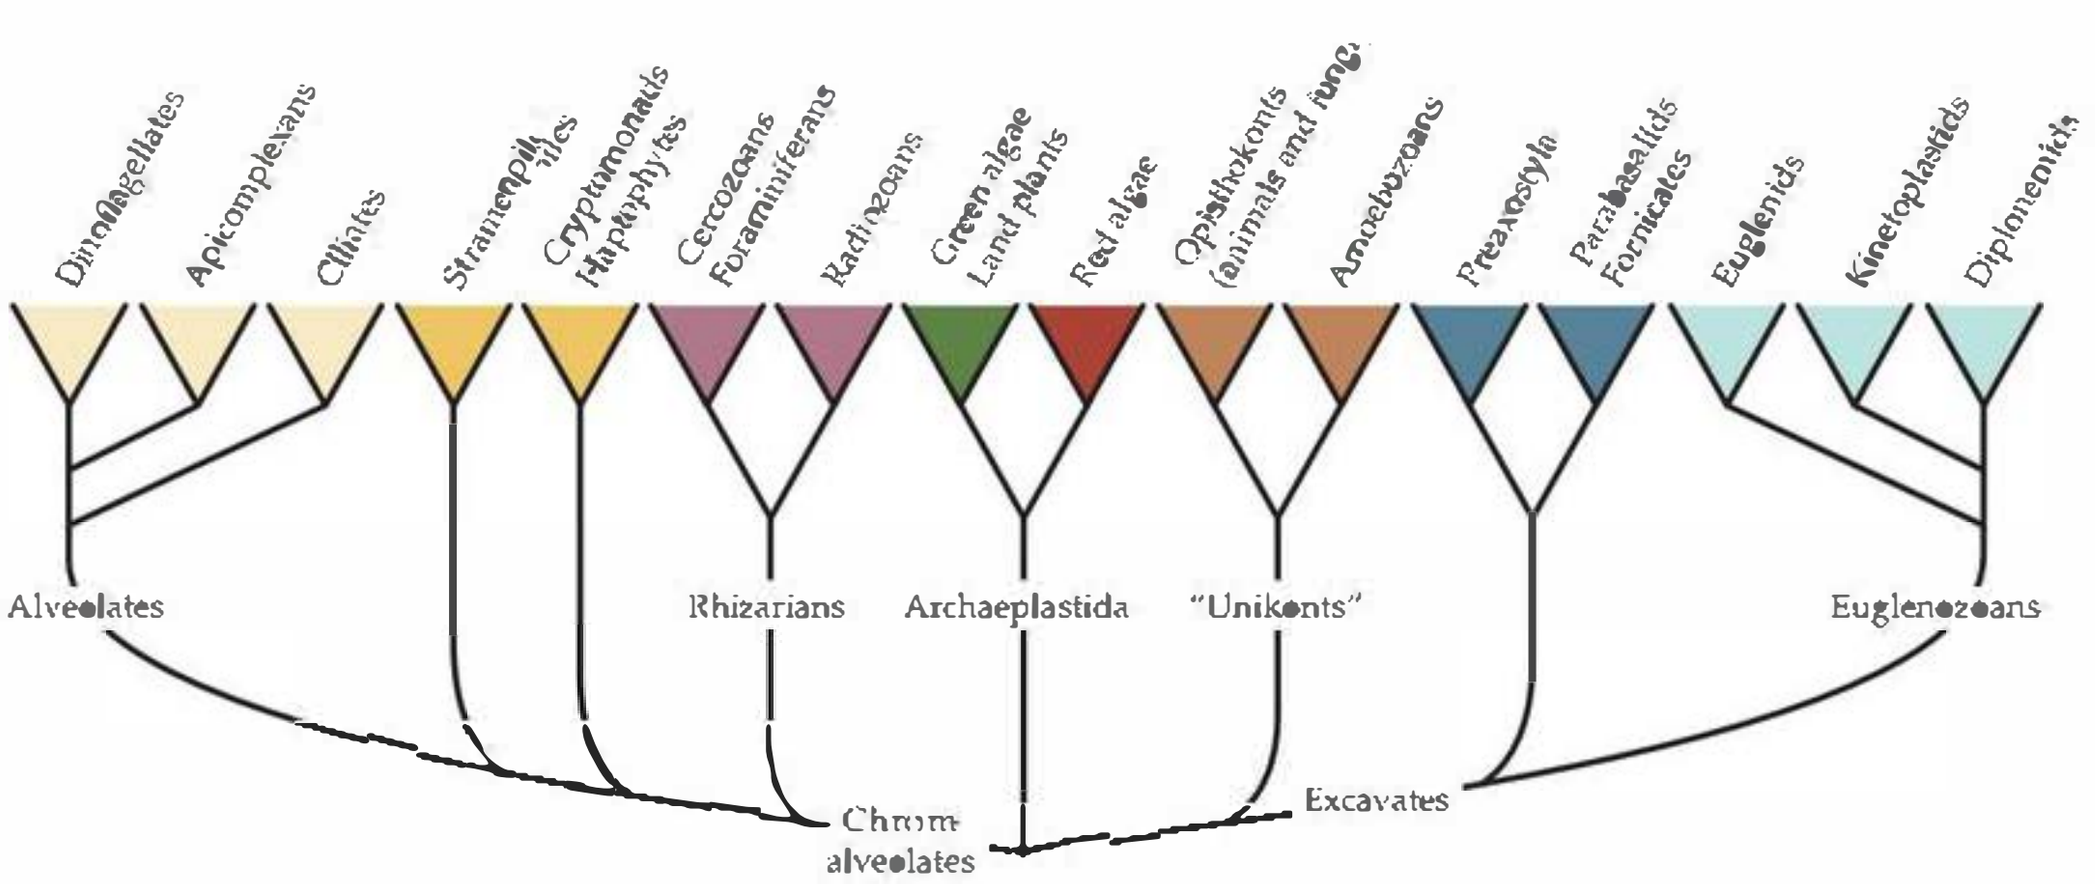

Figure 3.53 A phylogeny of the Eukaryota, showing current understandings of protist relationships.

molecular phylogenetic studies and later received confirmation from comparative anatomical work, notably the shared character of flagella lined with fine, tubular (hollow) hairs. The opalines and diatoms are usually included within the Stramenopila, and they are thought to have secondarily lost the hollow hairs. The Haptophyta (coccolithophores and their relatives) and the Cryptomonada (e.g., *Cryptomonas*) have plastids that contain chlorophyll *a* and *c*, suggesting they also belong to the chromalveolate assemblage. Multigene phylogenetic analyses indicate that these two phyla are closely related to each other, and perhaps these in turn allied with stramenopiles and alveolates.

The clade called Rhizaria contains the mixotrophic, green chloroplast-containing phylum Chlorarachniophyta, and the phyla Granuloreticulosa (forams and their kin), Radiolaria, Haplosporidia, and a few others. Amoeboid species in this clade have filopods or axopods (filopods supported by microtubules), neither of which are unique to this group. Rhizaria was discovered and delineated primarily by analyses of molecular sequence data, but the relationships of the major rhizarian clades remain unresolved. Some recent molecular evidence suggests that Radiolaria may be the basal group, with the remaining groups forming the subgroup called Cercozoa (e.g., forams, chlorarachniophytes, plasmodiophorids, haplosporids, and a few other odd groups), or with those that are sister to the Granuloreticulosa, called cercozoans (i.e., granuloreticulosans and cercozoans form a sister group, that is in turn sister to Radiolaria). However, it has also been proposed that Granuloreticulosa and Radiolaria are a clade. Chlorarachniophytes are unusual among the Rhizaria in their possession of chloroplasts, which they acquired via a secondary endosymbiotic event with a green alga (Chlorophyta) symbiont. Like the Rhizaria itself, the clade Cercozoa has no known unique morphological synapomorphies.

Growing evidence from molecular phylogenetics is suggesting an alliance of Rhizaria with most of the Chromalveolata, as the SAR group (stramenopiles, alveolates, rhizarians). Some workers feel that the molecular data are also strong enough to unite the Chromalveolata and Rhizaria as a larger group, the Chromista, a term proposed by Thomas Cavalier Smith in 1981. In fact, Cavalier Smith has championed the idea that protists should be reassigned to two kingdoms: "Protozoa" (a redefined version of this taxon containing the groups Amoebozoa, Excavata and the choanoflagellates) and Chromista (containing the groups Chromalveolata and Rhizaria, and a few other odds-and-ends). However, molecular phylogenetic analyses have yet to provide strong support for the Chromista; thus we have not used it in our classification, nor have we used the proposed SAR clade as a formal taxon.

The clade Excavata is supported mainly by cellular ultrastructural features and only modestly by molecular phylogenetic studies. Excavates typically have a suspension feeding cytostome of the "excavate" type (i.e., a feeding groove used for capture and ingestion of small particles from a feeding current generated by a posteriorly directed flagellum; margin and floor of groove supported by the microtubular root). The cytostome is presumed to be secondarily lost in many taxa. Currently included within the Excavata are Parabasalida (trichomonads, hypermastigotes, etc.), Diplomonada, Heterolobosea, Jakobida, Oxymonada, Retortamonada, and a few others. Molecular and cell structure evidence also support placing the phyla Euglenida and Kinetoplastida (trypanosomes, bodonids, and their kin) within the Excavata, the two forming a clade known as Euglenozoa which is in turn thought to be closely related to the Heterolobosea and Jakobida. Two principal anatomical features distinguish the euglenozoans: (1) a spiral, or crystalline rod inside each of their two flagella, which inserts into an anterior pocket; and (2) disk shaped mitochondrial cristae.

The jakobids have the most primitive (bacteria-like) mitochondrial genomes known. The phylum Heterolobosea is more closely related to euglenids and kinetoplastids than to other amebas. Broad-pseudopod-forming amebas have evolved in one group (Heterolobosea), independently of the Amoebozoa (which have similar pseudopods), and heterolobosids even include their own clade of "slime molds" (the acrasids).

Two excavate taxa, Parabasalida and Diplomonada, were long thought to lack mitochondria, but recent evidence suggests these groups simply have highly reduced or modified mitochondria lacking DNA. Parabasalida and Diplomonada also lack plastids, electron transport chains, and the enzymes that are normally needed for the citric acid cycle. Also, most species are found in anaerobic environments. For these reasons, and due to early molecular phylogenetic analyses, it was long thought that these two phyla might represent the oldest (earliest) surviving branches in the eukaryote tree. However, there is now growing evidence that the absence of mitochondrial DNA and electron transport chains are not primary losses, but instead represent secondary losses—reductions that took place in the evolution of these two groups. Most workers now consider parabasalids' and diplomonads' earlier positioning at the base of the protist tree in molecular studies to have been an artifact of long-branch attraction. The two are closely related to each other, and could derive from a common ancestor that had already secondarily lost the classic features of mitochondria noted above.

The clade known as Opisthokonta comprises the protist phylum Choanoflagellata, the kingdoms Metazoa and Fungi (= Eumycota), and a few other obscure groups. The group Opisthokonta is well supported by molecular sequence studies, and its members

also share the attributes of flattened mitochondrial cris tae and a single posterior cilium/flagellum on the male reproductive cells. As we noted above, the choano-flagellates comprise the sister group called Holozoa, and Choanoflagellata is the probable direct ancestor of Metazoa (although see Chapter 6). Choanoflagellates, most animal sperm, and the zoospores of chytrids (the only fungi with flagella) all swim with their sin-gle, unadorned flagellum emerging from their pos terior end. Surprisingly, this arrangement is nearly unique, and it appears to have been inherited from the common ancestor of opisthokonts. The true Fungi include the well-known groups Basidiomycota, Ascomycota, Saccharomycetes, Microsporidia and Chytridiomycetes (the chytrids being implicated in the global die-off of amphibians). Fungi are heterotrophic (not phagotrophic), with cell walls (when present) con-taining β glucan and usually chitin; plastids and tubu-lar mast:gonemes are absent.

We recognize the clade Plantae, or Archaeplastida, to include all organisms that contain chlorophylls *a* and *b*, store their photosynthetic products as starch (inside the double membrane bounded chloroplasts in which it is produced), and typically have cell walls made of cellulose. These are the primary plastid containing lin eages (hence the descriptive name, "Archaeplastida"), although some groups have secondarily lost or re-duced their plastids. As this book went to press, two major groupings of plants were recognized, the Biliphyta (phyla Glaucophyta and Rhodophyta) and the Viridiplantae (including the phyla Chlorophyta and Charophyta, plus the embryophytes phyla Anthocerotophyta, Bryophyta, Marchantiophyta and Tracheophyta). Glaucophytes comprise a small group of microscopic freshwater algae. Rhodophytes are the red algae, and chlorophytes are the green algae. Charophytes are an obscure group of freshwater green algae that include the Charales, or stoneworts). Anthocerotophytes are the hornworts, flattened green plants (gametophytes) that produce hornlike sporo-phyte structures. Bryophytes are mosslike ground-hugging plants. Although the name "bryophyte" was long used to denote any nonvascular plant, today it is restricted to a specific clade of them. Marchantiophytes are the liverworts. Tracheophytes are the vascu-lar, or "higher" plants (including the clubmosses, horsetails, ferns, gymnosperms, and angiosperms). Anthocerotophyta, Bryophyta, Marchantiophyta, and Tracheophyta (the vascular plants) are often classified together under the name Embryophyta, a descriptive term referring to the origination of tissue layers during embryogeny in this group. The plastids (chloroplasts) of Plantae/Archaeplastida appear to be monophylet-ic that is, to be descended from a single, original pri-mary endosymbiotic event.

Although the Chlorophyta may rest at the base of the clade leading to the land plants, the precise phylogenetic relationships of Glaucophyta, Rhodophyta, Chlorophyta, Charophyta and the embryophytes have not yet been resolved. The Charophyta, especially the Charales (e.g., *Chara* and Coleochaetales), appear to be the most closely related to the embryophytes (the "land plants"), with which they share several synapomorphies: rose-shaped com-plexes for cellulose synthesis, peroxisome enzymes (the specialized enzymes of peroxisomes help mini-mize the loss of organic products as a result of pho-torespiration), the structure of the flagellated sperm, and formation of a phragmoplast (an alignment of cytoskeletal elements and Golgi-derived vesicles across the midline of dividing cells during cell divi sion). The phylogenetic branching order of the green algal groups that gave rise to the land plants remains uncertain.

Recent biochemical and molecular phylogenetic analyses also place the phylum Rhodophyta (red algae) in the Archaeplastida. The oldest fossil rhodophytan, *Bangiomorpha pubescens*, strongly resembles the modern *Bangia* but occurs in rocks dated at 1 2 billion years.

On the microscopic level, embryophyte cells re-main similar to those of green algae, although they lack flagella and centrioles, except in certain gametes. Embryophytes probably evolved out of green algae (Chlorophyta) in the Paleozoic era. The algaelike stone-worts (Charales) are perhaps the best living illustration of that early evolutionary stage. In the first embryo-phytes, the sporophytes were very small and dependent on the parent for their entire brief life these are the nonvascular plants. During the Silurian and Devonian, land plants radiated rapidly and during this time the Tracheophyta, or vascular plants emerged. Vascular plants have vascular tissues that transport water throughout the body Some time in the Devonian (~385 million years ago), desiccation resistant capsules, called seeds, appeared, a feature distinguishing that group of tracheophytes called the Spermatophyta. Five groups of spermatophytes are recognized: Cycadophyta (cy-cads), Ginkgophyta (ginkos), Pinophyta (conifers), Gnetophyta (gnetaens), and Magnoliophyta (flowering plants). The first four groups are the gymnosperms. The angiosperms were the last to evolve, probably some time in the Jurassic period, spreading globally and rap idly in the Cretaceous Categorical names and taxonom-ic assignments vary considerably among botanists and textbooks

Thus we see that the origins of the three familiar multicelled kingdoms (Metazoa, Plantae, Fungi) lie in three different protist ancestors and embryogenic tissue-layering processes evolved independently in each line. Other than the embryonic formation of tissues, there are few obvious differences between the ancestral protists and their earliest multicelled descendants. Thus most unicellular green algae strongly resemble primitive green plants (embryophytes), and choanoflagellates are

strikingly similar to sponges. In addition to embryonic tissue layering, metazoans (animals) are distinguished by: cells that are typically held together by intercellular junctions; an extracellular matrix (the basement membrane, or basal lamina) with fibrous proteins, typically collagens, between two dissimilar epithelia; sexual reproduction with the generation of eggs cells that are fertilized by smaller, monociliated, sperm cells; phagotrophy; and, lack of a cell wall (typical of plants).

Of course, most unicellular clades are not directly related to any of the three multicellular kingdoms. As the protistan lineages come into focus, it becomes clear that the commonly used six-kingdom classification scheme is inadequate for describing the true nature of diversity among the Eukaryota. New kingdoms, or groups, based on very different criteria than have traditionally been used, are now beginning to be recognized, as noted above.

CHAPTER 4

Introduction to the Animal Kingdom

Animal Architecture and Body Plans

Animal bodies are marvelous things—so complex, yet so consistent and true to form within a species. All the parts seem to work together in perfect harmony, like the architecture of a beautiful building, which is how it should be after millions of years of evolutionary fine-tuning. This chapter is about the architecture of animals. The German language includes a wonderful word that expresses the essence of animal architecture—*bauplan* (pl. *baupläne*). The word means, literally, "a structural plan or design," but a direct translation is not entirely adequate. The concept of a *bauplan* captures in a single word the essence of structural range and architectural limits, as well as the functional aspects of a design. The term "body plan" is a close English equivalent. If an organism is to "work," all of its body components must be both structurally and functionally compatible. The entire organism encompasses a definable body plan, and the specific organ systems themselves also encompass structural plans; in both cases the structural and functional components of the particular plan establish both capabilities and limits. Thus, body plans determine the major constraints that operate at both the organismic and the organ system levels.

The diversity of form in the biological world is dazzling, yet there are real limits to what may be successfully molded by evolutionary processes. All animals must accomplish certain basic tasks in order to survive and reproduce. They must acquire, digest, and metabolize food and distribute its usable products throughout their bodies. They must obtain oxygen for cellular respiration, while at the same time ridding themselves of metabolic wastes and undigested materials. The strategies employed by animals to maintain life are extremely varied, but they rest upon relatively few biological, physical, and chemical principles, regardless of what body plan they have. But within the constraints imposed by particular body plans, animals have a limited number of options available to accomplish life's tasks. For this reason, a few recurring fundamental themes are apparent. This chapter is a general review of these themes: the structural/functional aspects of invertebrate body plans and the basic survival strategies employed within each. It is a description of how invertebrates are put together and how they manage to survive and reproduce. Each subject discussed here reflects fundamental principles of animal mechanics, physiology, and adaptation. We realize that much of

Figure 4.1 Examples of asymmetrical animals and protists. (A) An assortment of sponges. (B) Two amebas.

this chapter presents material that students learn in introductory biology courses, but here we provide specific viewpoints that set the stage for topics covered in more detail in each "animal" chapter of this book.

Keep in mind that even though this chapter is organized on the basis of what might be called the "components" of animal structure, whole animals are integrated functional combinations of these components. Furthermore, there is a strong element of predictability in the concepts discussed in this chapter. For example, given a particular type of symmetry, one can make reasonable guesses about other aspects of an animal's structure that should be compatible with that symmetry—some combinations work, others do not. Herein are explained many of the concepts and terms used throughout this book, and we encourage you to become familiar with this material now as a basis for understanding the remainder of the text.

Body Symmetry

A fundamental aspect of an animal's body plan is its overall shape or geometry. In order to discuss invertebrate architecture and function, we must first acquaint ourselves with a basic aspect of body form: symmetry. Symmetry refers to the regular arrangement of body structures relative to the axis of the body. Animals that can be bisected or split along at least one plane, so that the resulting halves are similar to one another, are said to be symmetrical. For example, a shrimp can be bisected vertically through its midline, head to tail, to produce right and left halves that are mirror images of one another. Some animals have no body axis and no plane of symmetry, and are said to be asymmetrical. Many sponges, for example, have an irregular growth form and lack any clear plane of symmetry. Similarly, many protists, particularly the ameboid forms, are asymmetrical (Figure 4.1).

One form of symmetry is spherical symmetry. It is seen in creatures whose bodies lack an axis and have the form more or less of a sphere, with the body parts arranged concentrically around, or radiating from, a central point (Figure 4.2). A sphere has an infinite number of planes of symmetry that pass through its center to divide it into like halves. Spherical symmetry is rare in nature; in the strictest sense, it is found only in certain protists. Organisms with spherical symmetry share an important functional attribute with asymmetrical organisms, in that both groups lack polarity. That is, there exists no clear differentiation along an axis. In all other forms of symmetry, some level of polarity has been achieved; and with polarity comes specialization of body regions and structures.

A body displaying radial symmetry has the general form of a cylinder, with one main axis around which the various body parts are arranged (Figure 4.3). In a body displaying perfect radial symmetry, the body

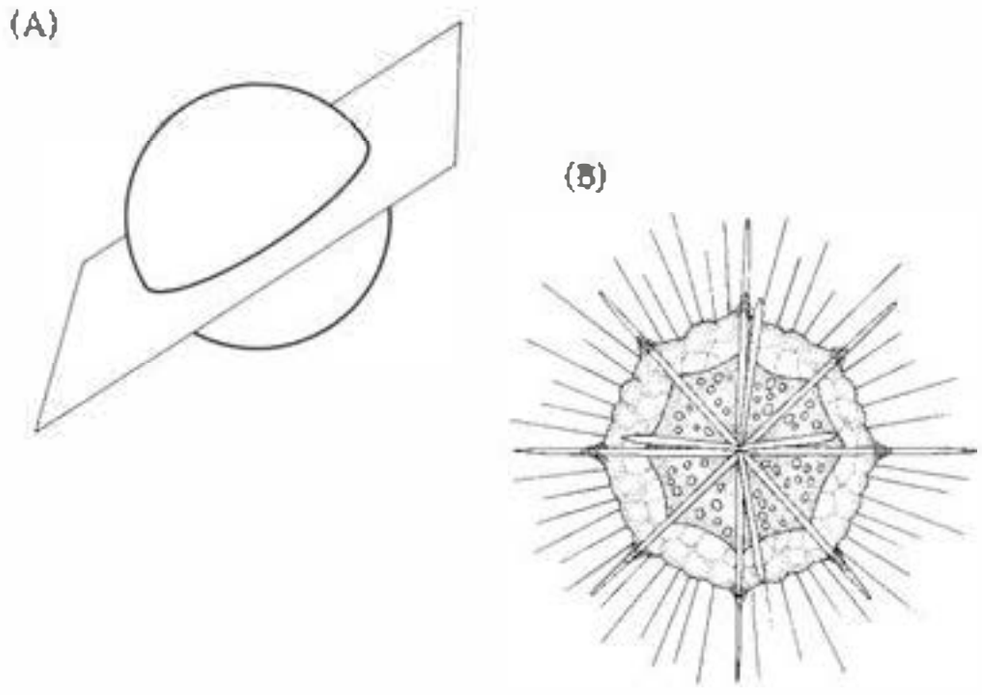

Figure 4.2 Spherical symmetry in animals. (A) An example of spherical symmetry; any plane passing through the center divides the organism into like halves. (B) A radiolarian (protist).

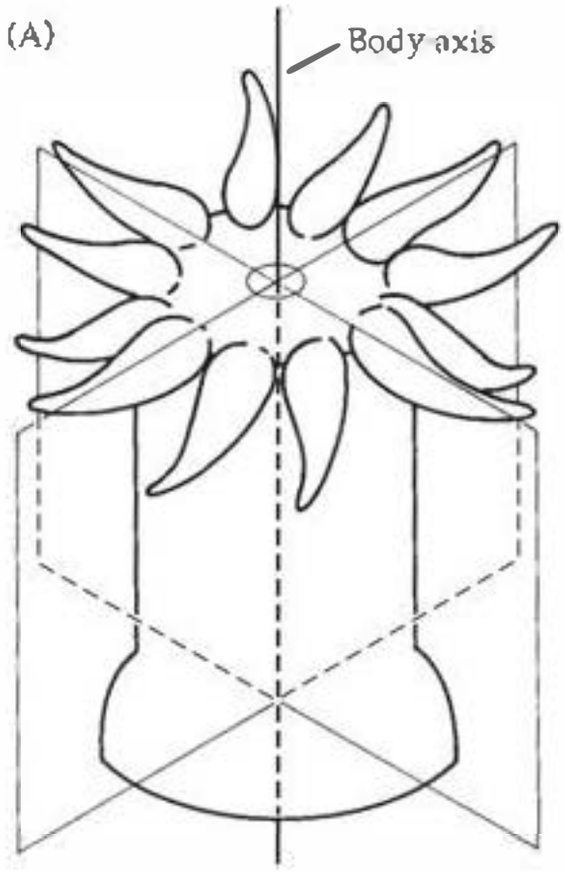

Figure 4.3 Radial symmetry in invertebrates. The body parts are arranged radially around a central oral–aboral axis. (A) Representation of perfect radial symmetry. (B) The barrel-like sponge *Xestospongia*. (C) The sea anemone *Epiactis*, whose mouth alignment and internal organization produce biradial symmetry. parts are arranged equally around the axis, and any plane of sectioning that passes along that axis results in similar halves (rather like a cake being divided and subdivided into equal halves and quarters). Nearly perfect radial symmetry is rare in nature but occurs in some sponges and cnidarian polyps (Figure 4.3A,B). But most radially symmetrical animals have evolved modifications on this theme. Biradial symmetry, for example, occurs where portions of the body are specialized and only two planes of sectioning can divide the animal into perfectly similar halves. Common examples of biradial organisms are ctenophores and many sea anemones (Figure 4.3C).

Further specializations of the basic radial body plan can produce nearly any combination of multiradiality. For example, many jellyfishes possess quadriradial symmetry (Figure 4.3D). Most echinoderms have pentaradial symmetry (Figure 4.3E,F), although many multiarmed starfish are also known. In fact, the presence in starfish of certain organs (e.g., the madreporite) allows for only one plane by which perfectly matching halves exist, and thus starfish actually possess a form of pentaradial bilaterality. But this is splitting hairs. The adaptive significance of body symmetry operates at a much coarser level than organ position, and in this regard most echinoderms, including starfish, are functionally radially symmetrical although their pentaradiality is unique in the animal kingdom and should not be ignored (see Chapter 25).

A radially symmetrical animal has no front or back end; rather it is organized about an axis that passes through the center of its body, like an axle through a wheel. When a gut is present, this axis passes through the mouth-bearing (oral) surface to the opposite (aboral) surface. Radial symmetry is most common in

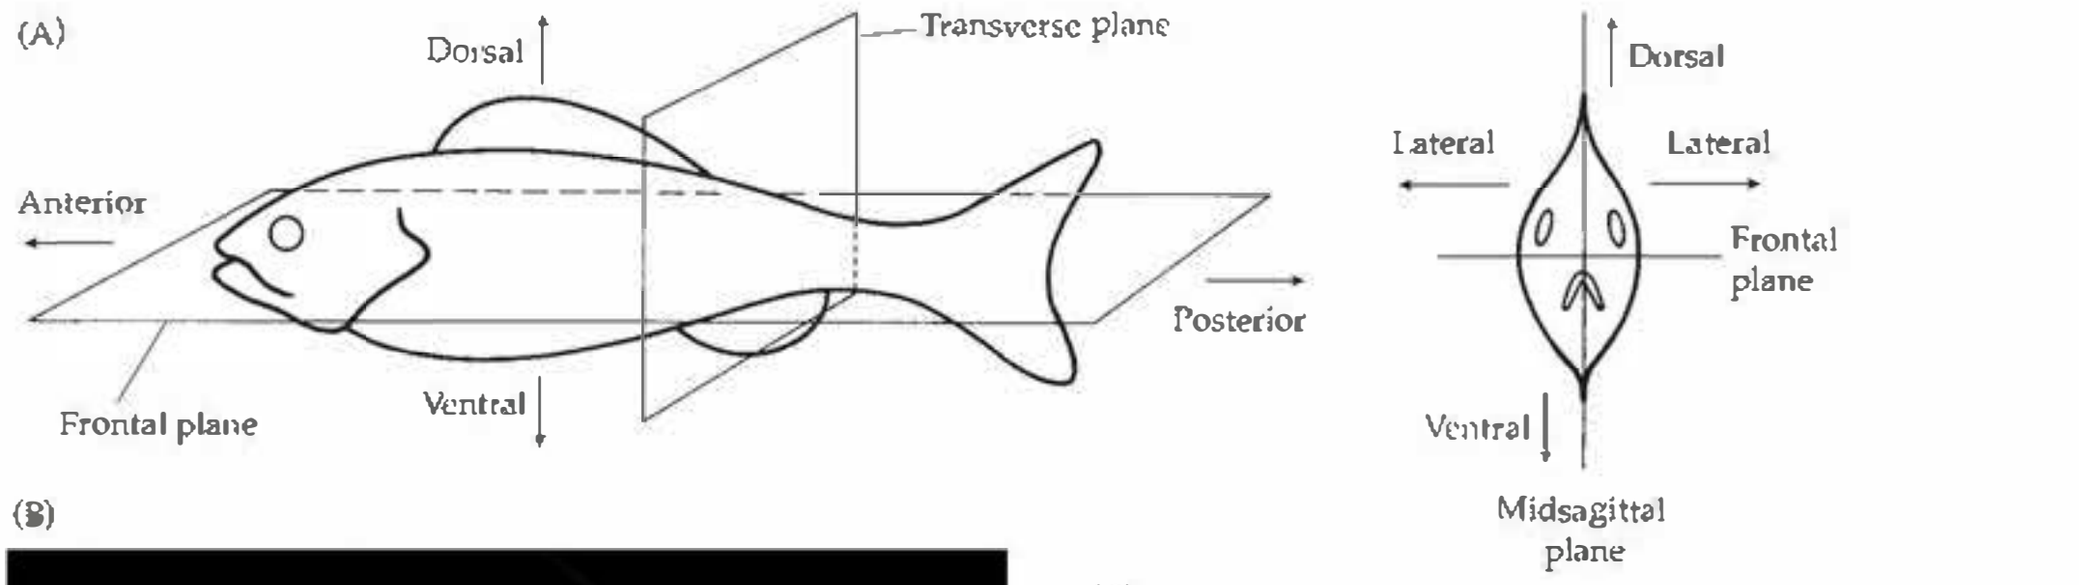

Figure 4.4 Bilateral symmetry in animals; a single plane—the midsagittal plane—divides the body into equal halves. (A) Diagrammatic illustration of bilateral symmetry, with terms of orientation and planes of sectioning. A shrimp (B) and a scorpion (C) show obvious bilateral symmetry.

sessile and sedentary animals (e.g., sponges, starfish, and sea anemones) and drifting pelagic species (e.g., jellyfishes and ctenophores). Given these lifestyles, it is clearly advantageous to be able to confront the environment equally from a variety of directions. In such creatures the feeding structures (tentacles) and sensory receptors are distributed at equal intervals around the periphery of the organisms, so that they contact the environment more or less equally in all directions. Furthermore, many bilaterally symmetrical animals have become functionally radial in certain ways associated with sessile lifestyles. For example, their feeding structures may be in the form of a whorl of radially arranged tentacles, an arrangement allowing more efficient contact with their surroundings.

The body parts of bilaterally symmetrical animals are oriented about an axis that passes from the front (anterior) to the rear (posterior) end. A single plane of symmetry—the **midsagittal plane** (or median sagittal plane)—passes along the axis of the body to separate right and left sides. Any longitudinal plane passing perpendicular to the midsagittal plane and separating the upper (dorsal) from the underside (ventral) is called a frontal plane (Figure 4.4). Any plane that cuts across the body perpendicular to the main body axis and the midsagittal plane is called a transverse plane (or, simply, a cross section). In bilaterally symmetrical animals the term lateral refers to the sides of the body, or to structures away from (to the right and left of) the midsagittal plane. The term medial refers to the midline of the body, or to structures on, near, or toward the midsagittal plane.

Whereas spherical and radial symmetry are typically associated with sessile or drifting animals, bilaterality is generally found in animals with highly directional mobility. In these animals, the anterior end of the body confronts the environment first. Associated with bilateral symmetry and unidirectional movement is a concentration of feeding and sensory structures at the anterior end of the body. The evolution of a specialized "head," containing those structures and the nervous tissues that innervate them, is called cephalization (from the Greek *kephalos*, "head"). Furthermore, the surfaces of the animal differentiate as dorsal and ventral regions, the latter becoming locomotory and the former being specialized for protection. A variety of secondary asymmetrical modifications of bilateral (and radial) symmetry have occurred, for example, the spiral coiling of snails and hermit crabs.

Cellularity, Body Size, Germ Layers, and Body Cavities

One of the main characteristics used to define grades of animal complexity is the presence or absence of true tissues. Tissues are aggregations of morphologi-

cally and physiologically similar cells that perform a specific function. As we saw in Chapter 3, protists do not possess tissues, but occur only as single cells or as simple colonies of cells. In a sense, they are all at a unicellular grade of construction. Beyond the protists is the vast array of multicelled animals, the Metazoa. The Metazoa are often divided into two major levels, or grades—the non-bilateria (diploblastic animals) and the bilateria (= triploblastic animals), as described below. These names do not represent formal taxa, but may be used to group the Metazoa by their level of overall structural complexity. The non-bilateria comprise a nonmonophyletic grouping; the bilateria is almost certainly a clade.

Each of these two grades of body complexity is associated with inherent constraints and capabilities, and within each grade there are obvious limits to size As the British biologist D'Arcy Thompson wrote, "Everything has its proper size...men and trees, birds and fishes, stars and star systems, have...more or less narrow ranges of absolute magnitudes." As a cell (or an organism) increases in size, its volume increases at a rate faster than the rate of increase of its surface area (surface area increases as the square of linear dimensions; volume increases as the cube of linear dimensions). Because a cell ultimately relies on transport of material across its plasma membrane for survival, this disparity quickly reaches a point at which the cytoplasm can no longer be adequately serviced by simple cellular diffusion. Some unicellular forms develop complexly folded surfaces or are flattened or threadlike in shape. Such creatures can be quite large, but eventually a limit is reached; thus we have no meter long protists.

To increase in size, ultimately the only way around the **surface to volume dilemma** is to increase the number of cells constituting a single organism; hence the Metazoa. But size increase in the Metazoa is also limited. Those Metazoa lacking complex specializations of tissues and organs must rely on diffusion into and out of the body, and this is inadequate to sustain life unless a majority of the body's cells are near or in contact with the external environment. In fact, diffusion is an effective method of oxygenation only when the diffusion path is less than about 1.0 mm. So here, too, there are limits. An animal simply cannot increase indefinitely in volume when most of its cells must lie close to the body surface. Some animals solve this problem to some degree by arranging their cellular material so that diffusion distances from cell to environment are comfortably short. One method of accomplishing this is to pack the internal bulk of the body with nonliving (or largely nonliving) material, such as the jelly-like mesoglea of medusae and ctenophores. Another is to assume a body geometry that maximizes the surface area. Increase in one dimension leads to a vermiform body plan, like that of cestid ctenophores (Ctenophora; Figure 8.1E) or ribbon worms (Nemertea). Increase in two dimensions results in a flat, sheetlike body like that of flatworms (Platyhelminthes). In these cases the diffusion distances are kept short Sponges effectively increase their surface area by a process of complex branching and folding of the body, both internally and externally. This folding keeps most of the body cells close to the environment.

If these were the only solutions to the surface-to-volume dilemma, the natural world would be filled with tiny, thin, flat animals and convoluted, spongelike creatures. However, many organisms increase in size by one to several orders of magnitude during their ontogeny, and life forms on Earth span about 19 orders of magnitude (in mass). Thus, another solution arose during the course of animal evolution that allowed for increases in body size. This solution was to bring the "environment" functionally closer to each cell in the body by the use of internal transport and exchange systems with large surface areas. A significant three dimensional increase in body size thus necessitated the development of sophisticated internal transport mechanisms (e.g., circulatory systems) for nutrients, oxygen, waste products, and so on. These evolving transport structures became the organs and organ systems of higher animals. For example, the body volume of humans is so large that we require a highly branched network of gas exchange surfaces (our lungs) to provide an adequate surface area for gas diffusion. This network has about 1,000 square feet of surface—as much area as half a tennis court! The same constraints apply to food absorption surfaces; hence the evolution of very long, highly folded, or branched guts.

The embryonic tissue layers of eumetazoans are called germ layers (from the Latin *germen*, "a sprout, bud, or embryonic primordium"), and it is from these germ layers that all adult structures develop. Chapter 5 provides an overview of germ layer formation and other aspects of metazoan developmental patterns. Here we need only point out that the germ layers initially form as outer and inner sheets or coherent masses of embryonic cells, termed **ectoderm** and **endoderm** (or entoderm), respectively. In the embryogeny of the radiate phyla Cnidaria and Ctenophora, only these two germ layers develop (or if a middle layer does develop, it is produced by the ectoderm, is largely noncellular, and is not considered a true germ layer). These animals are regarded as **diploblastic** (Greek *diplo*, "two"; *blast*, "bud" or "sprout"). In the embryogeny of most animals, however, a third cellular germ layer, the mesoderm, arises between the ectoderm and the endoderm; these metazoans are said to be **triploblastic**.

The evolution of a mesoderm greatly expanded the evolutionary potential for animal complexity. As we shall see, the triploblastic phyla have achieved many more highly sophisticated body plans than are possible within the confines of a diploblastic body plan. Simply

put, a developing triploblastic embryo has more building material to work with than does a diploblastic embryo.

One of the major trends in the evolution of the triploblastic Metazoa has been the development of a fluid-filled cavity between the outer body wall and the digestive tube; that is, between the adult derivatives of the ectoderm and the endoderm. The evolution of this space created a radically new architecture, a tube-within-a-tube design in which the inner tube (the gut and its associated organs) was largely freed from the constraint of being attached to the outer tube (the body wall). The fluid-filled cavity not only served as a mechanical buffer between these two largely independent tubes, but also allowed for the development and expansion of new structures within the body, served as a storage chamber for various body products (e.g., gametes), provided a medium for circulation, and was in itself an incipient hydrostatic skeleton. The nature of this cavity (or the absence of it) is associated with the formation and subsequent development of the mesoderm, as discussed in detail in Chapter 5.

Three major grades of construction are recognizable among the triploblastic Metazoa: acoelomate, blastocoelomate, and eucoelomate. The acoelomate grade (Greek *a*, "without"; *coel*, "hollow, cavity") occurs in numerous triploblastic phyla: Xenacoelomorpha, Platyhelminthes, Entoprocta, Cycliophora, Gnathostomulida, Micrognathozoa, Nematomorpha, and Gastrotricha. In these animals, the mesoderm forms a more or less solid mass of tissue, sometimes with small open spaces (lacunae), between the gut and body wall (Figure 4.5A). In nearly all other triploblastic animals, an actual space develops as a fluid-filled cavity between the body wall and the gut. In many phyla (e.g., annelids and echinoderms), this cavity arises within the mesoderm itself and is completely enclosed within a thin lining called the peritoneum, which is derived from the mesoderm. Such a cavity is called a true coelom (eucoelom). Notice that the organs of the body are not actually free within the coelomic space itself, but are separated from it by the peritoneum (Figure 4.5C). Peritoneum is usually a squamous epithelial layer, at least that portion of it covering the gut and internal organs.

Several groups of triploblastic Metazoa (e.g., Rotifera, Nematoda, Loricifera, Priapula, Tardigrada, and some Kinorhyncha) possess small or large body cavities that are neither formed from the mesoderm nor fully lined by peritoneum or any other form of mesodermally derived tissue. Such a cavity used to be called a "pseudocoelom" (Greek *pseudo*, "false"; *coel*, "hollow, cavity") (Figure 4.5B). The organs of these animals actually lie free within the body cavity and are bathed directly in its fluid. In most cases the space represents persistent remnants of the embryonic blastocoel, and since there is nothing "false" about it, we use the more descriptive term blastocoelom in this text.

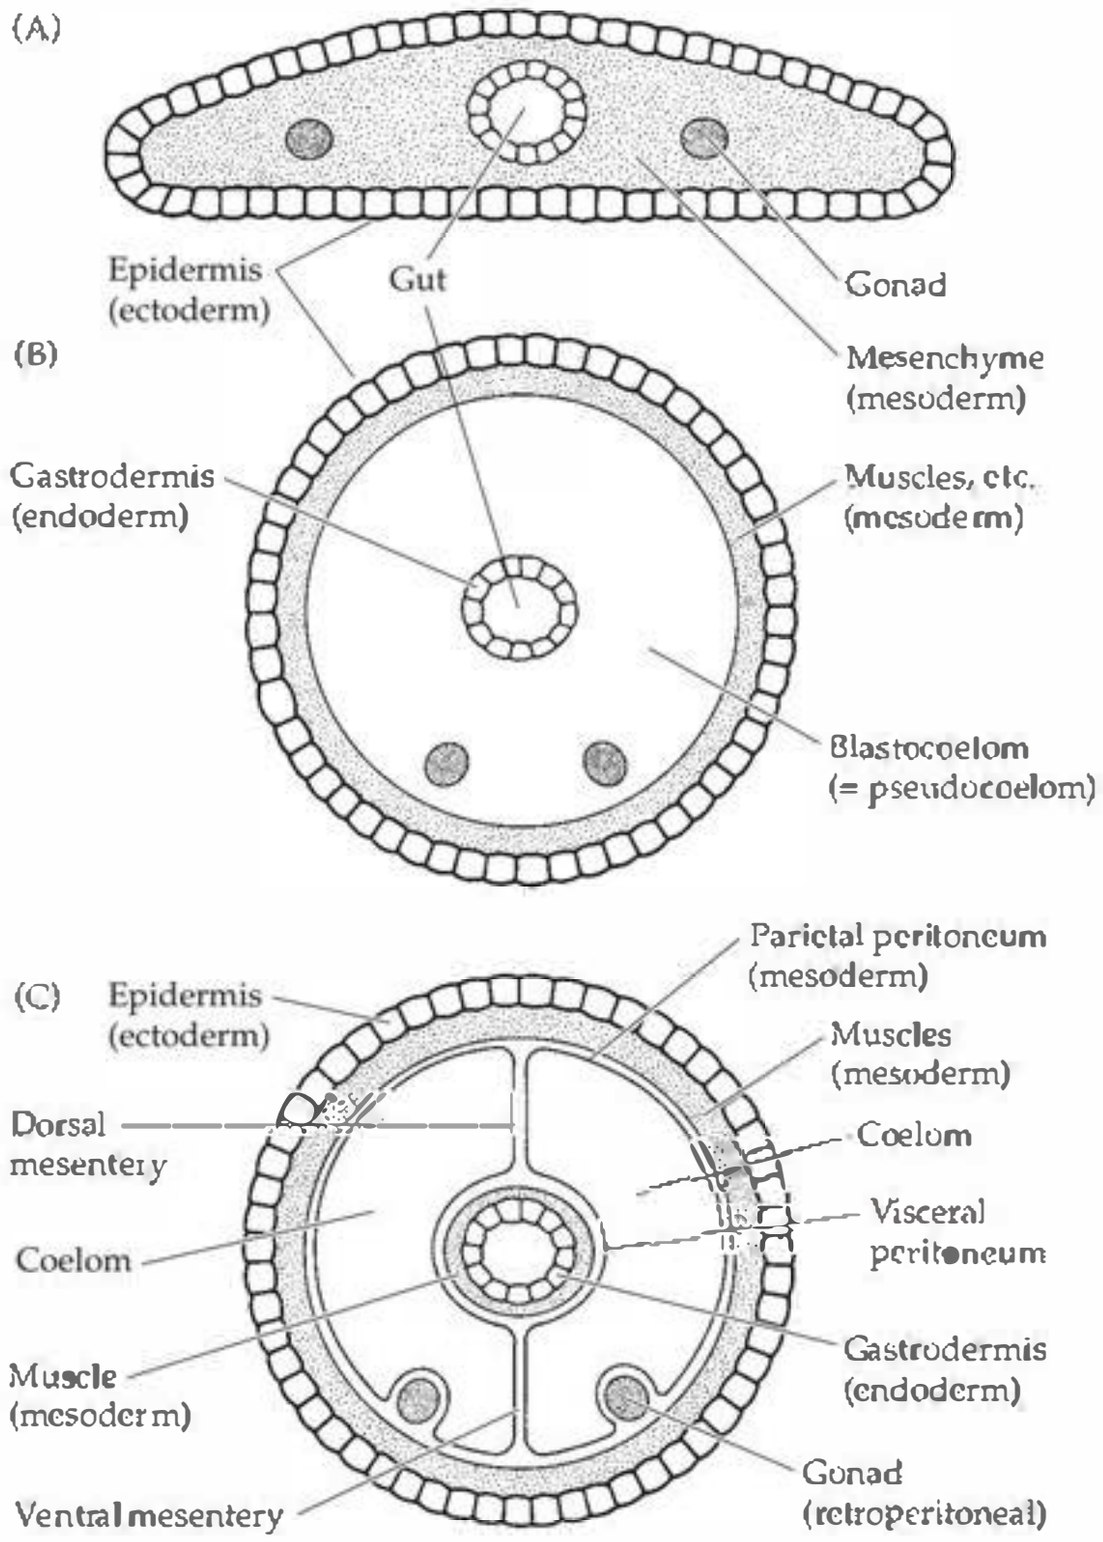

Figure 4.5 Principal body plans of triploblastic Metazoa (diagrammatic cross sections). (A) The acoelomate body plan. (B) The blastocoelomate body plan. (C) The coelomate (= eucoelomate) body plan.

The organization of the body cavity shows only a loose correlation to phylogeny. However, within the constraints inherent in each of the basic body organizations discussed above, animals have evolved a multitude of variations on these themes. Throughout the remainder of this chapter we describe the fundamental organizational plans of major body systems as they have evolved within these basic body plans. In subsequent chapters, we describe how members of the various phyla have modified these basic plans through their own particular evolutionary program or direction.

Locomotion and Support

As eukaryotic life progressed from the singlecelled stage to multicellularity, body size increased dramatically. And this increase in body size, coupled with directed movement, was accompanied by the evolution of a variety of support structures and locomotor

mechanisms. Because these two body systems evolved mutually and usually work in a complementary fashion, they are conveniently discussed together. And of course, there was a rapid evolut.onary boost in body size and support in the Cambrian, approximately 540 to 485 million years ago an event known as the Cambrian Explosion. The reasons for this rapid radiation of larger animals are still being debated (Chapter 1).

There are four fundamental locomotor patterns in protists and Metazoa: ameboid movement, ciliary and flagellar movement, hydrostatic propulsion, and loco motor limb movement. There are three basic kinds of support systems: structural endoskeletons, structural exoskeletons, and hydrostatic skeletons. In this section we briefly describe the basic architecture and mechanics of the various combinations of these systems.

Reynolds Number

Most invertebrate lineages inhabit water, and aquatic environments present obstacles and advantages to support and locomotion that are quite different from those of terrestrial environments. Just staying in one place in the face of swiftly moving water, without being damaged or dislodged, can require both support and flexibility. Animals moving through water (or moving water over their bodies the effect is much the same) face problems of fluid dynamics created by the interaction between a solid body and a surrounding liquid. What happens during this interaction is tied to the concept of Reynolds number, a unitless value based on the experiments of Osborne Reynolds (1842 1912). Reynolds number represents a ratio of inertial force to vis cous force. At higher Reynolds numbers, inertial force predominates and determines the behavior of water flow around an object. At lower Reynolds numbers, viscous force predominates and determines the behavior of the water flow. The importance of this concept is being increasingly recognized and applied to biological systems. Although there is still a great deal to be done in this area, some interesting generalizations can be made about locomotion of aquatic animals and, as we discuss later, aquatic suspension feeding. Reynolds number is expressed by the following equation:

$$R_e = \frac{plU}{v}$$

where p equals the density of fluid, l is some measure ment of the size of the solid body, U equals the relative velocity of the fluid over the body surface, and v is the viscosity of the fluid. The formula was derived by Reynolds to describe the behavior of cylinders in water. Of course, since animals' bodies are not perfect cylinders, the size variable (l) is difficult to standardize. Nonetheless, meaningful relative values can be derived and applied to living creatures in water.

Without belaboring this issue beyond its importance here, it turns out that the problems of a large animal swimming through water are very different from those of a small animal. Large animals such as fishes, whales, or even humans, by virtue of their size or high velocity or both, move in a world of high Reynolds numbers. With increased body size, fluid viscosity becomes less and less significant as far as the animal's energy output during locomotion is concerned. At the same time, however, inertia becomes more and more important. A large animal must expend more energy than a small animal does to put its body in motion. But, by the same token, inertia works in favor of the moving large animal by carrying it forward when the animal stops swimming. When large animals move at high Reynolds numbers, the effect of inertia also imparts motion to the water around the animal's body. Thus, as the Reynolds number increases, a point is reached at which the flow of water changes from laminar to turbulent, decreasing swimming efficiency.

Small organisms generally move in a world of low Reynolds numbers. For example, a larva 1 mm in diam eter, moving at a speed of 1 mm/sec, has a Reynolds number of about 1.0. Inertia and turbulence are virtually nonexistent, but viscosity becomes important increasingly so as body size and velocity decrease (i e , as the Reynolds number decreases). Small organisms swimming through water have been likened to a human swimming through liquid tar or thick molasses. The effect of this situat.on is that tiny creatures, such as ciliate and flagellate protists and many small Metazoa, start and stop instantaneously, and the motion of the water set up by their swimming also ceases immediately if the animal stops moving. Thus, small creatures neither pay the price nor reap the benefits of the effects of inertia. The organism only moves forward when it is expending energy to swim; as soon as it stops moving its cilia, or flagella, or appendages, it stops and so does the fluid surrounding it. Tiny organisms swimming at low Reynolds numbers (i.e., < 1.5) must expend an incredible amount of energy to propel themselves through their "viscous" surroundings.

Ameboid Locomotion

Ameboid movement is used principally by certain protists and by numerous kinds of ameboid cells that occur within the bodies of most Metazoa. Ameboid cells possess a gel like **ectoplasm**, which surrounds a more fluid **endoplasm** (Figure 4.6). Movement is facilitated by changes in the states of these regions of the cell. At one (or several) points on the cell surface, **pseudopods** (or pseudopodia) develop; and as endoplasm flows into a growing pseudopod (or pseudopodium), the cell creeps in that direction. This seemingly simple process actually involves complex changes in cell fine structure, chemistry, and behavior. The innermost endoplasm moves "forward" while the outermost endoplasm takes on a granular appearance and remains fairl y stable. The advancing portion of endoplasm pushes

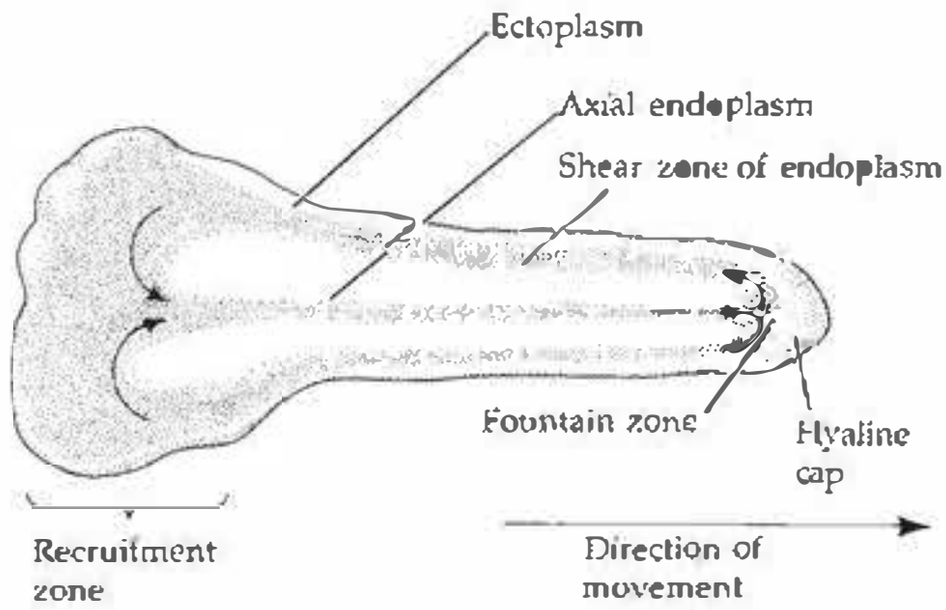

Figure 4.6 Ameboid locomotion by way of pseudopod formation in an ameba.

forward and then becomes semirigid ectoplasm at the tip of the advancing pseudopodium. Concurrently, endoplasm is recruited from the trailing end of the cell, from whence it streams forward to join in the "growing" pseudopod. Many protists, and certain cells of eukaryotes, have wide, blunt-tipped pseudopods called **lobopods** (or lobopodia). In many protist groups long, slender, tapering pseudopods occur—**filopods** (or filopodia). The formation of filopodia appears to involved actin polymerization. **Reticulopods** (or reticulopodia) are filopods that are very long and anastomose in a net-like fashion. Evidence suggests that reticulopods are supported by microtubules. Overall, it appears that various forms of pseudopods have evolved multiple times within the protists.

The molecular basis of ameboid movement may be essentially the same as that of vertebrate muscle contraction, involving actin, myosin, and ATP. Two principal theories exist to explain the process. Perhaps the more popular of the two ideas has the actin molecules floating freely in the endoplasm, polymerizing into their filamentous form at the point of active pseudopodium growth, where they interact with myosin molecules. The resultant contraction literally pulls the streaming endoplasm forward, while at the same time converting it to the ectoplasm that rings the forward-streaming pseudopodium. The second theory suggests that the actin–myosin interaction takes place at the rear of the cell, where it produces a contraction of the ectoplasm. The contraction squeezes the cell like a tube of toothpaste, causing the endoplasm to stream forward and create a pseudopodium directly opposite the point of ectoplasmic contraction. Some modifications of pseudopodial movement were discussed in Chapter 3.

Cilia and Flagella

Cilia or flagella or both occur in virtually every animal phylum (with the qualified exception of the Arthropoda). Structurally, cilia and flagella are nearly identical (and clearly homologous), but the former are shorter and tend to occur in relatively larger numbers (in patches or tracts), whereas the latter are long and generally occur singly or in pairs. During cell development, each new flagellum or cilium arises from an organelle called the **kinetosome** (sometimes called a basal body or a blepharoplast), to which it remains anchored.

The movement of cilia and flagella creates a propulsive force that either moves the organism through a liquid medium or, if the animal (or cell) is anchored, creates a movement of fluid over it. Such action always occurs at very low Reynolds numbers. When the animal is large, the viscosity may be increased by secretion of mucus, which lowers the Reynolds number. The general structure of a flagellum or cilium consists of a long, flexible rod, the outer covering of which is an extension of the plasma membrane of the cell (Figure 4.7A). Inside is a circle of nine paired microtubules (often called doublets) that runs the length of the flagellum or cilium. One microtubule of each doublet bears two rows of projections, the dynein arms, directed toward the adjacent doublet. Flagella and cilia move as the microtubules slide up or down against one another, bending the flagellum or cilium in one direction or another. Microtubule sliding is driven by the dynein arms, particularly by protein complexes called radial spokes that arise from the arms. The radial spokes attach to each doublet microtubule immediately adjacent to the inner row of dynein arms and project centrally. Down the center of the doublet circle is an additional pair of microtubules. This familiar 9+2 pattern is characteristic of nearly all flagella and cilia (Figure 4.7B).[1] Flagellar/ciliary microtubules are modified hollow tubules similar to those present in the matrix of most cells. The principal function of these cellular tubules appears to be support. Just as the ectoplasm helps retain the shape and integrity of a protozoan cell (acting as a type of rudimentary "exoskeleton"), so the cytoplasmic microtubules act as a sort of simple "endoskeleton" that help protists (and other cells) retain their shape. Microtubules are also components of the spindle and help distribute the chromosomes during cell division.

In addition to the locomotor function seen in some protists and small Metazoa, cilia and flagella have an enormous variety of functions in many other animals. For example, they create feeding and gas exchange currents, they line digestive tracts and facilitate food movement, and they propel sex cells and larvae. They also form sensory structures of many kinds. Here we focus on their use as locomotor structures.

Analysis by high-speed photography reveals that the movement of these structures is complex and differs among taxa, and even at different locations on the same organism. Some flagella beat back and forth,

[1] Dyneins are a family of adenosine triphosphatases that cause microtubule sliding in ciliary and flagellar axonemes.

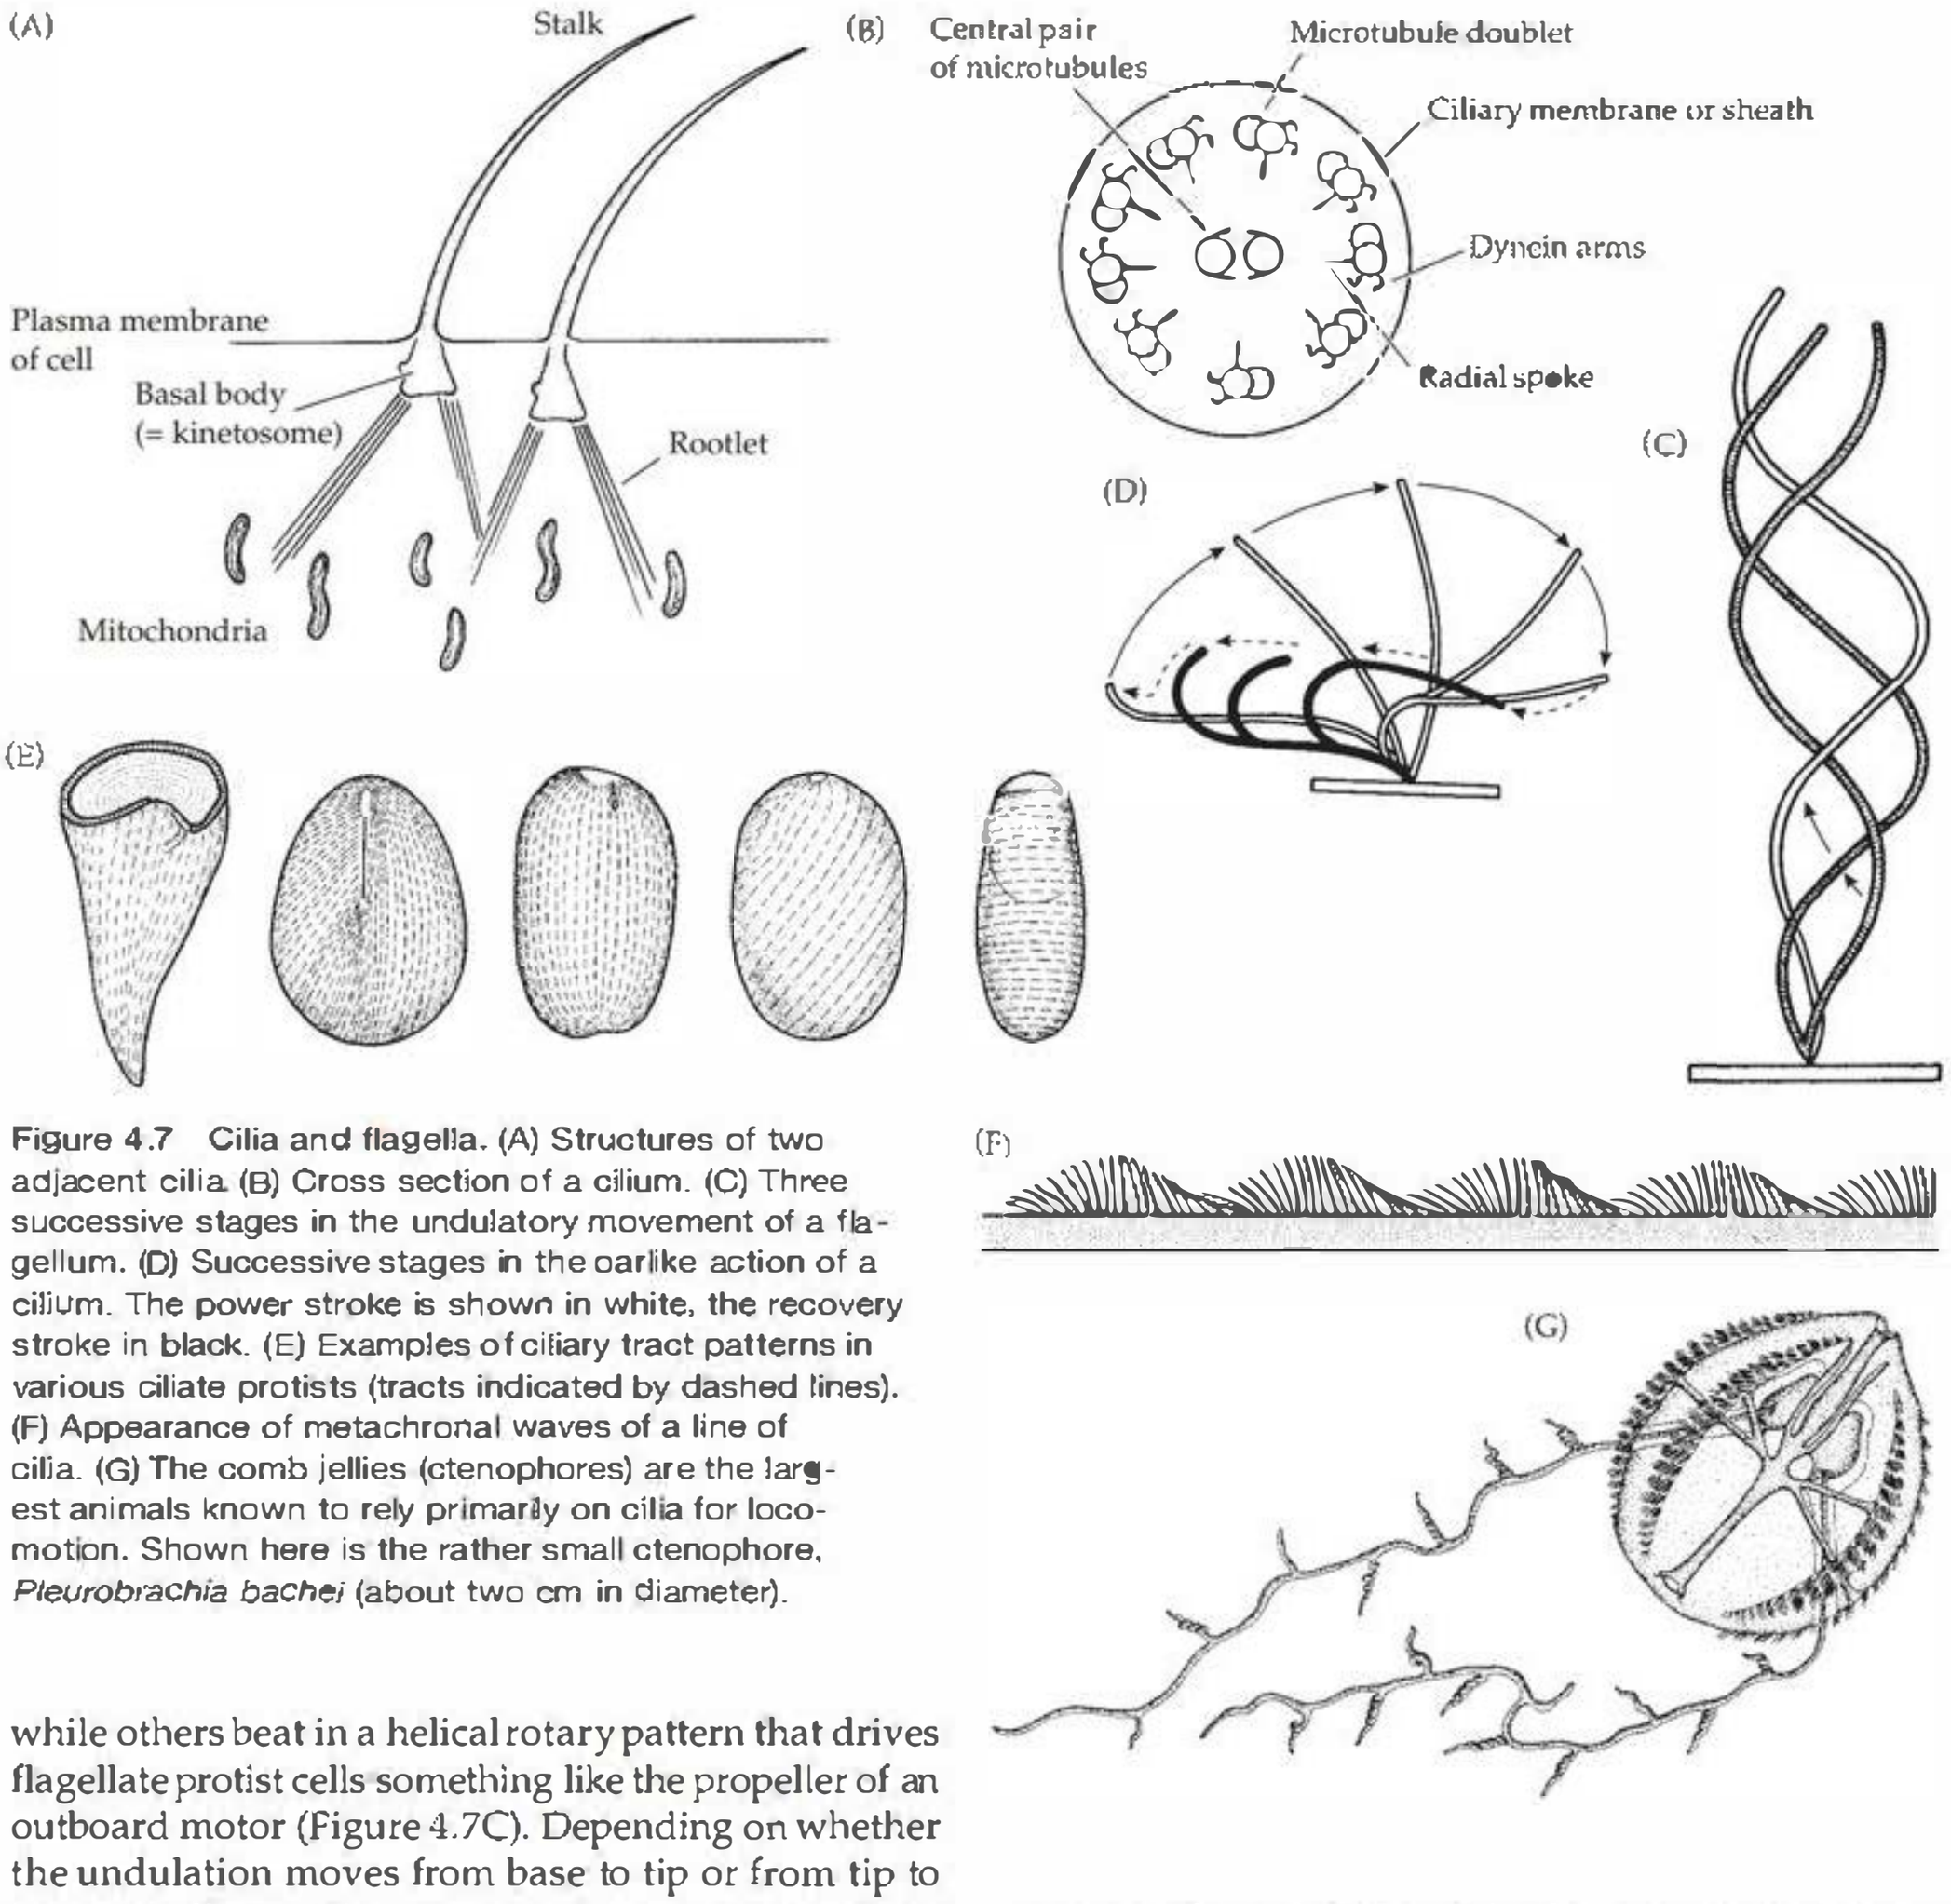

Figure 4.7 Cilia and flagella. (A) Structures of two adjacent cilia. (B) Cross section of a cilium. (C) Three successive stages in the undulatory movement of a flagellum. (D) Successive stages in the oarlike action of a cilium. The power stroke is shown in white, the recovery stroke in black. (E) Examples of ciliary tract patterns in various ciliate protists (tracts indicated by dashed lines). (F) Appearance of metachronal waves of a line of cilia. (G) The comb jellies (ctenophores) are the largest animals known to rely primarily on cilia for locomotion. Shown here is the rather small ctenophore, *Pleurobrachia bachei* (about two cm in diameter).

while others beat in a helical rotary pattern that drives flagellate protist cells something like the propeller of an outboard motor (Figure 4.7C). Depending on whether the undulation moves from base to tip or from tip to base, the effect will be, respectively, to push or pull the cell along.

Some flagella possess tiny, hairlike side branches called **mastigonemes** that increase the effective surface area and thus improve the propulsive capability. The beat of a cilium is generally simpler, consisting of a power stroke and a relaxed recovery stroke (Figure 4.7D). When many cilia are present on a cell, they often occur in distinct tracts, and their action is integrated, with beats usually moving in metachronal waves over the cell surface (Figure 4.7E,F). Since at any one time some cilia are always performing a power stroke, metachronal coordination ensures a uniform and continuous propulsive force.

It was once suggested that ciliary tracts on individual cells were coordinated by a primitive sort of cellular "nervous system," but this hypothesis was never confirmed. Current thinking suggests that the coordinated beating of cilia is probably due to hydrodynamic constraints imposed on them by the interference effects of the surrounding water layers and by the simple mechanical stimulation of moving, adjacent cilia. Nevertheless, some ciliary responses in animals are clearly under neural control, for example, reversal of power stroke direction.

Ciliated protists are the swiftest of the single-celled organisms. Flagellated protists are the next most rapid, and amebas are the slowest. Most amebas move at rates around 5 μm /sec (about 2 cm/hr), or about 100 times slower than most ciliates. Cilia are also used for locomotion by members of several metazoan phyla (including Rhombozoa, Orthonectida, Ctenophora, Platyhelminthes, Rotifera, and some gastropod molluscs), and by the larval stages of a great many taxa.

Muscles and Skeletons

Almost all animals have some sort of a skeleton, the major functions of which are to maintain body shape, provide support, serve as attachments for muscles, transmit the forces of muscle contraction to perform work, and extend relaxed muscles. These functions may be attained either by hard tissues or secreted skeletons, or even by the turgidity of body fluids or tissues under pressure. Muscles, skeletons, and body form are closely integrated, both developmentally and functionally. When rigid skeletal elements are present, they can serve as fixed points for muscle attachment. For example, the rigid and jointed exoskeleton of arthropods allows for a complex system of levers that results in very precise and restricted limb movements. Many invertebrates lack hard skeletons and can change their body shape by alternate contraction and relaxation of various muscle groups attached to tough connective tissues or to the inside of the body wall. These "soft-bodied" invertebrates usually have a hydrostatic skeleton.

The hydrostatic skeleton The performance of a hydrostatic skeleton is based on two fundamental properties of liquids: their incompressibility and their ability to assume any shape. Because of these features, body fluids transmit pressure changes rapidly and equally in all directions. It is important to realize a basic physical limitation concerning the action of muscles—they can only perform work by getting shorter (contracting).[2] In hydrostatic skeletons, a body region is extended (or protruded) by the contractile force of a muscle being imparted to a fluid-filled body compartment, creating a hydrostatic pressure that displaces the wall of the compartment. Such indirect muscle actions can be compared to squeezing a rubber glove filled with water, thereby extending and stiffening the fingers. The enclosure of a fluid-filled chamber (e.g., a coelom) within sets of opposing muscle layers establishes a system in which muscles in one part of the body can contract, forcing body fluids into another region of the body, where the muscles relax; the body is thus extended or otherwise changed in shape (Figure 4.8).

In the most common plan, two muscle layers surround a fluid-filled body cavity, and the fibers of the layers run in different directions (e.g., a circular muscle layer and a longitudinal muscle layer). A soft-bodied invertebrate can move forward by using its hydrostatic skeleton in the following way. The circular muscles at the posterior end of the animal contract; the hydrostatic pressure generated then pushes anteriorly to extend the relaxed longitudinal muscles of the front of the body. Then contraction of the posterior longitudinal muscles pulls the rear end of the body forward. This sequence of muscle contractions results in a directed

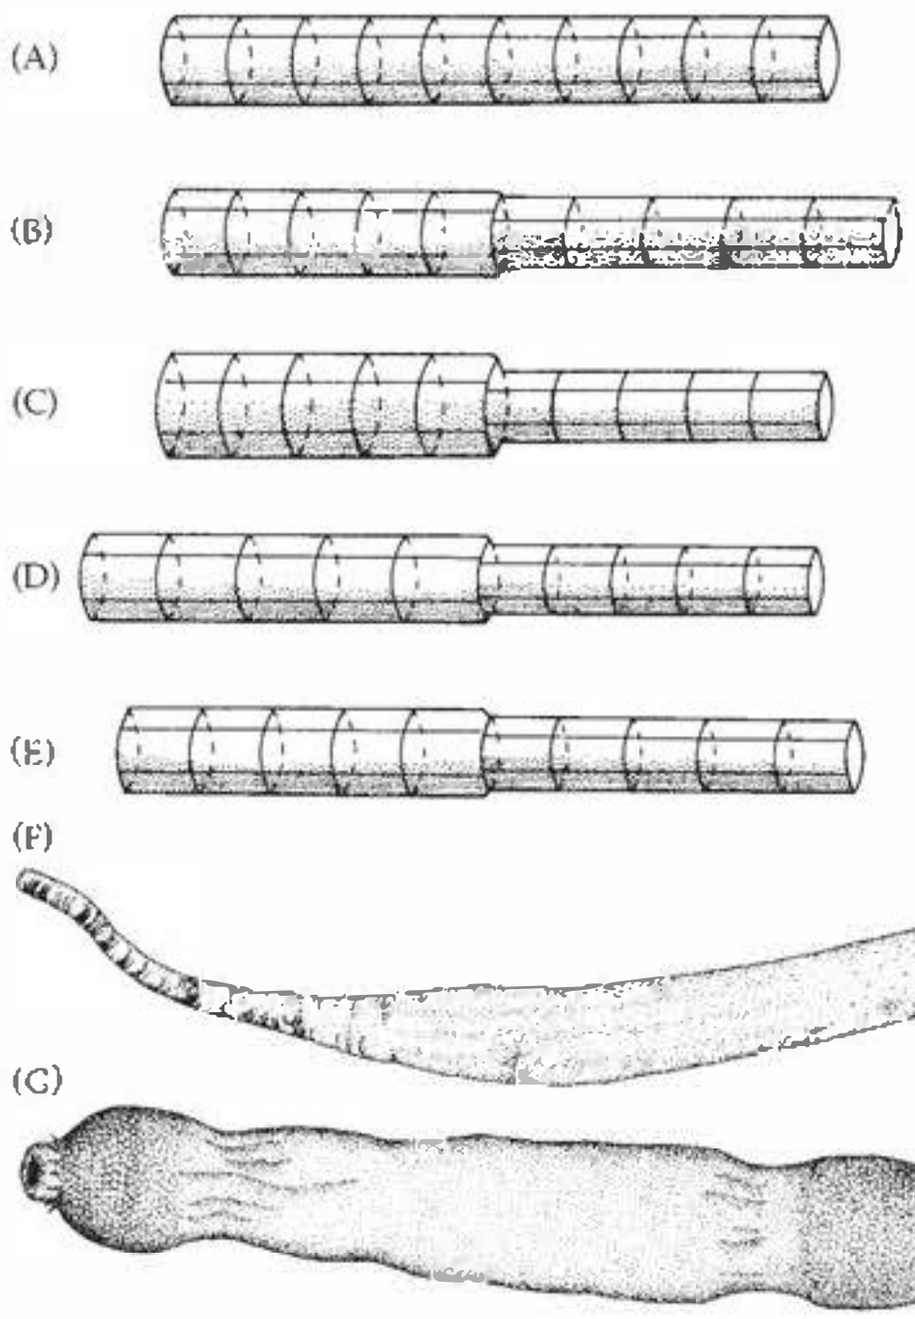

Figure 4.8 The hydrostatic skeleton. (A–E) The initial state and the four possible results of contraction of the circular muscles at one end of a cylindrical animal with a hydrostatic skeleton. (A) The muscles are all relaxed. (B) The circular muscles of the right-hand end have contracted and this end has elongated; the left-hand end has remained unaltered. (C) The length of the right-hand end has remained the same but the diameter of the left-hand end has increased. (D) The length of the right-hand end and the diameter of the left-hand end have remained the same, but the length of the left-hand end has increased. (E) The lengths of both ends have increased, but their respective diameters have remained the same. (F,G) Two animals that rely on hydrostatic skeletons for support and locomotion. (F) The sipunculan worm *Phascolosoma*. (G) The echiurid worm *Urechis caupo*.

and controlled movement forward. Such movement requires that the posterior end be anchored when the anterior end is extended, and that the anterior end be anchored when the posterior end is pulled forward. This system is commonly used for locomotion by many worms that generate posterior-to-anterior metachronal waves of muscle action, resulting in what is called peristalsis. A similar hydrostatic system can be used to temporarily or intermittently extend selected parts of the body, such as the feeding proboscis of worms, tube feet of echinoderms, and siphons of clams.

The contraction of the circular muscles at one end of a vermiform animal may actually have four possible effects: the contracting end may elongate, the opposite end may elongate or thicken, or both ends may

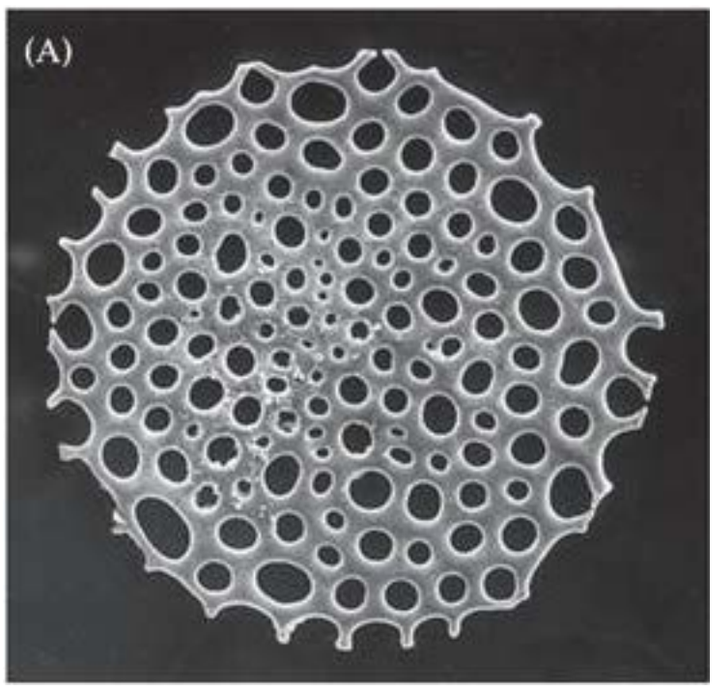
[2]Bear in mind that muscles can contract isometrically and do no work.

elongate. The event that transpires depends not on the contraction of the circular muscles of the contracting end, but instead on the state of contraction of the longi tudinal and circular muscles in other parts of the body (Figure 4.8). Such combinations of muscle contraction and relaxation create a versatile movement system based on very simple mechanical principles.

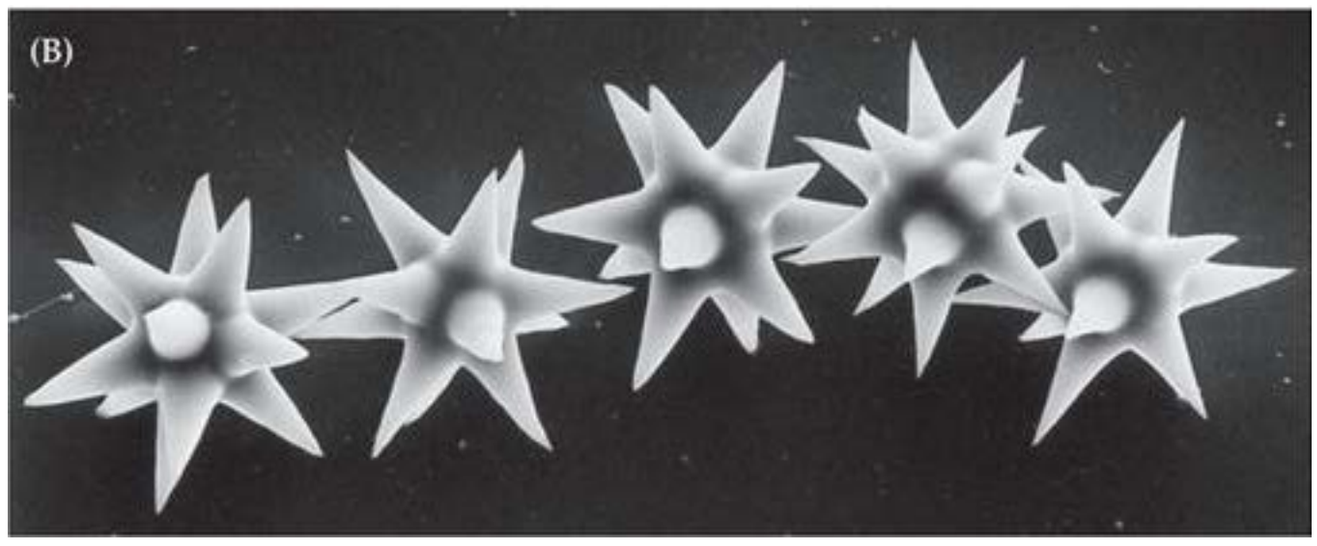
Reliance on only circular and longitudinal muscles could result in twists and kinks when a hydrostatic system engages itself against the resistance of the substratum. Hence, most animals that rely on hydrostatic movement also have helically wound, diagonal muscle fibers—a left- and right-handed set, intersecting at an angle between 0 and 180 degrees. The diagonal muscles allow extension and contraction, even at a con stant volume, without stretching and while preventing kinking and twisting. A good analogy is the children's toy the helically woven straw cylinder into which one youngster convinces another to insert his two index fingers; pushing your fingers together increases the di ameter of the cylinder (and decreases the length), pulling them apart decreases the diameter (and increases the length). All of this is accomplished without an appreciable stretching or compression of the straw fibers (or the diagonal muscles of an invertebrate). When a cylinder is extended, the fiber angle decreases; when it is compressed, the angle increases.

The volume of the working fluid in a hydrostatic skeleton should remain constant, thus any leakage should not be greater than the rate at which the fluid can be replaced. Body fluids must be retained despite "holes" in the body wall, such as the excretory pores of many coelomate animals or the mouth openings of cnidarians. Such openings are often encircled by sphincter muscles that can close and control the loss of body fluids.

One way in which movement by a hydrostatic skele ton can be made more precise is to divide an animal up into a series of separate compartments. For example, in annelid worms, partitioning of the coelom and body muscles into segments with separate neural control enables body expansions and contractions to be confined to a few segments at a time. By manipulating particular sets of segmental muscles, most annelids not only can move forward and backward but can turn and twist in complex maneuvers.



The rigid skeleton In "hard-bodied" invertebrates, a fixed or rigid skeleton prevents the gross changes in body form seen in softbodied invertebrates. This trade-off in flexibility gives hard-bodied animals several advantages: the capacity to grow larger (an advantage that is especially useful in terrestrial habitats, which lack the buoyancy provided by aquatic environments), more precise or controlled body movements, better defense against predators, and often greater speed of movement.



Hard skeletons can be broadly classed as either e n doskeletons or exoskeletons. Endoskeletons are generally derived from mesoderm, whereas exoskeletons are derived from ectoderm; both usually have organic and inorganic components. It has been hypothesized that rigid skeletons may have originated by chance, as b y products of certain metabolic pathways. By sheer accident (preadaptation or exaptation), for example, the accumulation of nitrogenous wastes and their incorporation into complex organic molecules might have resulted in the evolution of the chitinous exoskeleton so common among invertebrates. Similar speculation suggests that a metabolic system that originally functioned to eliminate excess calcium from the body might have produced the first calcareous shell of molluscs. In any event, marine invertebrates are capable of forming, through their various biological activities, a vast array of minerals, some of which cannot be formed inor ganically in the biosphere. Indeed, the ever increasing amounts of these biominerals have radically altered the character of the biosphere since the origin of hard skeletons in the earliest Cambrian. Most common among these biominerals are various carbonates, phosphates, halides, sulfates, and iron oxides.

Invertebrate skeletons may be of the articulating type (e g , the exoskeletons of arthropods, clams, and brachiopods and the endoskeleton of some echinoderms), or they may be of the nonarticulating type, as seen in the simple onepiece exoskeletons of snails and the rigid endoskeletons composed of interlocking fused plates of sea urchins and sand dollars. Animal endoskeletons may be as simple as the microscopic calcareous or siliceous spicules embedded in the body of a sponge, cnidarian, or sea cucumber, or they may be as complex as the bony skeleton of vertebrates (Figure 4 9). Hard skeletons of calcium carbonate have evolved in many animal (and some algal) phyla, but the use of silica in a mineralized skeleton occurs only in sponges (Porifera). Vertebrate skeletal tissues include a calcium phosphate collagen matrix. In invertebrates, collagen often forms a substratum upon which calcareous spicules or other skeletal structures form, but with a single exception (certain gorgonians) collagen is never incorporated directly into the calcareous skeletal material.[3]

In the broadest sense, virtually every group of inver tebrates has developed an exoskeleton of sorts (Figure 4.10). Even cells of protists possess a semirigid ectoplasm, and some have surrounded themselves with a test comprising bits of sand or other foreign matter glued together. Other protists build a test made from chemicals that they either extract from seawater or pro duce themselves.

[3]Collagen, of course, also is the primary component of basement membrane that underlies epithelia in all Metazoa, providing structural integrity to tissues

From their epidermis, many Metazoa secrete a nonliving external layer called the cuticle, which serves as an exoskeleton. The cuticle varies in thickness and complexity, but it often has several layers of differing structure and composition. In the arthropods, for example, the cuticle is a complex combination of the polysaccharide chitin and various proteins.[4] This skeleton may be strengthened by the formation of internal cross-linkages (a process called tanning) and by the addition of calcium and pigments. The chitinous layer of most invertebrates is the first line of defense against infective microbes and desiccation. In most insects, the outermost layer is impregnated with wax, which decreases its permeability to water. The cuticle is often ornamented with spines, tubercles, scales, or striations; frequently it is divided into rings or segments, a feature lending flexibility to the body. Other examples of exoskeletons are the calcareous shells of many molluscs and the casings of corals (Figure 4.10).

[4]The term chitin refers to a family of closely related chemical compounds, which, in various forms, are produced by and incorporated into the cuticles of many invertebrates. Certain types of chitin are also produced by some fungi and diatoms. Chitins are high-molecular weight, nitrogenous polysaccharide polymers that are tough yet flexible (Figure 4.10F). In addition to its supportive and protective functions in the formation of exoskeletons, chitin is also a major component of the teeth, jaws, and grasping and grinding structures of a wide variety of invertebrates. That chitin is one of the most abundant macromolecules on earth is evidenced by the estimated 10^{11} tons produced annually in the biosphere—most of it in the ocean.

Most skeletons act as body elements against which muscles operate and by which muscle action is converted to body movement. Because muscles cannot elongate by themselves, they must be stretched by antagonistic forces—usually other muscles, hydrostatic forces, or elastic structures. In animals possessing rigid but articulated skeletons, antagonistic muscles often appear in pairs, for example, flexors and extensors. These muscles extend across a joint and are used to move a limb or other body part (Figure 4.11). Most muscles have a discrete origin, where the muscle is anchored, and an insertion, which is the point of major body or limb movement. A classic vertebrate example of this system is the biceps muscle of the human arm, in which the origin is on the scapula and the insertion is on the radius bone of the forearm; contraction of the biceps causes flexion of the arm by decreasing the angle between the upper arm and the forearm. Movement of a limb toward the body is brought about by flexor muscles, of which the biceps is an example (Figure 4.11A,B). The muscle antagonistic to the biceps is the triceps, an extensor muscle whose contraction extends the forearm away from the body. Other common sets of antagonistic muscles and actions are protractors and retractors, which respectively cause anterior and posterior movement of entire limbs at their place of juncture with the body; and adductors and abductors, which move a body part toward or away from a particular point of reference. Although vertebrates have endoskeletons and arthropods have exoskeletons, most muscles of arthropods are arranged in antagonistic sets

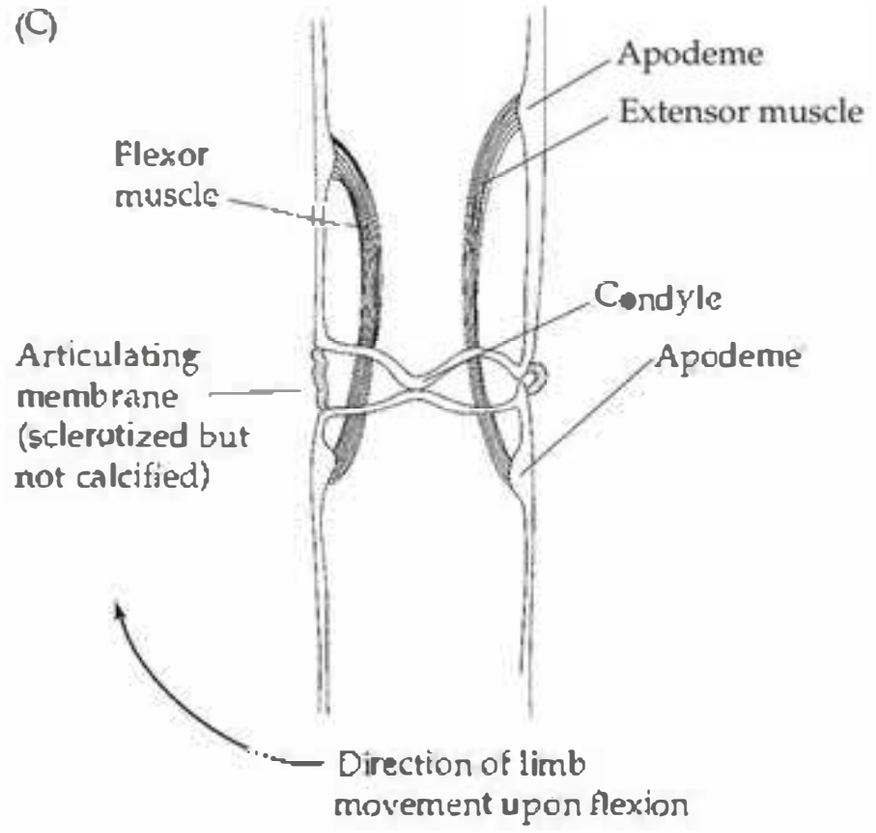

Figure 4.11 How antagonistic muscles work. (A) The biceps is contracted and the triceps relaxed; this combination flexes the forearm. (B) The biceps is relaxed and the triceps is contracted; this combination extends the forearm. (C) A diagrammatic representation of an arthropod joint, illustrating a similar relationship between flexor and extensor. In arthropods, however, the muscles attach to the inside of the skeleton.

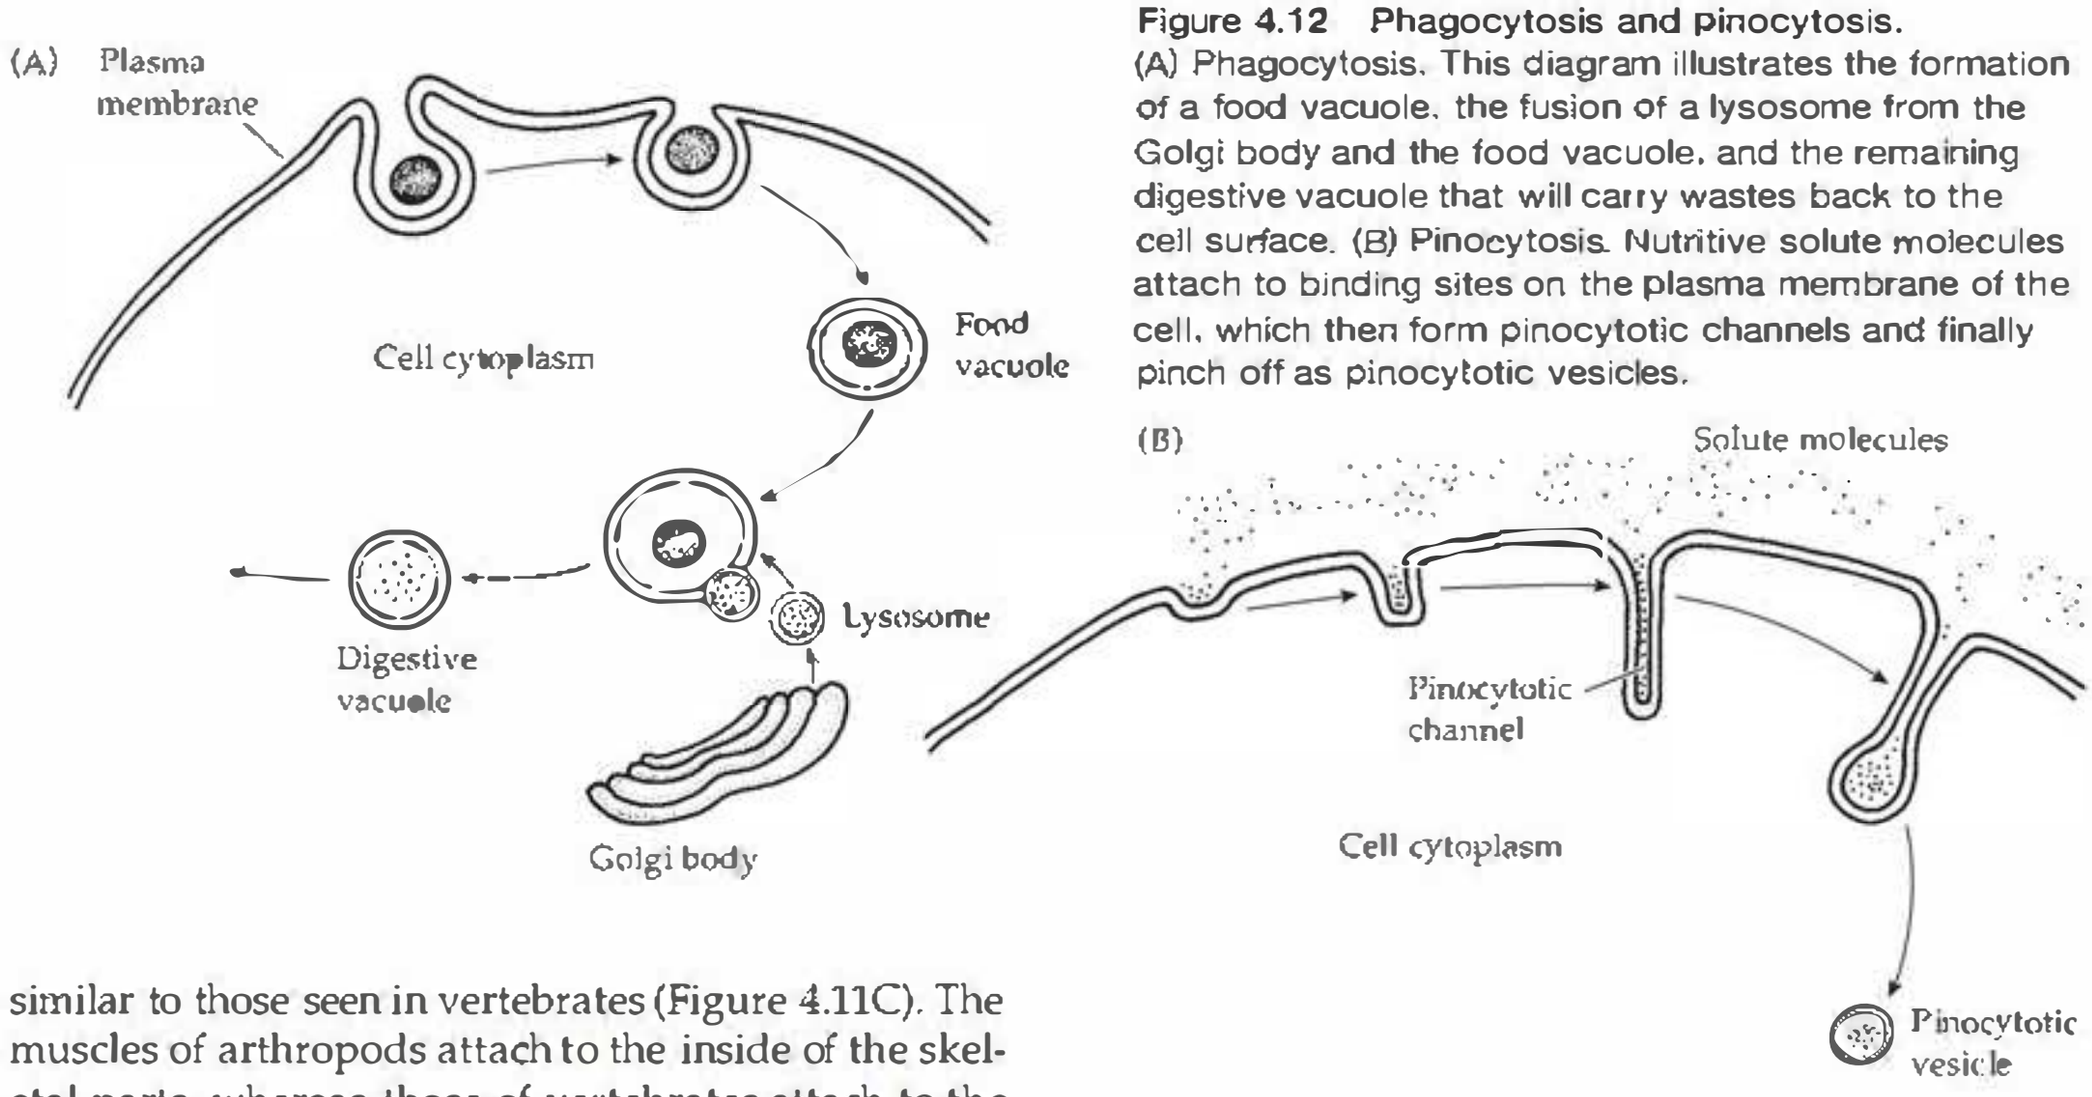

Figure 4.12 Phagocytosis and pinocytosis. (A) Phagocytosis. This diagram illustrates the formation of a food vacuole, the fusion of a lysosome from the Golgi body and the food vacuole, and the remaining digestive vacuole that will carry wastes back to the cell surface. (B) Pinocytosis. Nutritive solute molecules attach to binding sites on the plasma membrane of the cell, which then form pinocytotic channels and finally pinch off as pinocytotic vesicles.

similar to those seen in vertebrates (Figure 4.11C). The muscles of arthropods attach to the inside of the skeletal parts, whereas those of vertebrates attach to the outside, but they both operate systems of levers.

Not all muscles attach to rigid endo- or exoskeletons. Some form masses of interlacing muscle fibers, like those in the body wall of a worm, the foot of a snail, or the muscle layers in the walls of "hollow" organs (like those surrounding a gut tube or uterus). In these cases, the muscles have no definite origin and insertion but act on each other and the surrounding tissues and body fluids to affect changes in the shape of the body or body parts.

The basic physiology and biochemistry of muscle contraction is the same in vertebrates and invertebrates, although a variety of specialized variations on the basic model have evolved. For example, the adductor muscle of a clam (the muscle that holds the shell closed) is divided into two parts. One part is heavily striated and used for rapid shell closure (the phasic, or "quick" muscle); the other is smooth, or tonic, and is used to hold the shell closed for hours or even days at a time (the "catch" muscle). Brachiopods have a similar adductor muscle specialization—a good example of convergent evolution. Other specializations are found in crustacean muscle innervation, which differs from that typically seen in other invertebrates, and in certain insect flight muscles that are capable of contracting at frequencies far higher than can be induced by nerve impulses alone.

Feeding and Digestion

Intracellular and Extracellular Digestion

Virtually all Metazoa and heterotrophic protists must locate, select, capture, ingest, and finally digest and assimilate food. Although the physiology of digestion is similar at the biochemical level, considerable variation exists in the mechanisms of capture and digestion as a result of constraints placed on organisms by their overall body plans.

Digestion is the process of breaking down food by hydrolysis into units suitable to the nutrition of cells. When this breakdown occurs outside the body, it is called extracorporeal digestion; when it occurs in a gut chamber of some sort, it is referred to as extracellular digestion; and when the process occurs within a cell, it is called intracellular digestion. Regardless of the site of digestion, all organisms are ultimately faced with the fundamental challenge of cellular capture of nutritional products (food, digested or not). This cellular challenge is met by the process of **phagocytosis** (literally, "eating by cells") and **pinocytosis** ("drinking by cells"). These processes, collectively called **endocytosis**, are mechanically simple and involve the engulfment of food "particles" at the cell surface.

In 1892 the great comparative anatomist Elie Metchnikoff made a discovery that led to his receiving the Nobel Prize 16 years later. Metchnikoff discovered the process by which certain ameboid cells in the coelomic fluid of starfish engulf and destroy foreign matter such as bacteria. He named this process phagocytosis. In phagocytosis, extensions of a cell's plasma membrane encircle the particle to be captured (whether it be food or a foreign microbe), form an inpocketing on the cell surface, and then pinch off the pocket inside the cell (Figure 4.12A). The resultant intracellular membrane-bounded structure is called a food vacuole. Because the food particle is inside a chamber formed and bounded by a piece of the original plasma membrane of the cell, some biologists consider that it is not actually "inside" the cell, but this point is of little consequence. The

plasma membrane surrounding the food vacuole is, of course, no longer part of the cell's outer membrane and in this sense it and whatever is in the vacuole are now "inside" the cell, and the subsequent digestive processes that take place are considered intracellular, not extracellular. However, food inside the food vacuole is not actually incorporated into the cell's cytoplasm until it is digested and the resultant molecules are released.

Protists and sponges rely on phagocytosis as a feeding mechanism, and the digestive cells of metazoan guts take up food particles in the same fashion. Once a cell has phagocytosed a food particle and intracellular digestion has been completed, any remaining waste particles may be carried back to the cell surface by what remains of the old food vacuole, which fuses with the plasma membrane to discharge its wastes in a sort of reverse phagocytosis, called exocytosis.

Pinocytosis can be thought of as a highly specialized form of phagocytosis, in which moleculesized particles are taken up by the cell. Such molecules are always dissolved in some fluid (e g , a body fluid, or sea water). During pinocytosis, minute invaginations (pinocytotic channels) form on the cell surface, fill with liquid from the surrounding medium (which includes the dissolved nutritional molecules), and then pinch off to enter the cytoplasm as pinocytotic vesicles (Figure 4 12B). Pinocytosis generally occurs in cells lining some body cavity (e.g., the gut) in which considerable extracellular digestion has already taken place and nutritive molecules have been released from the original food source. In some cases, however, nutritional molecules may be taken up directly from seawater, and there is growing evidence that many invertebrates rely substantially on the direct uptake of dissolved organic matter (DOM) from their environment.

Some animals have no true digestive tract (e.g., Porifera, Placozoa, tapeworms, acanthocephalans), but most metazoans possess some sort of dedicated, internal chamber into which food is moved for processing. In some (e.g., Cnidaria, Ctenophora, Xenacoelomorpha, Platyhelminthes) there is only one opening through which food is ingested and undigest ed materials eliminated. These animals are said to have an incomplete gut (or blind gut). Most other Metazoa have both mouth and anus (a complete gut, or through gut), an arrangement that allows the one way flow of food and the specialization of different gut regions for functions such as grinding, secretion, storage, digestion, and absorption. As the noted biologist Libbie Hyman so aptly put it, "The advantages of an anus are obvious."

The overall anatomy and physiology of an animal's gut are closely tied to the type and quality of food con sumed. In general, the guts of herbivores are long and often have specialized chambers for storage, grinding, and so on because vegetable matter is difficult to digest and requires long residence times in the digestive system. Carnivores tend to have shorter, simpler guts; the animal foods they consume are higher quality and easier to digest.

Feeding Strategies

Just as body architecture influences and limits the digestive modes of invertebrates, it is also intimately associated with the processes of food location, selection, and ingestion. Animals and animal like protists are generally defined as **heterotrophic** organisms (as opposed to autotrophs and saprophytes); they ingest organic material in the form of other organisms, or parts thereof. However, in several groups of protists (e.g., many euglenoids and chlorophytans), both photosynthesis and heterotrophy can occur as nutritional strategies. In addition, many nonphotosynthetic invertebrate groups have developed intimate symbiotic relationships with single celled algae, especially with certain species of dinoflagellates. These invertebrates use photosynthetic by-products as an accessory (or occasionally as the primary) food source. Notable in this regard are reef-building corals, giant clams (*Tridacna*), and certain flatworms, sea slugs, hydroids, a s cidians, sea anemones, freshwater sponges, and even some species of the protist *Paramecium*. However, the overwhelming majority of invertebrates lead strictly heterotrophic lives.

Biologists classify heterotrophic feeding strategies in a number of ways. For example, organisms can be considered herbivores, carnivores, or omnivores; or they can be classed as grazers, predators, or scavengers. Organisms can also be classified as microphagous or macrophagous by the comparative size of their food or prey, or they can be classified by the environmental source of their food as suspension feeders, deposit feeders, or detritivores. In the remainder of this section we define some important feeding strategy terms and explain some common themes of feeding.

Few invertebrates are strictly herbivores or carnivores, even though most show a clear preference for either a vegetable or a meat diet. For example, the Atlantic purple sea urchin *Arbacia punctulata* usually feeds on micro- and macroalgae. However, in certain portions of its range, where algae may become seasonally scarce, epifaunal animals constitute the bulk of this urchin's diet. Omnivores, of course, must have the anatomical and physiological capability to capture, handle, and digest both plant and animal material. Among invertebrates, there are two large categories of feeding strategies in which omnivory prevails: suspension feeding and deposit feeding.

Suspension feeding Suspension feeding is the re moval of suspended food particles from the surrounding medium by some sort of capture, trapping, or filtration mechanism. Lest you think suspension feeding is a sideline strategy in the animal kingdom, let us remind

you that the largest living animals utilize it baleen whales and several lineages of sharks and rays. This mode of feeding has three basic steps: transport of water past the feeding structures, removal of particles from the water, and transport of the captured particles to the mouth. It is a major mode of feeding in sponges, ascidians, appendicularians, brachiopods, ectoprocts, entoprocts, phoronids, most bivalves, and many crustaceans, polychaetes, and gastropods. The main food selection criterion is particle size, and the size limits of food are determined by the nature of the particle capturing device. In some cases potential food particles may also be sorted on the basis of their specific gravity, or even their perceived nutritional quality

Suspension feeding invertebrates generally consume bacteria, phytoplankton, zooplankton, and some detritus. All suspension feeders probably have optimal ranges of particle size; but some are capable, experimentally, of preferentially selecting "enriched" artificial food capsules over nonenriched (nonfood) capsules, an observation suggesting that chemosensory selectivity may occur in situ as well. To capture food particles from their environment, suspension feeders either must move part or all of their body through the water, or water must be moved over their feeding structures. As with locomotion in water, the relative motion between a solid and liquid during suspension feeding creates a system that behaves according to the concept of Reynolds numbers. Virtually all suspension-feeding invertebrates capture particles from the water at low Reynolds numbers. The flow rates in such systems are very low and the feeding structures are small (e.g., cilia, flagella, setae).

Recall that at low Reynolds numbers viscous forces dominate, and water flow over small feeding structures is laminar and nonturbulent and ceases instantaneously when energy input stops. Thus, in the absence of inertial influence, suspension feeders that generate their own feeding currents expend a great deal of energy. Some suspension feeders conserve energy by depending to various degrees on prevailing ambient water movements to continually replenish their food supplies (e.g., barnacles on waveswept shores and mole crabs in the wash zone on sandy beaches). For most organisms, however, the effort expended for feeding is a major part of their energy budget.

Only a relatively few suspension feeders are true filterers. Because of the principles outlined above, it is energetically extremely costly to drive water through a fine-meshed filtering device For small animals, this is somewhat analogous to moving a finemesh filter through thick syrup. Such actual sieving does occur, most notably in many bivalve molluscs, many tunicates, some larger crustaceans, and some worms that produce mucous nets. However, most suspension feeders employ a less expensive method of capturing particles from the water, one that does not involve continuous filtration. Many invertebrates simply expose a sticky surface, such as a coating of mucus, to flowing water Suspended particles contact and adhere to the surface and then are moved to the mouth by ciliary tracts (as in crinoids), setal brushes (as in certain crustaceans), or by some other means of transport. Other "contact suspension feeders" living in still water may simply expose a sticky surface to the rain of particulate material settling downward from the water above, thus letting gravity do much of the work of food getting. Some oysters are suspected of this feeding strategy, at least on a part time basis. Several other contact methods of suspension feeding may occur, but all eliminate the costly activity of actual sieving in the highly viscous world of low Reynolds numbers

Another nonfiltering suspension feeding method is called "scan and trap." The general strategy here is to move water over part or all of the body, detect suspended food particles, isolate the particles in a small parcel of water, and process only that parcel by some method of particle extraction. The animal thus avoids the energetic expense of continuously driving water over the feeding surface at low Reynolds numbers. The precise methods of particle detection, isolation and capture vary among invertebrates that use the scan and trap technique, and this basic strategy is probably employed by certain crustaceans (e.g., planktonic copepods), many bryozoans, and a variety of larval forms.

The trick of removing small food particles from the surrounding environment is achieved through four fundamentally different mechanisms. Because there are a limited number of ways in which animals can suspension feed, it is not surprising that a great deal of evolutionary convergence has appeared among their feeding mechanisms.

Among some crustaceans, certain limbs are equipped with rows of feather like setae adapted for removing particles from the water (Figure 4.13). The size of the particles captured is often directly proportional to the "mesh" size of the interlaced setae on the food-capture structure. In sessile crustaceans such as barnacles, the feeding appendages are swept through the water or held taut against moving water. In either case, sessile animals are dependent upon local currents to continually replenish their food supply. Motile setal-net feeders, like many larger planktonic crustaceans and certain benthic crustaceans (e.g., porcelain crabs), may have modified appendages that generate a current across the feeding appendages that bear the capture setae. Sometimes these same appendages serve simultaneously for locomotion. In cephalocarid and many branchiopod crustaceans, for example, complex coordinated movements of the highly setose thoracic legs propel the animal forward and also produce a constant current of water (Figure 4.13D). These appendages simultaneously capture food particles from the water and collect them in a median ventral food groove at the leg bases, where they are passed forward to the mouth region.

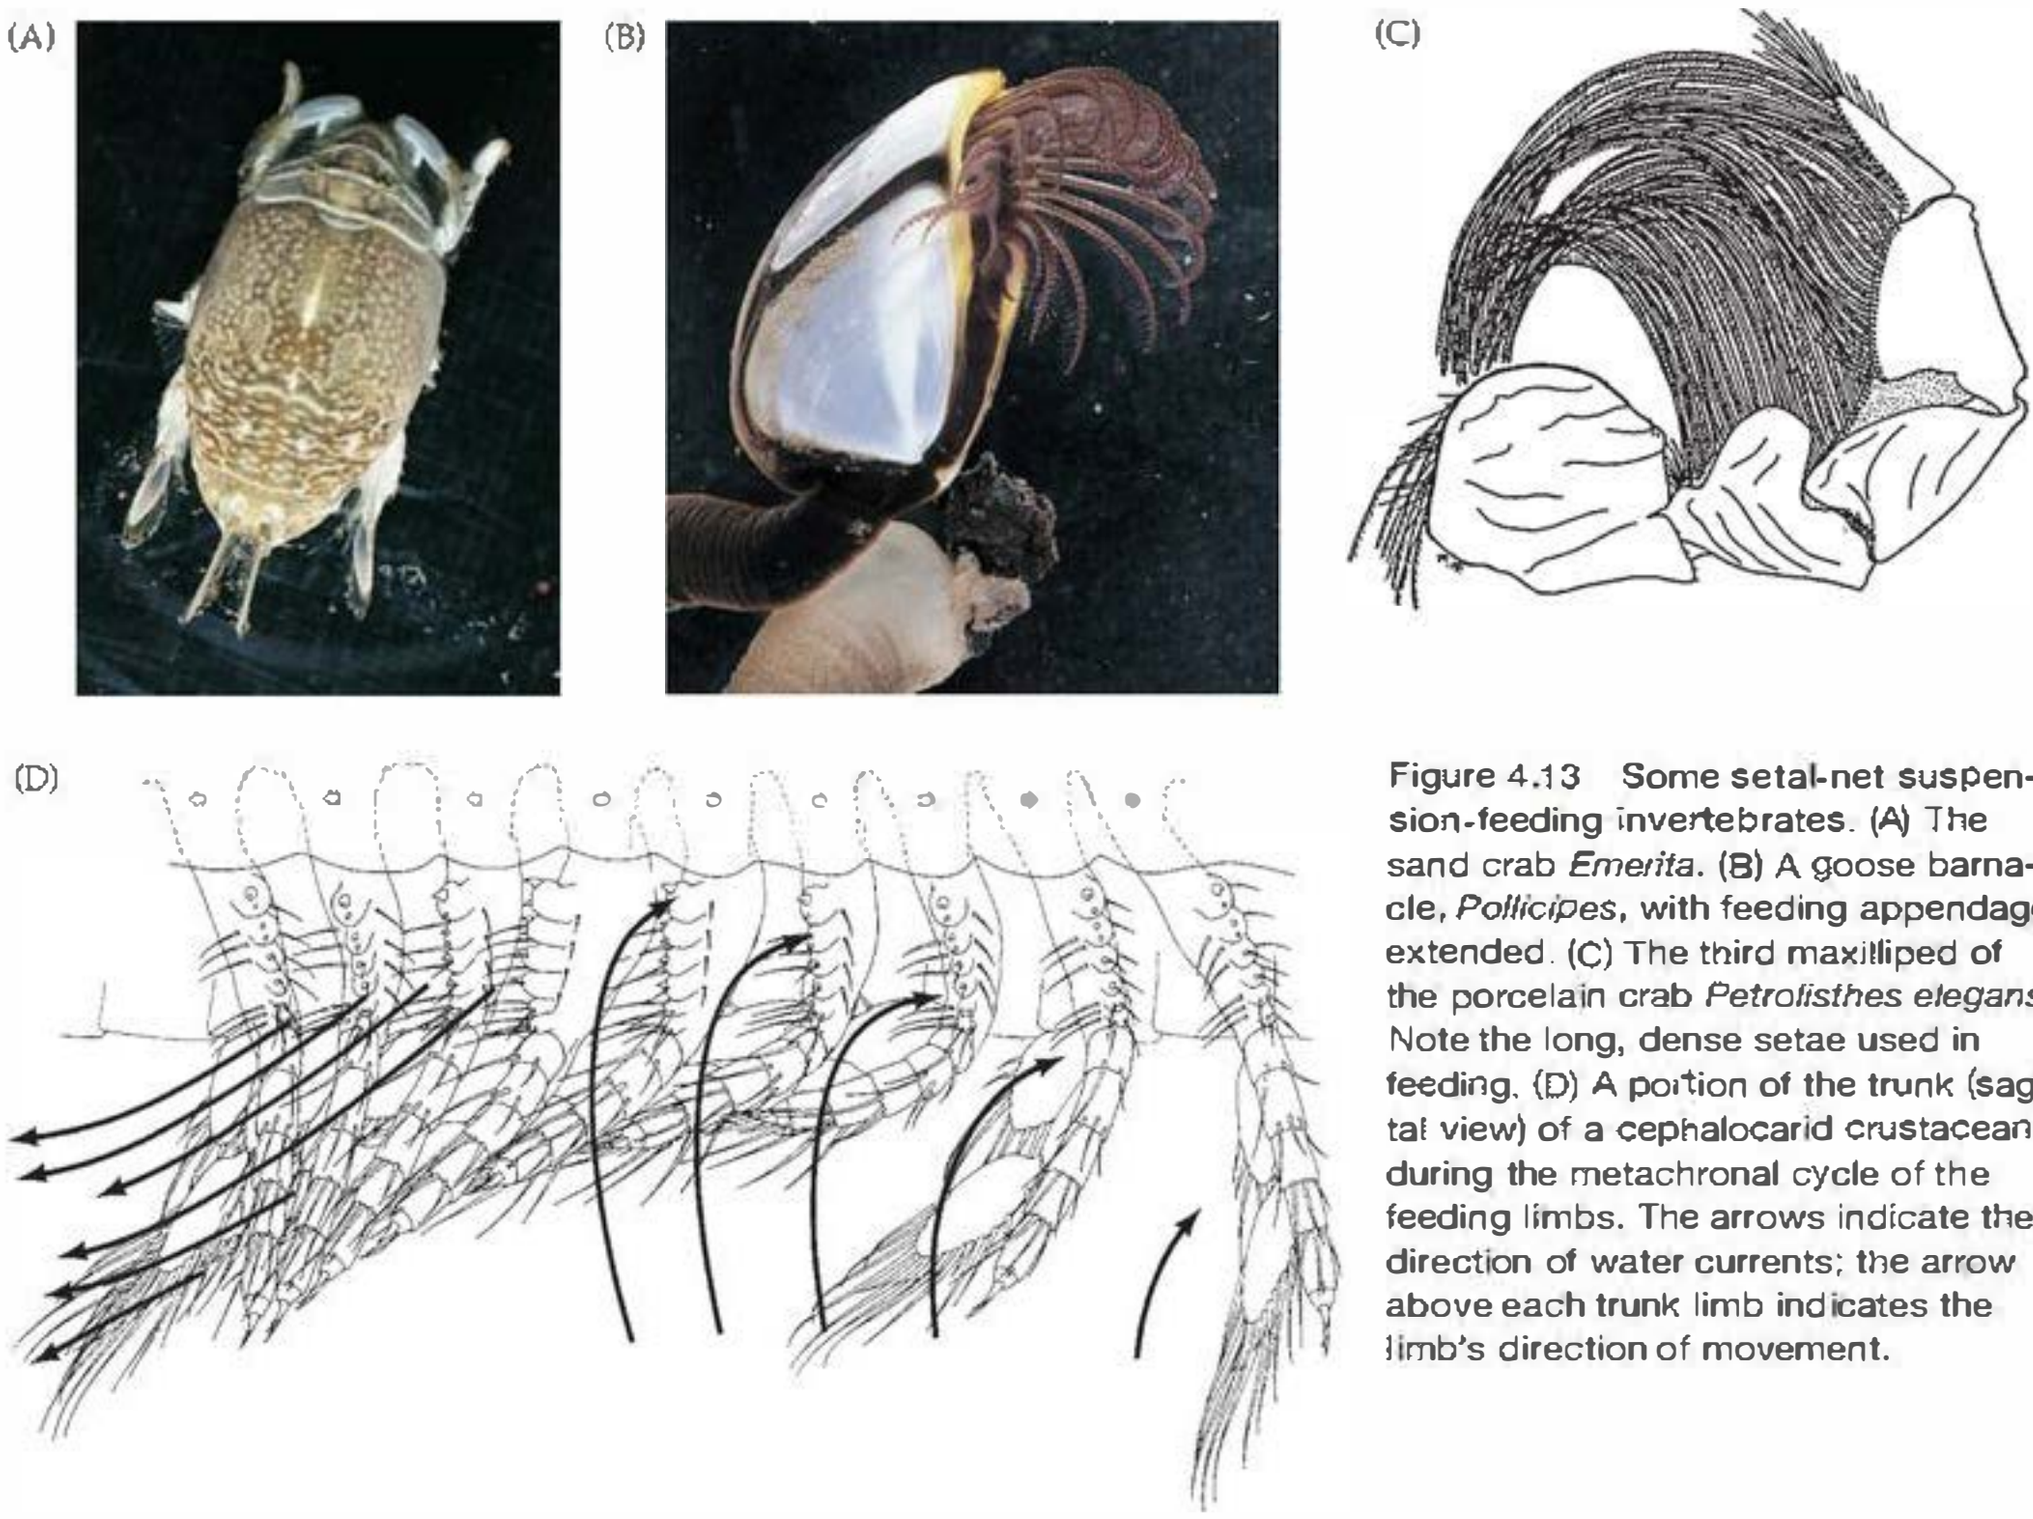

Figure 4.13 Some setal-net suspension-feeding invertebrates. (A) The sand crab *Emerita*. (B) A goose barnacle, *Pollicipes*, with feeding appendages extended. (C) The third maxilliped of the porcelain crab *Petrolisthes elegans*. Note the long, dense setae used in feeding. (D) A portion of the trunk (sagittal view) of a cephalocarid crustacean during the metachronal cycle of the feeding limbs. The arrows indicate the direction of water currents; the arrow above each trunk limb indicates the limb's direction of movement.

A second suspension-feeding device is the mucous net, or mucous trap, wherein patches or a sheet of mucus are used to capture suspended food particles. Most mucous-net feeders consume their net along with the food and recycle the chemicals used to produce it. Again, sessile and sedentary species often rely largely on local currents to keep a fresh supply of food coming their way. Some, however, especially benthic burrowers, actively pump water through their burrow or tube, where it passes across or through the mucous sheet. A classic example of mucous-net feeding is seen in the annelid worm *Chaetopterus* (Figure 4.14A). This animal lives in a U-shaped tube in the sediment and pumps water through the tube and through a mucous net. As the net fills with trapped food particles, it is periodically manipulated and rolled into a ball, which is then passed to the mouth and swallowed. An example of mucous-trap feeding is seen in the tube-building gastropods (family Vermetidae). These wormlike snails construct colonies of meandering calcareous tubes in the intertidal zone. Each animal secretes a mucous trap that is deployed just outside the opening of the tube, until nearly the entire colony surface is covered with mucus. Suspended particulate matter settles and becomes trapped in the mucus. At periodic intervals, each animal withdraws its mucous sheet and swallows it, whereupon a new sheet is immediately constructed.

Another type of suspension feeding is the ciliary-mucous mechanism, in which rows of cilia carry a mucous sheet across some structure while water is passed through or across it. Ascidians (sea squirts; Figure 4.14B) move a more or less continuous mucous sheet across their sievelike pharynx, while at the same time pumping water through it. Fresh mucus is secreted at one side of the pharynx while the food-laden mucus at the other side is moved into the gut for digestion. Several polychaete groups also make use of the ciliary-mucous feeding technique (Figure 4.14C). For example, some species of tube-dwelling fan worms feed with a crown of tentacles that are covered with cilia and mucus and bear ciliated grooves that slowly move captured food particles to the mouth. Many sand dollars capture suspended particles, especially diatoms, on their mucus-covered spines; food and mucus are transported by the tube feet and ciliary currents to food tracts, and then to the mouth.

Still another kind of suspension feeding is tentacle or tube feet suspension feeding. In this strategy, some sort of tentacle-like structure captures larger food particles, with or without the aid of mucus. Food particles captured by this mechanism are generally larger than those captured by setal or mucous traps or sieves. Examples of tentacle or tube feet suspension feeding are most commonly encountered in the echinoderms

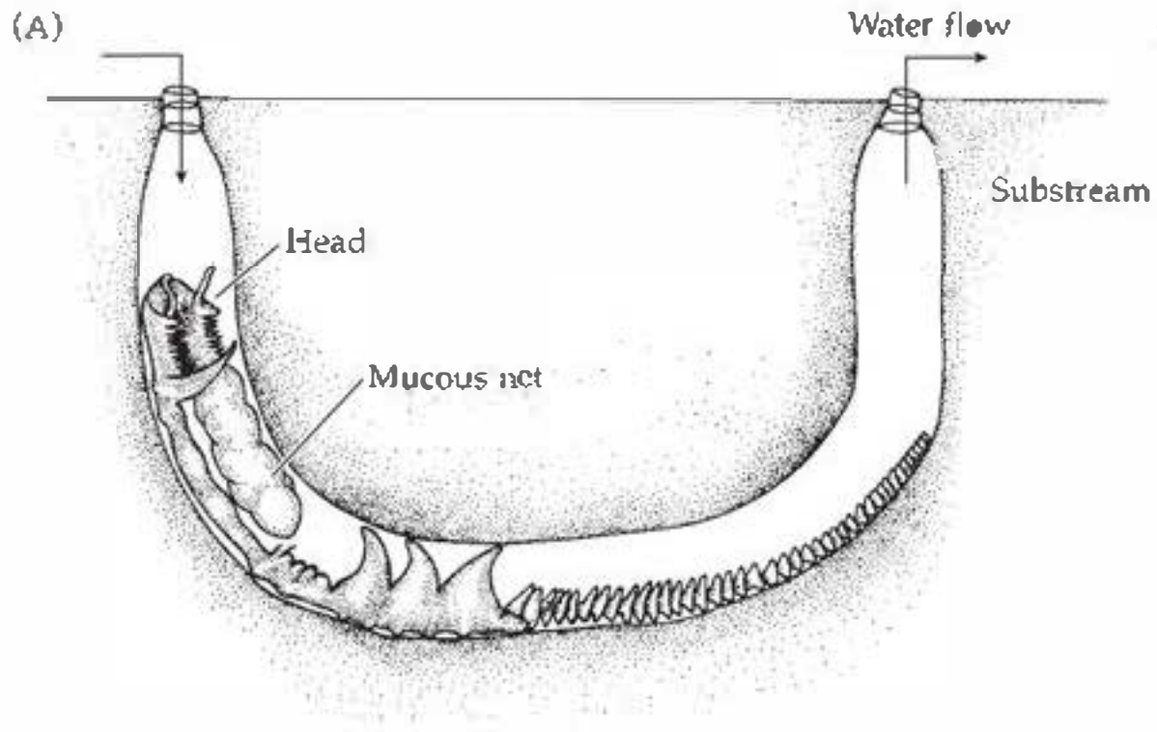

Figure 4.14 Some mucous-net and ciliary-mucous suspension feeders. (A) The annelid worm *Chaetopterus* in its burrow. Note the direction of water flow through its mucous net. (B) The solitary ascidian *Styela* has incurrent and excurrent siphons through which water enters and leaves the body. Inside, the water passes through a sheet of mucus covering holes in the wall of the pharynx. (C) A maldanid polychaete, *Praxillura maculata*. This animal constructs a membranous tube that bears 6–12 stiff radial spokes. A mucous web hangs from these spokes and passively traps passing food particles. The worm's head is seen sweeping around the radial spokes to retrieve the mucous web and its trapped food particles.

(e.g., many brittle stars and crinoids) and cnidarians (e.g., certain sea anemones and corals; Figure 4.15).

Much research has been done on suspension feeding, and we now know what size range of particles many animals feed on and what kinds of capture rates they have. In general, feeding rates increase with food particle concentration to a plateau, above which the rate levels off. At still higher particle concentrations, entrapment mechanisms may become overtaxed or clogged and feeding is inhibited or simply ceases. In sessile and sedentary suspension feeders, for example, pumping rates decrease quickly as the amount of suspended inorganic sediment (mud, silt, and sand) increases beyond a given concentration. For this reason, the amount of sediment in coastal waters limits the distribution and abundance of certain invertebrates such as clams, corals, sponges, and ascidians. Many tropical coral reefs are dying as a result of increased coastal sediment loads generated by run-off from land areas subjected to deforestation or urban development.

Deposit feeding The deposit feeders make up another major group of omnivores. These animals obtain nutrients from the sediments of soft-bottom habitats (muds and sands) or terrestrial soils, but their techniques for feeding are diverse. Direct deposit feeders

Figure 4.15 Tube feet suspension feeding. Food-particle capture in the brittle star *Ophiothrix fragilis*. The photographs show two views of a captured food particle being transported by the arm tentacles to the mouth.

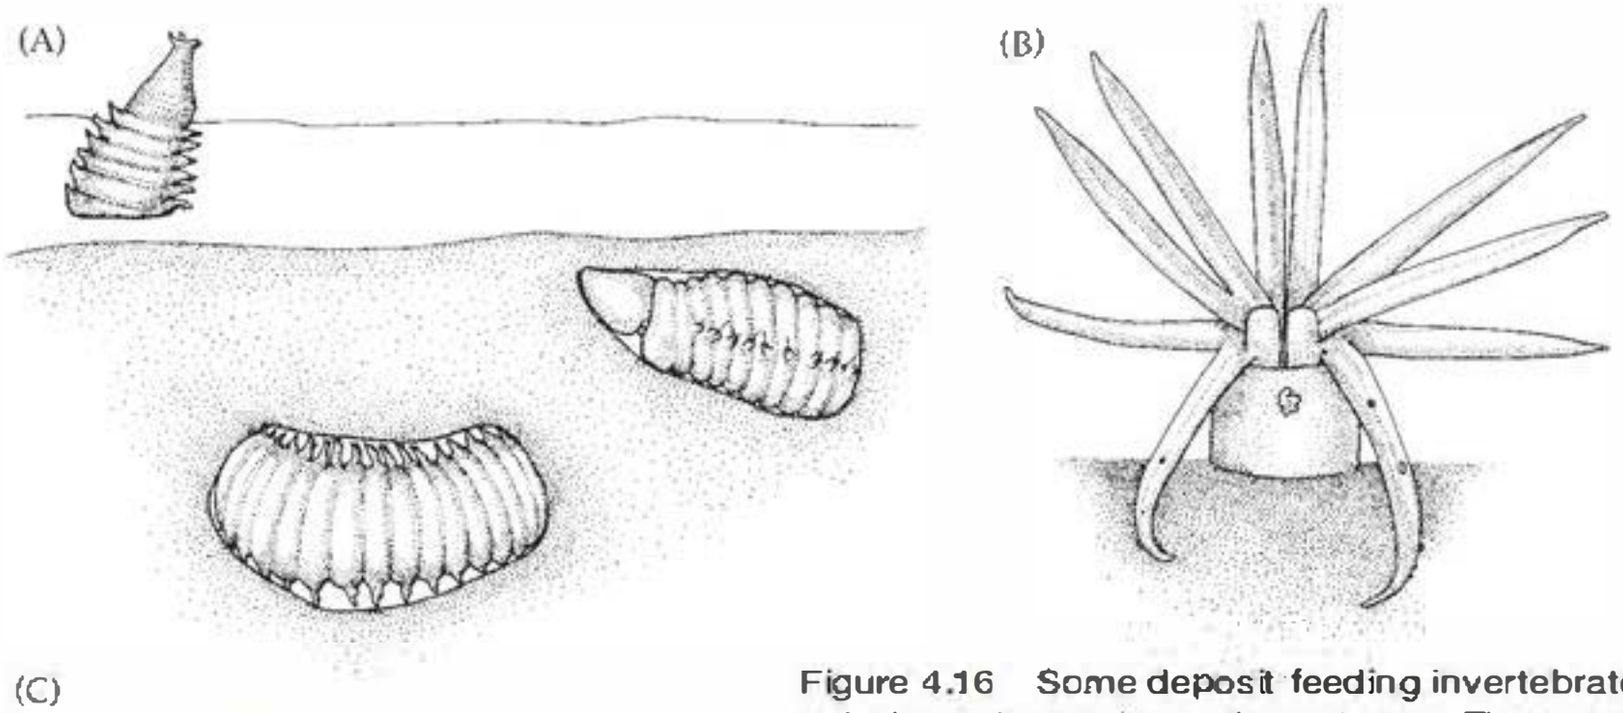

Figure 4.16 Some deposit feeding invertebrates. (A) A lumbrinerid polychaete burrowing in the sediment. This worm is a subsurface deposit feeder. (B) The sabellid polychaete *Manayunkia aestuarina* in its feeding posture. A pair of branchial filaments are being used to feed. simply swallow large quantities of sediment—mud, sand, soil, organic matter, everything. They may consume up to 500 times their body weight daily. The usable organics are digested and the unusable materials passed out the anus. The resultant fecal material is essentially "cleaned dirt." This kind of deposit feeding is seen in many polychaete annelids (Figure 4.16A), some snails, some sea urchins, and most earthworms. Some deposit feeders utilize tentacle-like structures to consume sediment, such as some sea cucumbers, most sipunculans, certain clams, and several types of polychaetes (Figure 4.16B,C). Tentacle-utilizing deposit feeders preferentially remove only the uppermost deposits from the sediment surface and thus consume a far greater percentage of living (especially bacteria, diatoms, and protists) and detrital organic material that accumulates there than do the burrowing deposit feeders. These animals are generally called selective deposit feeders. Aquatic deposit feeders may also rely to a significant extent on fecal material that accumulates on the bottom, and many will actively consume their own fecal pellets (coprophagy), which may contain some undigested or incompletely digested organic material as well as microorganisms. Studies have shown that only about half of the bacteria ingested by marine deposit feeders is digested during passage through the gut. In all cases, deposit feeders are microphagous.

The ecological role of deposit feeding in sediment turnover is a critical one. When burrowing deposit feeders are removed from an area, organic debris accumulates, subsurface oxygen is depleted by bacterial decomposition, and anaerobic sulfur bacteria eventually bloom. On land, earthworms and other burrowers are important in maintaining the health of agricultural and garden soils.

Herbivory The following discussion deals with macroherbivory, or the consumption of macroscopic plants. Herbivory is common throughout the animal kingdom. It is most dramatically illustrated when certain invertebrate herbivores undergo a temporary population explosion. Famous examples are outbreaks of locust, which can destroy virtually all plant material in their path of movement In a similar fashion, herbivory by extremely high numbers of the Pacific sea urchin *Strongylocentrotus* results in the wholesale destruction of kelp beds. Unlike suspension- and deposit-feeding herbivory, in which mostly singlecelled and microscopic plant matter is consumed, macroherbivory requires the ability to "bite and chew" large pieces of vegetable matter. Although the evolution of biting and chewing mechanisms has taken place within the architectural framework of a number of different invertebrate lineages, it is always characterized by the development of hard (usually calcified or chitinous) "teeth," which are manipulated by powerful muscles Members of a number of major invertebrate taxa have evolved macroherbivorous lifestyles, including molluscs, polychaetes, arthropods, and sea urchins.

Most molluscs have a unique structure called a radula, which is a muscularized, belt-like rasp armed with chitinous teeth. Herbivorous molluscs use the radula to scrape algae off rocks or to tear pieces of algal fronds or the leaves of terrestrial plants. The radula acts like a curved file that is drawn across the feeding surface

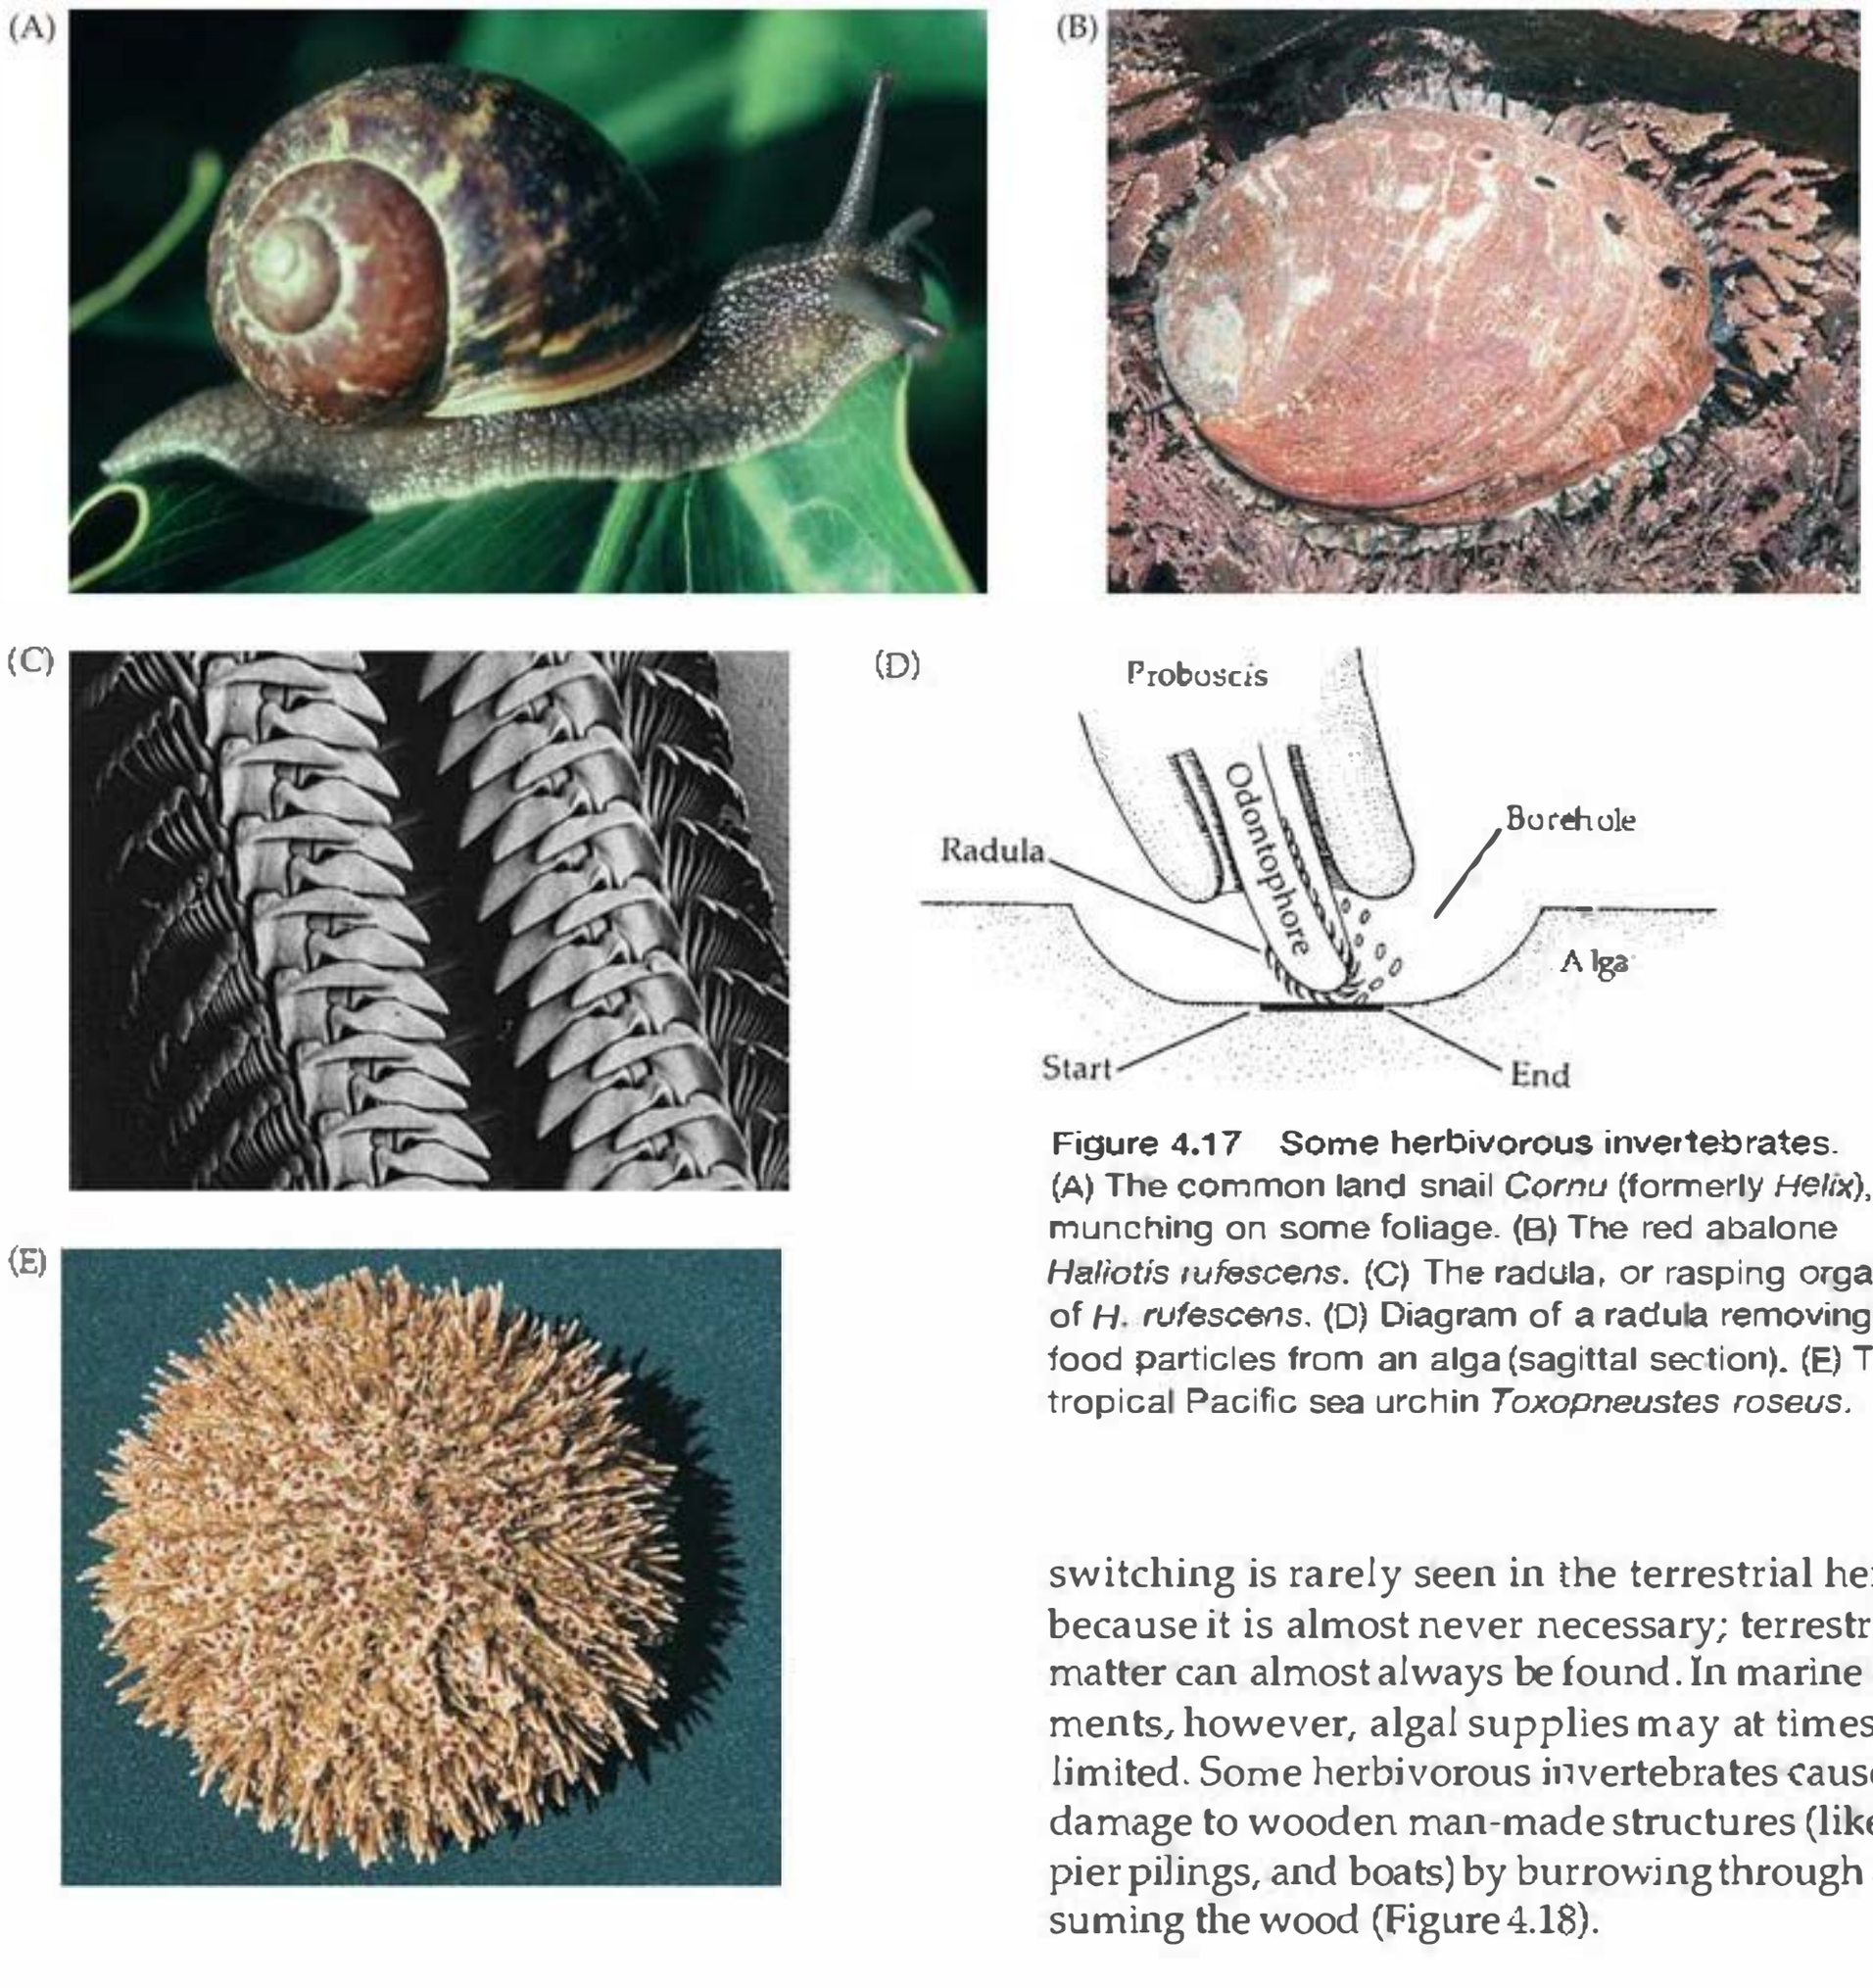

Figure 4.17 Some herbivorous invertebrates. (A) The common land snail *Cornu* (formerly *Helix*), munching on some foliage. (B) The red abalone *Haliotis rufescens*. (C) The radula, or rasping organ, of *H. rufescens*. (D) Diagram of a radula removing food particles from an alga (sagittal section). (E) The tropical Pacific sea urchin *Toxopneustes roseus*.

(Figure 4.17C,D). Some polychaetes such as nereids (family Nereidae) have sets of large chitinous teeth on an eversible pharynx or proboscis The proboscis is protracted by hydrostatic pressure, exposing the teeth, which by muscular action tear or scrape off pieces of algae that are swallowed when the proboscis is retracted. As might be expected, the toothed pharynx of polychaetes is also suited for carnivory, and many primarily herbivorous polychaetes can switch to meat-eating when algae are scarce.

Macroherbivory in arthropods is best illustrated by certain insects and crustaceans. Both of these large groups have powerful mandibles capable of biting off pieces of plant material and subsequently grinding or chewing them before ingestion. Some macroherbivorous arthropods are able to temporarily switch to carnivory when necessary. This switching is rarely seen in the terrestrial herbivores because it is almost never necessary; terrestrial plant matter can almost always be found. In marine environments, however, algal supplies may at times be very limited. Some herbivorous invertebrates cause serious damage to wooden man-made structures (like homes, pier pilings, and boats) by burrowing through and consuming the wood (Figure 4.18).

Carnivory and scavenging The most sophisticated methods of feeding are those that require the active capture of live animals, or predation.[5] Most carnivorous predators will, however, consume dead or dying animal matter when live food is scarce. Only a few generalizations about the many kinds of predation are presented here; detailed discussions of various taxa are presented in their appropriate chapters.

Active predation often involves five recognizable steps: prey location (predator orientation), pursuit (usually), capture, handling, and finally ingestion. Prey location usually requires a certain level of nervous system sophistication in which specialized sense organs

[5]Although in the broad sense, herbivory is a form of predation (on plants), for clarity of discussion we restrict the use of these terms to vegetable eating and animal eating/carnivory, respectively.

Figure 4.18 Shipworms. Wood from the submerged part of an old dock piling, spl t open to show the work of the wood-bor ng bivalve shipworm *Teredo navalis* (Mollusca). The shell valves are so reduced that they can no longer enclose the animal; instead they are used as "auger b ades" in boring. are present (discussed later in this chapter). Many carnivorous invertebrates rely primarily on chemosensory location of prey, although many also use visual orien tation, touch, and vibration detection. Chemoreceptors tend to be equally distributed around the bodies of radially symmetrical carnivores (e.g., jellyfish) but, coincidentally with cephalization, most invertebrates have their gustatory and olfactory receptors ("tasters" and "smellers") concentrated in the head region. A number of insects rely on CO_2 sensing to locate their food source, including fruit flies, mosquitoes, and moths, but the sensing mechanisms are not yet fully characterized.

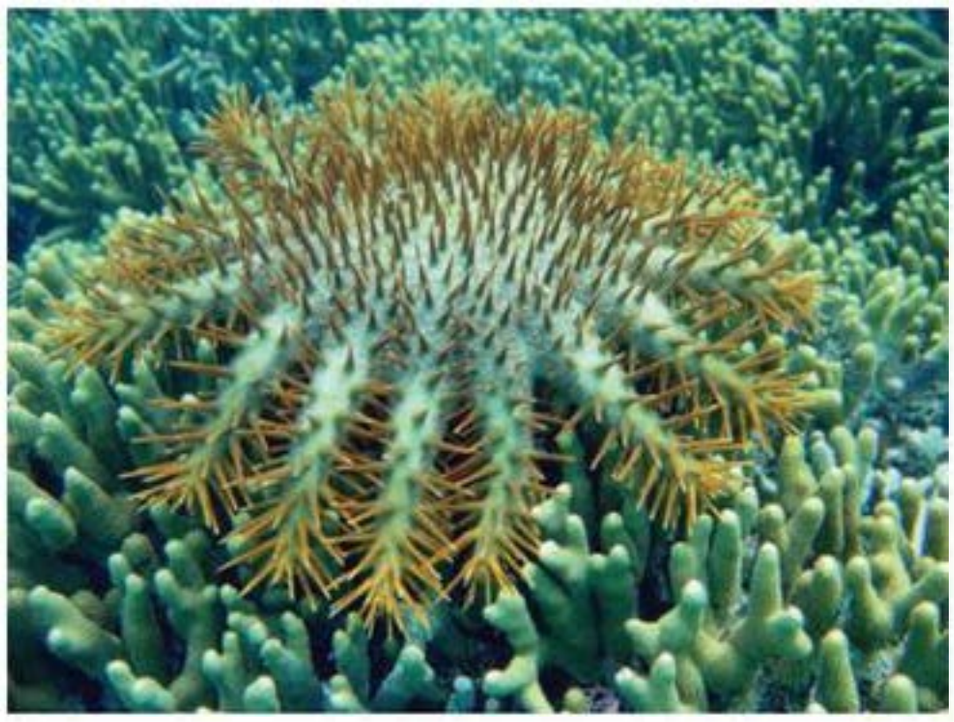
Predators may be classified by how they capture their prey as motile stalkers, lurking predators (ambushers), sessile opportunists, or grazers (Figure 4.19). Stalkers actively pursue their prey; they include members of such disparate groups as ciliate protists, polyclads, nemerteans, polychaete worms, gastropods, octopuses and squids, crabs, and starfish. In all these groups, chemosensation is highly important in locating potential prey, although some cephalopods are known to be the most highly visual of all the invertebrate predators.



Lurking predators are those that sit and wait for their prey to come within capture distance, whereupon they quickly seize the victim. Many lurking predators, such as certain species of mantis shrimps (stomatopods), crabs, snapping shrimp (Alpheidae), spiders, and polychaetes, live in burrows or crevices from which they emerge to capture passing prey. There are even ambushing planarian flatworms, which produce mucous patches that form sticky traps for their prey. The cost of building traps is significant. Ant lions, for example, may increase their energy consumption as much as eightfold when building their sand capture pits, and energy lost in mucus secretion by planarians may account for 20% of the worm's energy. Predatory invertebrates, especially lurking predators, are frequently more or less territorial.

Sessile opportunists operate in much the same fashion as lurking predators do, but they lack the mobil ity of the latter. The same may be said for drifting opportunists, such as jellyfishes. Many sessile predators, such as some protists, barnacles, and cnidarians, are actually suspension feeders with a strong preference for live prey.

Grazing carnivores move about the substratum picking at the epifauna. Grazers may be indiscriminate, consuming whatever happens to be present, or they may be fairly choosy about what they eat. In either case, their diet consists largely of sessile and slow-moving animals, such as sponges, ectoprocts, tunicates, snails, small crustaceans, and worms. Most grazers are omnivorous to some degree, consuming plant material along with their animal prey. Many crabs and shrimps are excellent grazers, continuously moving across the bottom and picking through the epifauna for tasty morsels. Sea spiders (pycnogonids) and some carniv orous sea slugs can also be classed as grazers on h y droids, ectoprocts, sponges, tunicates, and other sessile epifauna. Ovulid snails (family Ovulidae) inhabit, and usually mimic, the gorgonians and corals upon which they slowly crawl about, nipping off polyps as they go.

One special category of carnivory is cannibalism, or intraspecific predation Gary Polis (1981) examined over 900 published reports describing cannibalism in about 1,300 different species of animals. In general, he found that species of large animals (and also larger individuals in any given species) are the most likely to be cannibals By far, the majority of the victims are juveniles. However, in a number of invertebrate groups the tables turn and cannibalism occurs when smaller individuals band together to attack and consume a larger individual. Furthermore, females tend generally to be more cannibalistic than males, and males tend to be eaten far more often than females. In many species, filial cannibalism is common, in which a parent eats its dying, deformed, weak, or sick offspring. Polis

concluded that cannibalism is a major factor in the b i ology of many species and may influence population structure, life history, behavior, and competition for mates and resources. He went so far as to point out that *Homo sapiens* may be "the only species capable of worrying whether its food is intra- or extraspecific."

Dissolved organic matter The total living biomass of the world's oceans is estimated to be about 2×10^9 tons of organic carbon (roughly 500 times the amount of organic carbon in the terrestrial environment). Furthermore, an additional 20×10^9 tons of particulate organic matter is estimated to occur in the seas, and another 200×10^9 tons of organic carbon (C) may occur in the seas as **dissolved organic matter (DOM)**. Thus, at any moment in time, only a small fraction of the organic carbon in the world's seas actually exists in living organisms. Amino acids and carbohydrates may be the most common dissolved organics. Typical oce anic values of DOM range from 0.4 to 1.0 mg C/liter, but may reach 8 0 mg C/liter near shore. Pelagic and benthic algae release copious amounts of DOM into the environment, as do certain invertebrates. Coral mucus, for example, is an important fraction of suspended and dissolved organic material over reefs, and it contains significant amounts of energy-rich and nitrogen-rich compounds, including mono- and polysaccharides and amino acids. Other sources of DOM include decomposing tissue, detritus, fecal material, and metabolic by-products discharged into the environment.

The idea that DOM may contribute significantly to the nutrition of marine invertebrates has been around for over a hundred years. Marine microorganisms are known to use DOM, but the relative role of dissolved organic matter in the nutrition of aquatic Metazoa is uncertain. Available data strongly suggest that mem bers of all marine taxa (except perhaps arthropods and vertebrates) are capable of absorbing DOM to some extent, and in the case of ciliary-mucous suspension feeders, marine larvae, many echinoderms, and mussels, the ability to rapidly take up dissolved free amino acids from a dilute external medium is well established. But because of the complex chemical nature of dissolved organics, and the difficulty of measuring their rates of influx and loss, we still lack strong evidence of the a c tual use, or relative nutritional importance, of DOM to invertebrates.

Evidence from numerous studies indicates that absorption of DOM occurs directly across the body wall of invertebrates, as well as via the gills. Also, inorganic particles of colloidal dimensions provide a surface on which small organic molecules are concentrated by adsorption, to be captured and utilized by suspension-feeding invertebrates. Interestingly, most freshwater organisms seem incapable of removing small organic molecules from solution at anything like the rates characteristic of marine invertebrates. In fresh water, the uptake of DOM is probably retarded by the processes of osmoregulation. Also, with the exception of the aberrant hagfish, marine vertebrates seem not to utilize DOM to any significant extent.

Chemoautotrophy A special form of autotrophy that occurs in certain bacteria relies not on sunlight and photosynthesis as a source of energy to make organic molecules from inorganic raw materials (**photoautot rophy**), but rather on the oxidization of certain inor ganic substances. This is called **chemoautotrophy**. Chemoautotrophs use CO_2 as their carbon source, obtaining energy by oxidizing hydrogen sulfide (H_2S), ammonia (NH_3), methane (CH_4), ferrous ions (Fe^{2+}), or some other chemical, depending on the species. These prokaryotes are not uncommon in aerated soils, and certain species live as symbionts in the tissues of a few marine invertebrates

Some of the most interesting of these chemoautotrophic organisms derive their energy from the oxidation of hydrogen sulfide released at hot water vents on the deep-sea floor—where, in fact, they are the sole primary producers in the ecosystem. In this environment, chemoautotrophic bacteria inhabit the tissues of certain mussels, clams, and vestimentiferan tube worms, where they produce organic compounds that are utilized by their hosts. Similar invertebrate–bacteria relationships have been discovered in shallow cold water petroleum and salt (brine) seeps, where the chemoautotrophic microorganisms live off the methane- and hydrogen sulfide-rich waters associated with such sea floor phenomena. In all these cases, the bacteria actu ally live within the cells of their hosts. In bivalves, the bacteria inhabit the gill cells and extract methane or other chemicals from the water that flows over those structures. In the case of the tube worms, the host must transport the H_2S to their bacterial partners, which live i n tissues deep within the animals' body. The worms have a unique type of hemoglobin that transports not only oxygen (for the worm's metabolism) but sulfide as well.

Excretion and Osmoregulation

Excretion is the elimination from the body of metabolic waste products, including carbon dioxide and water (produced primarily by cellular respiration) and excess nitrogen (produced as ammonia from deamination of amino acids). The excretion of respiratory CO_2 is gener ally accomplished by structures that are separate from those associated with other waste products and is discussed in the section that follows.

The excretion of nitrogenous wastes is usually i n timately associated with osmoregulation the regulation of water and ion balance within the body fluids—so these processes are considered together here.

Excretion, osmoregulation, and ion regulation serve not only to rid the body of potentially toxic wastes, but also to maintain concentrations of the various components of body fluids at levels appropriate for metabolic activities. As we shall see, these processes are structurally and functionally tied to the overall level of body complexity and construction, the nature of other physiological systems, and the environment in which an animal lives. We again emphasize the necessity of looking at whole animals, the integration of all aspects of their biology and ecology, and the possible evolutionary histories that could have produced compatible and successful combinations of functional systems.

Nitrogenous Wastes and Water Conservation

The source of most of the nitrogen in an animal's system is amino acids produced from the digestion of proteins. Once absorbed, these amino acids may be used to build new proteins, or they may be deaminated and the residues used to form other compounds (Figure 4.20). The excess nitrogen released during deamination is typically liberated from the amino acid in the form of ammonia (NH_3), a highly soluble but quite toxic substance that either must be diluted and eliminated quickly or converted to a less toxic form. The excretory products of vertebrates have been studied much more extensively than those of invertebrates, but the available data on the latter allow some generalizations. Typically, one nitrogenous waste form tends to predominate in a given species, and the nature of that chemical is generally related to the availability of environmental water.

The major excretory product in most marine and freshwater invertebrates is ammonia, since their environment provides an abundance of water as a medium for rapid dilution of this toxic substance. Such animals are said to be ammonotelic. Being highly soluble, ammonia diffuses easily through fluids and tissues, and much of it is lost straight across the body walls of some ammonotelic animals. Animals that do not possess definite excretory organs (e.g., sponges, cnidarians, and echinoderms) are more or less limited to the production of ammonia and thus are restricted to aquatic habitats.

Terrestrial invertebrates (indeed, all land animals) have water conservation challenges. They simply cannot afford to lose much body water in the process of diluting their wastes. These animals convert their nitrogenous wastes to more complex but far less toxic substances. These compounds are energetically expensive to produce, but they often require relatively little or no dilution by water, and they can be stored within the body prior to excretion.

There are two major metabolic pathways for the detoxification of ammonia: the urea pathway and the uric acid pathway. The products of these pathways, urea and uric acid, are illustrated in Figure 4.20, along with ammonia for comparison. Ureotelic animals include amphibians, mammals, and cartilaginous fishes (sharks and rays); urea is a relatively rare and insignificant excretory compound among invertebrates. On the other hand, the ability to produce uric acid is critically associated with the success of certain invertebrates on land. Uricotelic animals have capitalized on the relative insolubility (and very low toxicity) of uric acid, which is generally precipitated and excreted in a solid or semisolid form with little water loss. Most land-dwelling arthropods and snails have evolved structural and physiological mechanisms for the incorporation of excess nitrogen into molecules of uric acid. We emphasize that various combinations of these and other forms of nitrogen excretion are found in most animals. In some cases, individual animals can actually vary the proportion of these compounds they produce, depending on short-term environmental changes affecting water loss.

Osmoregulation and Habitat

In addition to its relationship to excretion, osmoregulation is directly associated with environmental conditions. As mentioned in Chapter 1, the composition of seawater and that of the body fluids of most invertebrates is very similar, in terms of total concentration *and* the concentrations of many ions. Thus, the body fluids of many marine invertebrates and their habitats are close to being isotonic. We hasten to add, however, that probably no animal has body fluids that are exactly isotonic with sea water, and therefore all are faced with the need for some degree of ionic and osmoregulation. Nonetheless, marine invertebrates certainly do not face the extreme osmoregulatory problems encountered by land and freshwater forms.

As shown in Figure 4.21, the body fluids of freshwater animals are strongly hypertonic with respect to their environment, and thus they face serious problems

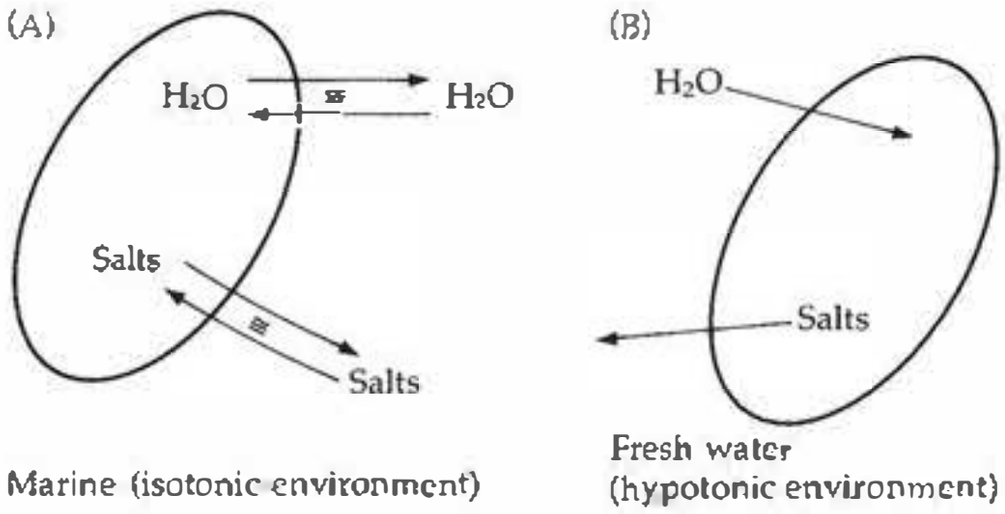

Figure 4.21 Relative osmotic and ionic conditions existing between marine, freshwater, and terrestrial invertebrates and their environments. The arrows indicate the directions in which water and salts move passively in response to concentration gradients. Remember that in each of these cases movement occurs in both directions, but it is the potential net movement along the gradient that is important and against which freshwater and terrestrial animals must constantly battle. For marine invertebrates, the body fluids and the environment are nearly isotonic to one another and there is little net movement in either direction. (A) The organism is isotonic to its environment. (B) The organism is hypertonic. (C) The organism is hypotonic.

of water influx as well as the potential loss of precious body salts. Terrestrial animals are exposed to air and thus to problems of water loss. The evolutionary invasion of land and fresh water was accompanied by the development of mechanisms that solved these problems, and only a relatively small number of invertebrate groups have managed to do this. Animals inhabiting freshwater and terrestrial habitats generally have excretory structures that are responsible for eliminating or retaining water as needed, and they often possess modifications of the body wall to reduce overall permeability. The most successful invertebrate body plans on land, and in some ways of all environments, are those of the arthropods and gastropods. Their effective excretory structures and thickened exoskeletons provide them with physiological osmoregulatory capabilities plus a barrier against desiccation.

Osmoregulatory problems of aquatic animals are, of course, determined by the salinity of the environmental water relative to the body fluids (Figure 4.21). Organisms respond physiologically to changes in environmental salinities in one of two basic ways. Some, such as most freshwater forms (certain crustaceans, protists, and oligochaetes), maintain their internal body fluid concentrations regardless of external conditions and are thus called **osmoregulators**. Others, including a number of intertidal and estuarine forms (mussels and some other bivalves, and a variety of soft-bodied animals), allow their body fluids to vary with changes in environmental salinities; they are appropriately called **osmoconformers**. Again, even the body fluids of marine, so-called osmoconformers are not exactly isotonic with respect to their surroundings; thus, these animals must osmoregulate slightly. Neither of these strategies is without limits, and tolerance to various environmental salinities varies among different species. Those that are restricted to a very narrow range of salinities are said to be **stenohaline**, while those that tolerate relatively extensive variations, such as many estuarine animals, are **euryhaline**.

Although the preceding discussion may seem clear-cut, it is an oversimplification. Experimental data from whole animals tell only part of the story of osmoregulation. When a whole marine animal is placed in a hypotonic medium, it tends to swell (if it is an osmoconformer) or to maintain its normal body volume (if it is an osmoregulator). Even at this gross level, most invertebrates usually show evidence of both conforming and regulating. For instance, an osmoconformer generally swells for a period of time in a lowered salinity environment and then begins to regulate. Its swollen volume will decrease, although probably not to its original size. The same is true of most osmoregulators when faced with a decrease in environmental salinity, but the degree of original swelling is much reduced. In both cases, the swelling of the body is a result of an influx of environmental water into the extracellular body fluids (blood, coelomic fluids, and intercellular fluids). Within limits, this excess water is handled by excretory organs and various surface epithelia of the gut and body wall. However, the second part of the osmoregulatory phenomenon takes place at the cellular level.

As the tonicity (relative concentrations) of the body fluids drops with the entrance of water, the cells in contact with those fluids are placed in conditions of stress—they are now in hypotonic environments. These stressed cells swell to some degree because of the diffusion of water into their cytoplasm, but not to the degree one might expect given the magnitude of the osmotic gradient to which they are subjected. Cellular-level osmoregulation is accomplished by a loss of dissolved materials from the cell into the surrounding intercellular fluids. The solutes released from these cells include both inorganic ions and free amino acids. Thus, osmoconformers are not passive animals that inactively tolerate extremes of salinities. Nor are marine invertebrates free from osmotic problems, even though we read statements that they are "98% water" or other such comments.

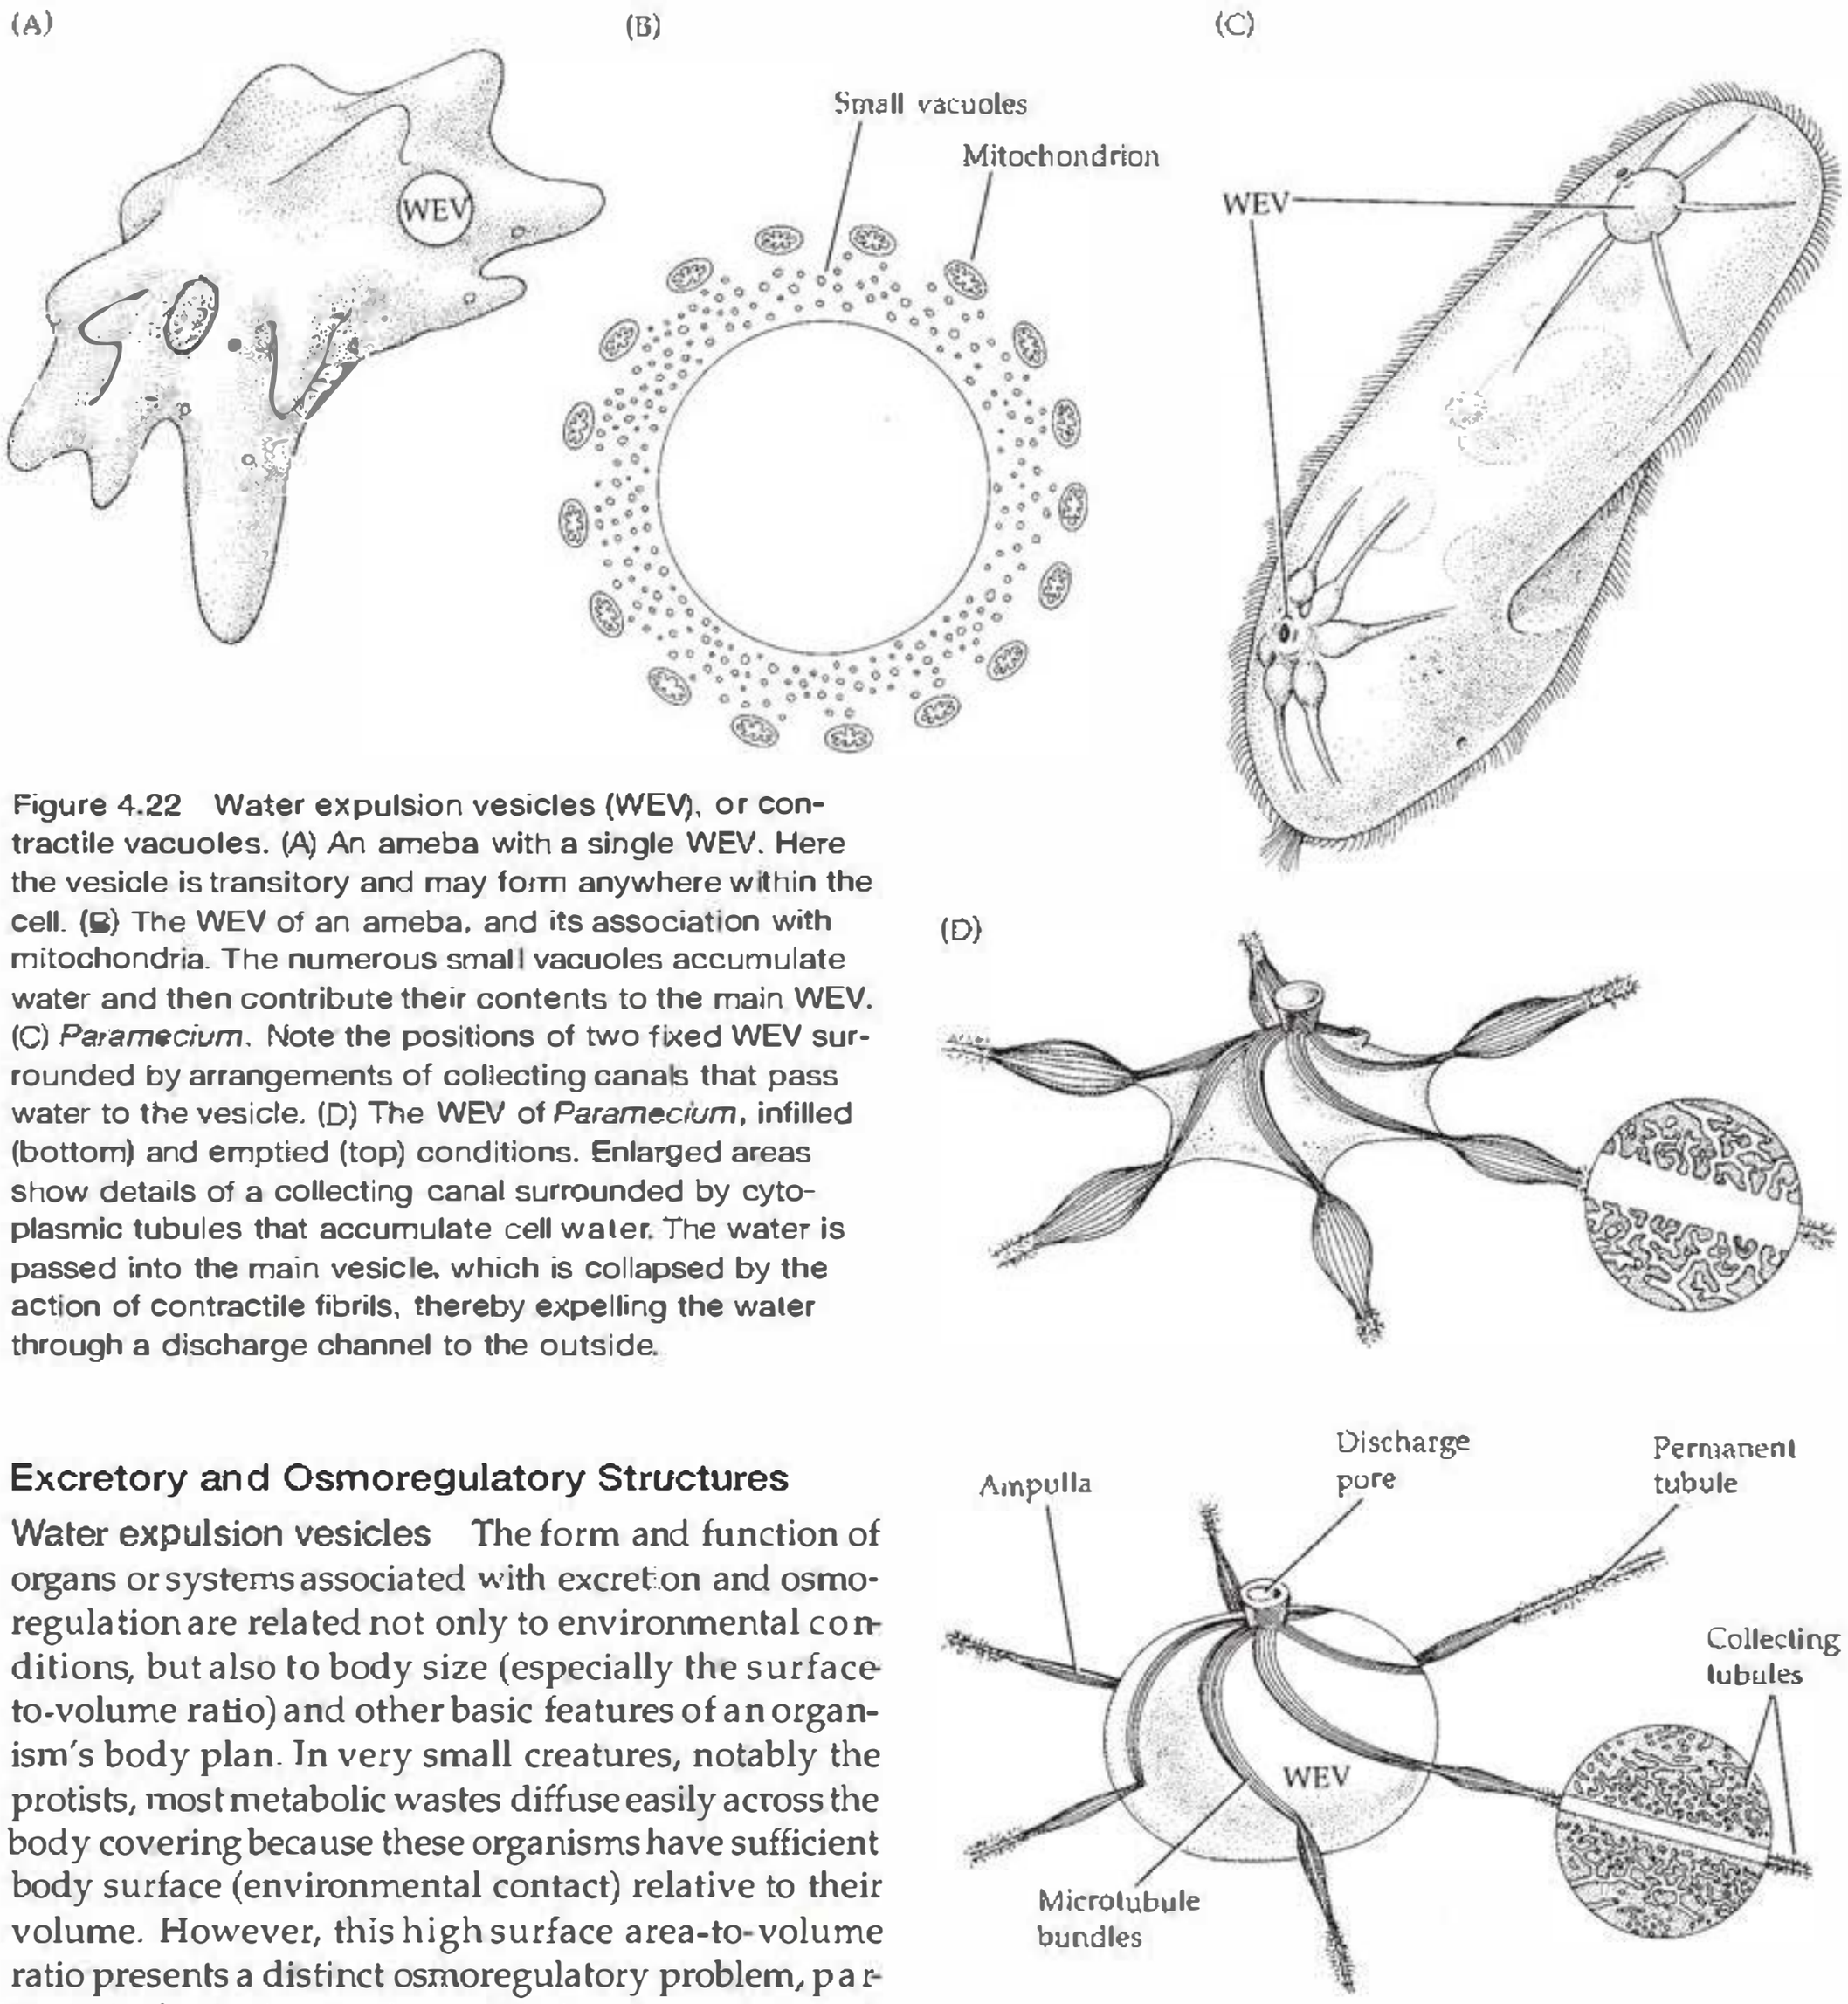

Figure 4.22 Water expulsion vesicles (WEV), or contractile vacuoles. (A) An ameba with a single WEV. Here the vesicle is transitory and may form anywhere within the cell. (B) The WEV of an ameba, and its association with mitochondria. The numerous small vacuoles accumulate water and then contribute their contents to the main WEV. (C) *Paramecium*. Note the positions of two fixed WEV surrounded by arrangements of collecting canals that pass water to the vesicle. (D) The WEV of *Paramecium*, infilled (bottom) and emptied (top) conditions. Enlarged areas show details of a collecting canal surrounded by cytoplasmic tubules that accumulate cell water. The water is passed into the main vesicle, which is collapsed by the action of contractile fibrils, thereby expelling the water through a discharge channel to the outside.

Excretory and Osmoregulatory Structures

Water expulsion vesicles The form and function of organs or systems associated with excretion and osmoregulation are related not only to environmental conditions, but also to body size (especially the surface-to-volume ratio) and other basic features of an organism's body plan. In very small creatures, notably the protists, most metabolic wastes diffuse easily across the body covering because these organisms have sufficient body surface (environmental contact) relative to their volume. However, this high surface area-to-volume ratio presents a distinct osmoregulatory problem, particularly for freshwater forms. Freshwater protists (and even some marine species) typically possess specialized organelles called contractile vacuoles, or water expulsion vesicles (WEVs), which actively excrete excess water (Figure 4.22). These structures accumulate cytoplasmic water and expel it from the cell. Both of these activities apparently require energy, as suggested in part by the large numbers of mitochondria typically associated with WEVs. The idea that WEVs are primarily osmoregulatory in function is supported by a good deal of evidence. Most convincing is the fact that their rates of filling and emptying change dramatically when the cell is exposed to different salinities. For example, the marine flagellate *Chlamydomonas pulsatilla* lives in supralittoral tidal pools and is exposed to low salinities during rainy periods, at which times it regulates its cell volume and internal osmotic pressure via the action of WEVs (which increase in activity as the salinity of their rock pool drops). Interestingly, WEVs also occur in freshwater sponges, where they probably perform similar osmoregulatory functions.

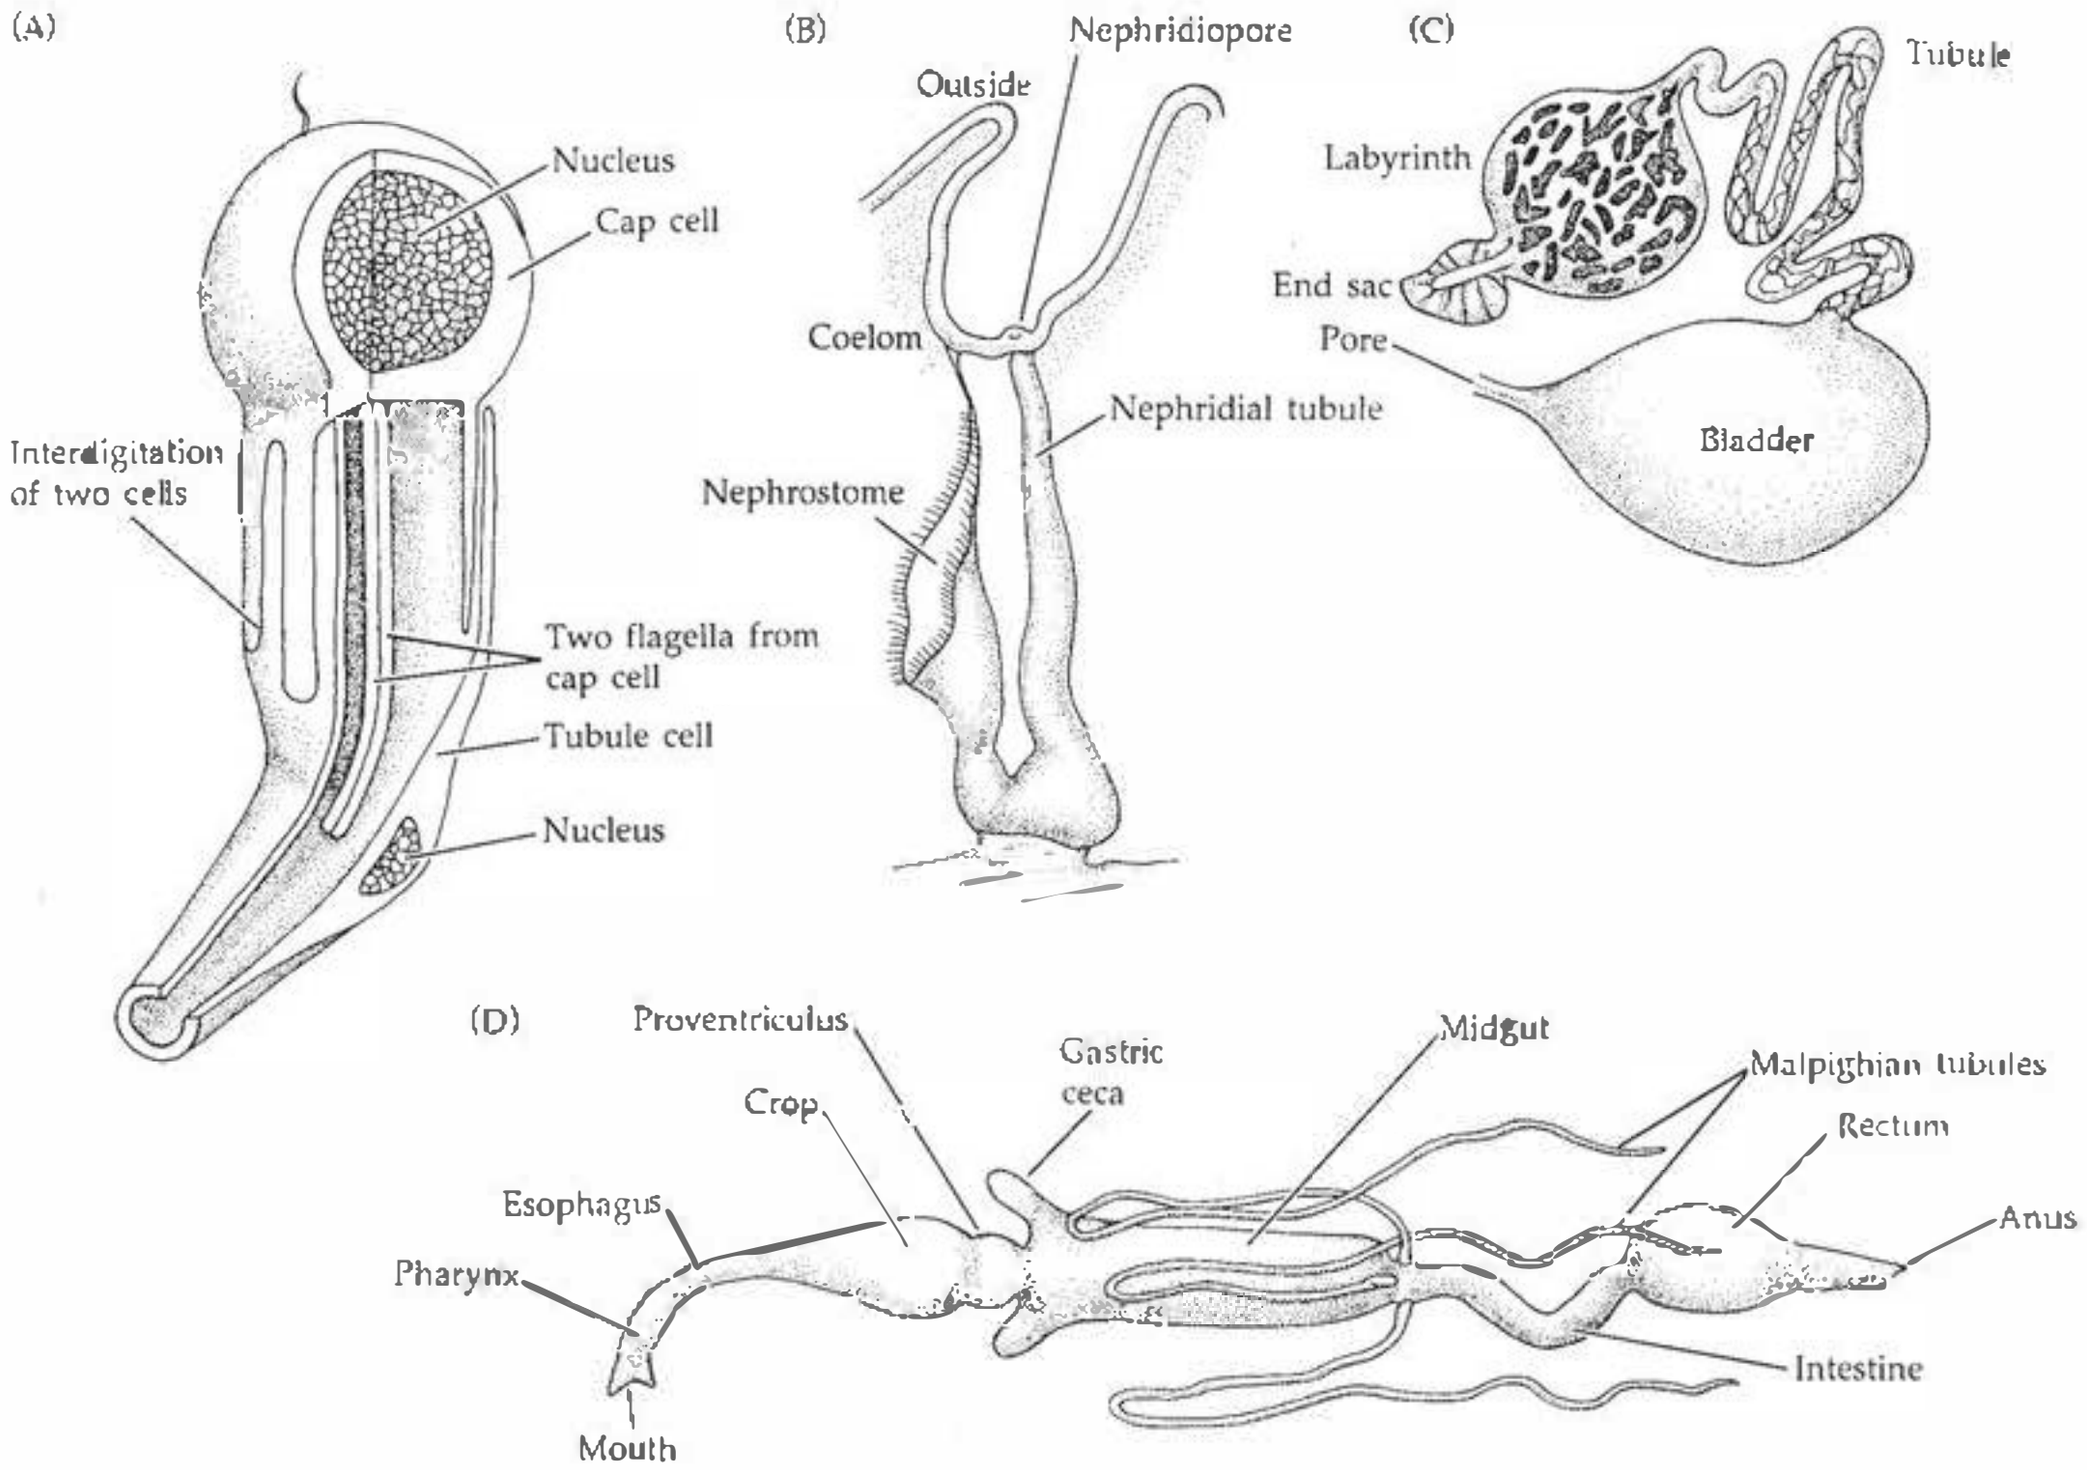

Figure 4.23 Some invertebrate excretory structures. (A) A single protonephridium, with the cap cell and tubule cell (cutaway view). (B) A simple metanephridium from a marine annelid. The nephrostome opens to the coelom, and the nephridiopore opens to the exterior. (C) The internally closed nephridium (antennal gland) of a crustacean. (D) An insect's digestive tract. Excretory Malpighian tubules extract wastes from the hemocoel and empty them into the gut.

Nephridia Although certain metazoan invertebrates possess no known excretory structures, most have some sort of ectodermally derived nephridia that serve for excretion or osmoregulation, or both. The evolution of various types of invertebrate nephridia and their relationships to other structures were discussed by E. S. Goodrich in 1945 in a classic paper, "The Study of Nephridia and Genital Ducts since 1895."

Probably the earliest type of nephridium to appear in the evolution of animals was the protonephridium (Figure 4.23A). Protonephridial systems are characterized by a tubular arrangement opening to the outside of the body via one or more nephridiopores and terminating internally in closed unicellular units. These units are the cap cells (or terminal cells) and may occur singly or in clusters. Each cell is folded into a cup shape, creating a concavity leading to an excretory duct (nephridioduct) and eventually to the nephridiopore. Two generally recognized types of protonephridia are flame bulbs, bearing a tuft of numerous cilia within the cavity, and solenocytes, usually with only one or two flagella. There is some evidence that several different types of flame bulb protonephridia have been independently derived from solenocyte precursors, but the details of nephridial evolution are still controversial.

The cilia or flagella drive fluids down the nephridioduct, thereby creating a lowered pressure within the tubule lumen. This lowered pressure draws body fluids, carrying wastes, across the thin cell membranes and into the duct. Selectivity is based primarily on molecular size. Protonephridia are common in adult acoelomates, many blastocoelomates, and some annelids, but are rare among most adult coelomates (although they occur frequently in various larval types). Protonephridia are probably more important in osmoregulation than in excretion. In most of these animals, nitrogenous wastes are expelled primarily by diffusion across the general body surface.

A second and probably more advanced type of excretory structure among invertebrates is the

metanephridium (Figure 4.23B). There is a critical structural difference between protonephridia and metanephridia: both open to the outside, but metanephridia are open internally to the body fluids as well. Metanephridia are also multicellular. The inner end typically bears a ciliated funnel (nephrostome), and the duct is often elongated and convoluted and may include a bladder-like storage region. Metanephridia function by taking in large amounts of body fluid through the open nephrostome and then selectively absorbing most of the reclaimable components back into the body fluids through the walls of the bladder or the excretory duct.

In very general terms, we can relate the structural and functional differences between proto- and metanephridia to the body plans with which they are commonly associated. Whereas protonephridia can adequately serve animals that have solid bodies (acoelomates), body cavities of small volume (blastocoelomates), or very small bodies (e.g., larvae), metanephridia cannot. Open funnels would be ineffective in acoelomates, and would quickly drain small blastocoelomates of their limited body fluids. Conversely, protonephridia are generally not capable of handling the relatively large body and fluid volumes typical of coelomate invertebrates. Thus, in many large coelomate animals (e.g., annelids, molluscs) one or more pairs of metanephridia are typically found.

We have very broadly interpreted the terms protonephridia and metanephridia in the above discussion, and we use them as explained above throughout this text unless specified otherwise. However, there are more complications than our simple usage suggests. For example, there is a frequent association of nephridia, especially metanephridia, with structures called coelomoducts. **Coelomoducts** are tubular connections arising from the coelomic lining and extending to the outside via special pores in the body wall. Their inner ends are frequently funnel-like and ciliated, resembling the nephrostomes of metanephridia. Coelomoducts may have arisen evolutionarily as a means of allowing the escape of gametes to the outside; they are, in fact, considered homologous to the reproductive ducts of many invertebrates. Primitively, the coelomoducts and nephridia were separate units, however, through evolution they have in many cases fused in various fashions to become what are called nephromixia.

Generally speaking, there are three types of nephromixia. When a coelomoduct is joined with a protonephridium and they share a common duct, the structure is called a **protonephromixium**. When a coelomoduct is united with a metanephridium, the result is either a **metanephromixium** or **mixonephridium**, depending on the structural nature of the union. Whereas coelomoducts originate from the coelomic lining, the nephridial components arise from the outer body wall, so nephromixia are a combination of mesodermally and ectodermally derived parts. Obviously there is some confusion at times about which term applies to a particular "nephridial" type if the precise developmental origin is not clear. We do not wish to belabor this point, so we leave it here to be resurrected periodically in later chapters

Other organs of excretion Not all Metazoa possess excretory organs that are clearly proto- or metanephridia. In some taxa (e.g., sponges, echinoderms, chaetognaths, cnidarians), no definite excretory structures are known. In such cases wastes are eliminated across the surface of the skin or gut lining, perhaps with the aid of ameboid phagocytic cells that collect and transport these products. Other groups possess excretory organs that may represent highly modified nephridia or secondarily derived ("new") structures. For example, the antennal and maxillary glands of crustaceans appear to be derived from metanephridia, whereas the Malpighian tubules of insects and spiders arose independently (Figure 4.23C,D). The details of these structures are discussed in appropriate later chapters.

Circulation and Gas Exchange

Internal Transport

The transport of materials from one place to another within an organism's body depends on the movement and diffusion of substances in body fluids. Nutrients, gases, and metabolic waste products are generally carried in solution or bound to other soluble compounds within the body fluid itself or sometimes in loose cells (such as blood cells) suspended in fluid. Any system of moving fluids that reduces the functional diffusion distance that these products must traverse may be referred to as a circulatory system, regardless of its embryological origin or its ultimate design. The nature of the circulatory system is directly related to the size, complexity, and lifestyle of the organism in question. Usually the circulatory fluid is an internal, extracellular, aqueous medium produced by the animal. There are, however, a few instances in which circulatory functions are accomplished at least partly by other means. For instance, in most protists the protoplasm itself serves as the medium through which materials diffuse to various parts of the cell body, or between the organism and the environment. Sponges and most cnidarians utilize water from the environment as a circulatory fluid, sponges by passing the water through a series of channels in their bodies, and cnidarians by circulating water through the gut (Figure 4.24A,B).

In all Metazoa, the intercellular tissue fluids play a critical role as a transport medium. Even where complicated circulatory plumbing exists, tissue fluids are still necessary to bring dissolved materials in contact with

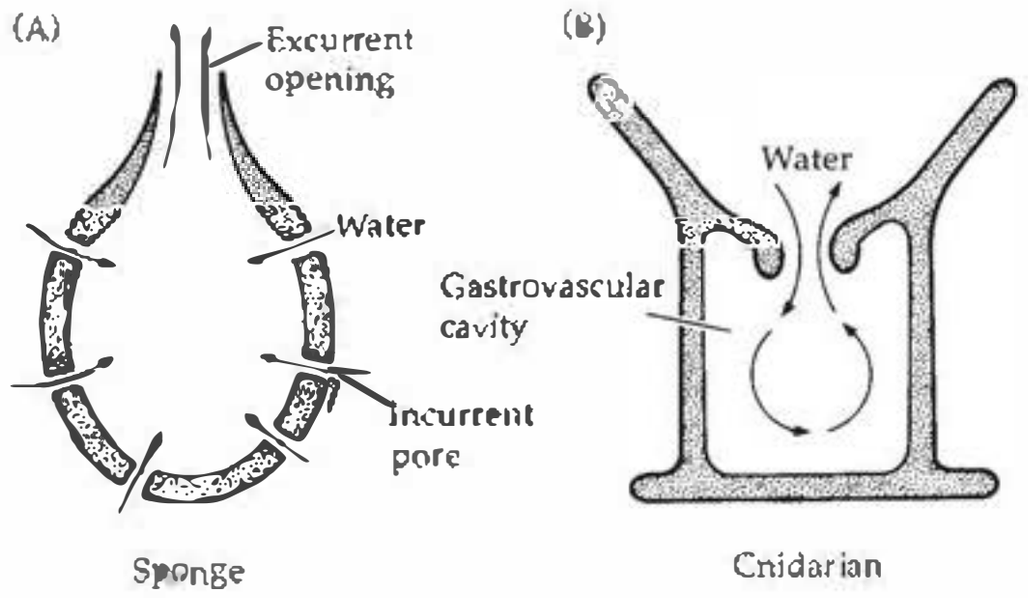

Figure 4.24 Invertebrate circulatory systems. Sponges (A) and cnidarians (B) utilize environmental water as their circulatory fluid. (C) Blastocoelomates (e.g., rotifers and nematodes) use their body cavity fluid for internal transport. (D) The closed circulatory system of an earthworm contains blood that is kept separate from the coelomic fluid. (E) Arthropods are characterized by an open circulatory system, in which the blood and body cavity (hemocoelic) fluid are one and the same.

cells, a vital process for life support. In some animals (e.g., flatworms), there are no special chambers or vessels for body fluids other than the gut and intercellular spaces through which materials diffuse on a cell-to-cell level. This condition limits these animals to relatively small sizes or to shapes that maintain low diffusion distances. Most animals, however, have some specialized structure to facilitate the transport of various body fluids and their contents. This structure may include the body cavities themselves or actual circulatory systems of vessels, chambers, sinuses, and pumping organs. Actually, many animals employ both their body cavity and a circulatory system for internal transport.

Blastocoelomate invertebrates use the fluids of the body cavity for circulation (Figure 4.24C). Most of these animals (e.g., rotifers and roundworms) are quite small, or are long and thin, and adequate circulation is accomplished by the movements of the body against the body fluids, which are in direct contact with internal tissues and organs. Several types of cells are generally present in the body fluids of blastocoelomates. These cells may serve in activities such as transport and waste accumulation, but their functions have not been well studied. A few coelomate invertebrates (e.g., sipunculans and most echinoderms) also depend largely on the body cavity as a circulatory chamber.

Circulatory Systems

Beyond the relatively rudimentary circulatory mechanisms discussed above, there are two principal designs or structural plans for accomplishing internal transport (exceptions and variations are discussed under specific taxa). These two organizational plans are closed and open circulatory systems, both of which contain a circulatory fluid, or blood. In **closed circulatory systems** the blood stays in distinct vessels and perhaps in lined chambers; exchange of circulated material with parts of the body occurs in special areas of the system such as capillary beds (Figure 4.24D). Since the blood itself is physically separated from the intercellular fluids, the exchange sites must offer minimal resistance to diffusion; thus one finds capillaries typically have membranous walls that are only a single cell-layer thick. Closed circulatory systems are common in animals with well developed or spacious coelomic compartments (e.g., annelids, phoronids, vertebrates). Such arrangements facilitate the transport from one body area to another of materials that might otherwise be isolated by the mesenteries or peritoneum of the body cavity. In such situations the blood and coelomic fluid may be quite different from one another, both in composition and in function. For example, blood may transport nutrients and gases, while coelomic fluid may accumulate metabolic wastes for removal by nephridia and also serves as a hydrostatic skeleton.

It takes power to keep a fluid moving through a plumbing system. Many invertebrates with closed

systems rely on body movements and the exertion of coelomic pressure on vessels (often containing one-way valves) to move their blood. These activities are frequently supplemented by muscles of the blood vessel walls that contract in peristaltic waves. In addition, there may be special heavily muscled pumping areas along certain vessels. These regions are sometimes referred to as hearts, but most are more appropriately called contractile vessels.

Open circulatory systems are associated with a reduction of the adult coelom, including a secondary loss of most of the peritoneal lining around the organs and inner surface of the body wall. The circulatory system itself usually includes a distinct heart as the primary pumping organ and various vessels, chambers, or ill defined sinuses (Figure 4.24E). The degree of elaboration of such systems depends primarily on the size, complexity, and to some extent the activity level of the animal. This kind of system, however, is "open" in that the blood, often called the **hemolymph**, empties from vessels into the body cavity and directly bathes the organs. The body cavity is called a hemocoel. Open circulatory systems are typical of arthropods and non cephalopod molluscs, and such animals are sometimes referred to as being hemocoelomate.

Just because the open circulatory system seems a bit sloppy in its organization, it should not be viewed as poorly "designed" or inefficient. In fact, in many groups this type of system has assumed a variety of functions beyond circulation. For example, in bivalves and gastropods, the hemocoel functions as a hydrostatic skeleton for locomotion and certain types of burrowing activities. In aquatic arthropods, it also serves a hydrostatic function when the animal molts and temporarily loses its exoskeletal support. In large terrestrial insects, the transport of respiratory gases has been largely assumed by the tracheal system, and one of the primary responsibilities taken on by the open circulatory system appears to be thermal regulation. In most spiders, the limbs are extended by forcing hemolymph into the appendages.

Hearts and Other Pumping Mechanisms

Circulatory systems, open or closed, generally have structural mechanisms for pumping the blood and maintaining adequate blood pressures. Beyond the influence of general body movements, most of these structures fall into the following categories: contractile vessels (as in annelids); ostiate hearts (as in arthropods); and chambered hearts (as in molluscs and vertebrates). The method of initiating contraction of these different pumps (the pacemaker mechanisms) may be intrinsic (originating within the musculature of the structure itself) or extrinsic (originating from motor nerves arising outside the structure). The first case describes the myogenic hearts of molluscs and vertebrates; the second describes the neurogenic hearts of most arthropods and, at least in part, the contractile vessels of annelids.

Blood pressure and flow velocities are intimately associated not only with the activity of the pumping mechanism but also with vessel diameters. Energetically, it costs a good deal more to maintain flow through a narrow pipe than through a wide pipe. This cost is minimized in animals with closed circulatory systems by keeping the narrow vessels short and using them only at sites of exchange (i.e., capillary beds), and by using the larger vessels for long distance transport from one exchange site to another. In the human circulatory system, for example, arteries have an average radius of 2.0 mm, veins 2.5 mm, and capillaries 0.006 mm. But reducing the diameter of a single vessel increases flow velocity, which poses problems at an exchange site. This problem is solved by the presence of large numbers of small vessels, the total cross sectional area of which exceeds that of the larger vessel from which they arise. The result is that blood pressure and total flow velocity actually decrease at capillary exchange sites. A drop in blood pressure and a relative rise in blood osmotic pressure along the capillary bed facilitate exchanges between the blood and surrounding tissue fluids. In open systems, both pressure and velocity drop once the blood leaves the heart and vessels and enters the spacious hemocoel

Gas Exchange and Transport

One of the principal functions of most circulatory fluids is to carry oxygen and carbon dioxide through the body and exchange these gases with the environment. With few exceptions, oxygen is necessary for cellular respiration. Although a number of invertebrates can survive periods of environmental oxygen depletion—either by dramatically reducing their metabolic rate or by switching to anaerobic respiration most cannot; they depend upon a relatively constant oxygen supply.

All animals can take in oxygen from their surroundings while at the same time releasing carbon dioxide, a metabolic waste product of respiration. We define the uptake of oxygen and the loss of carbon dioxide at the surface of the organism as gas exchange, reserving the term respiration for the energy-producing metabolic activities within cells. Some authors distinguish these two processes with the terms external respiration and cellular (internal) respiration.

Gas exchange in nearly all animals operates according to certain common principles regardless of any structural modifications that serve to enhance the process under different conditions. The basic strategy is to bring the environmental medium (water or air) close to the appropriate body fluid (blood or body cavity fluid) so that the two are separated only by a wet membrane across which the gases can diffuse. The system must be moist because the gases must be in solution in order to diffuse across the membrane. The diffusion process

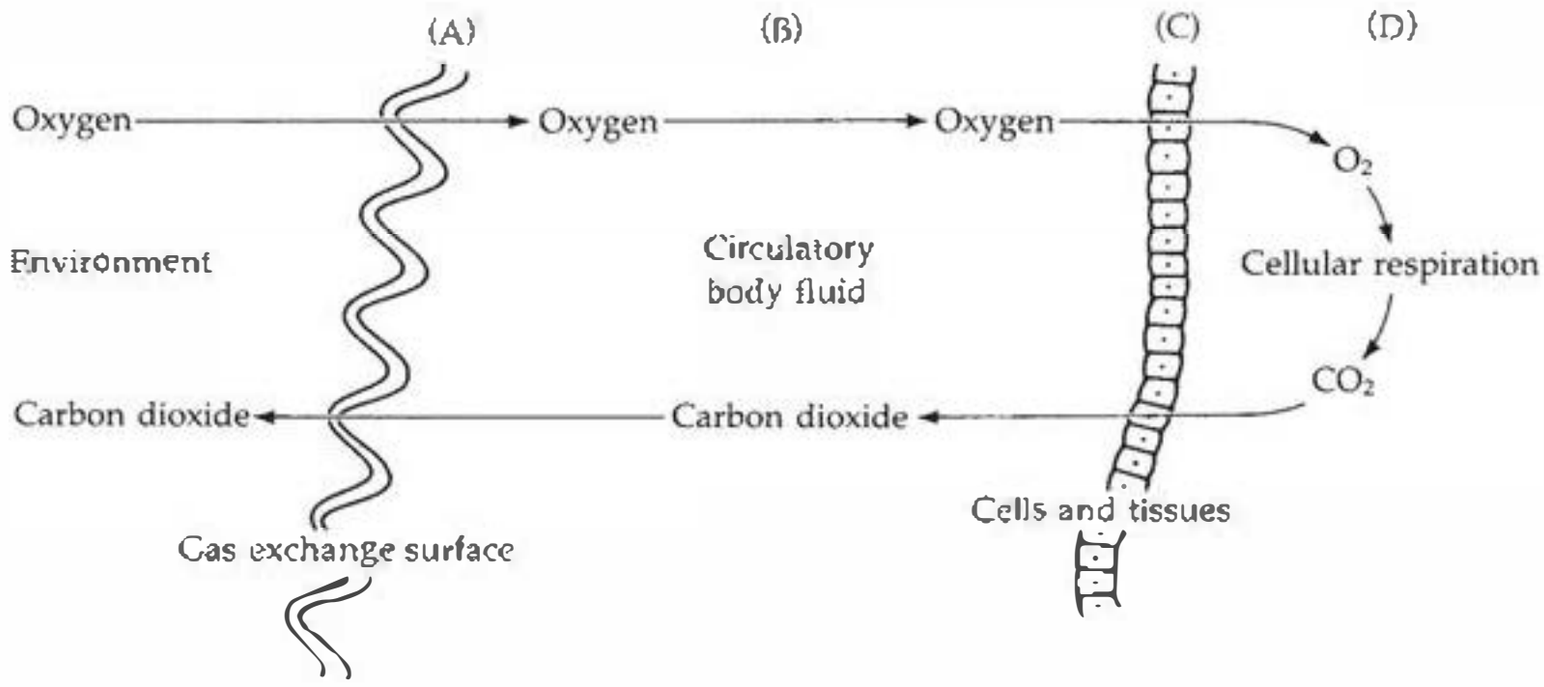

Figure 4.25 Gas exchange in animals. Oxygen is obtained from the environment at a gas exchange surface, such as an epithelial layer (A), and is transported by a circulatory body fluid (B) to the body's cells and tissues (C), where cellular respiration occurs (D). Carbon dioxide follows the reverse path. See text for details.

depends on the concentration gradients of the gases at the exchange site; these gradients are maintained by the circulation of internal fluids to and away from these areas (Figure 4.25).

Gas exchange structures Protists and a number of invertebrates lack special gas exchange structures. In such animals gas exchange is said to be integumentary or cutaneous, and occurs over much of the body surface. Such is the case in many tiny animals with very high surface-to-volume ratios and in some larger soft-bodied forms (e.g., cnidarians and flatworms). Most animals with integumentary gas exchange are restricted to aquatic or damp terrestrial environments where the body surface is kept moist. Integumentary gas exchange also supplements other methods in many animals, even certain vertebrates (e.g., amphibians).

Most marine and many freshwater invertebrates possess gills (Figure 4.26A–C,G), which are external organs or restricted areas of the body surface specialized for gas exchange. Basically, gills are thin-walled processes, well supplied with blood or other body fluids, which promote diffusion between this fluid and the environment. Gills are frequently highly folded or digitate, increasing the diffusive surface area. A great number of nonhomologous structures have evolved as gills in different taxa, and they often serve other functions in addition to gas exchange (e.g., sensory input and feeding). By their very nature, gills are permeable surfaces that must be protected during times of osmotic stress, such as occur in estuaries and intertidal environments. In these instances, the gills may be housed within chambers or be retractable.

A few marine invertebrates employ the lining of the gut as the gas exchange surface. Water is pumped in and out of the hindgut, or a special evagination thereof, in a process called **hindgut irrigation**. Many sea cucumbers and echiurid worms use this method of gas exchange (Figure 4.26F).

As you can imagine, protruding gills would not work on dry land. Here, the gas exchange surfaces must be internalized to keep them moist and protected and to prevent body water loss through the wet surfaces. The lungs of terrestrial vertebrates are the most familiar example of such an arrangement. Among the invertebrates, the arthropods have managed to solve the problems of "air-breathing" in two basic ways. Spiders and their kin possess book lungs, and most insects, centipedes, and millipedes possess tracheae (Figure 4.26D,E). Book lungs are blind inpocketings with highly folded inner linings across which gases diffuse between the hemolymph and the air. Tracheae, however, are branched, usually anastomosed invaginations of the outer body wall and are open both internally and externally.

The tracheae of most insects allow diffusion of oxygen from air directly to the tissues of the body; the blood plays little or no role in gas transport. Rather, intercellular fluids extend part way into the tracheal tubes as a solvent for gases. Atmospheric pressure tends to prevent these fluids from being drawn too close to the external body surface where evaporation is a potential problem. In addition, the outside openings (spiracles) of the tracheae are often equipped with some mechanism of closure. In many insects, especially large ones, special muscles ventilate the tracheae by actively pumping air in and out. Terrestrial isopod crustaceans (e.g., sowbugs and pillbugs) have invaginated gas exchange structures on some of their abdominal appendages. These inpocketings are called pseudotrachea, but are probably not homologous to the trachea or the book lungs of insects and spiders.

The only other major group of terrestrial invertebrates whose members have evolved distinct air-breathing structures are the land snails and slugs (Figure 4.26H). The gas exchange structure here is a lung that opens to the outside via a pore called the pneumostome. This lung is derived from a feature common to molluscs in general, the mantle

cavity, which in other molluscs houses the gills and other organs.

Gas transport As illustrated in Figure 4.25, oxygen must be transported from the sites of environmental gas exchange to the cells of the body, and carbon dioxide must get from the cells where it is produced to the gas exchange surface for release. Generally, groups displaying marked cephalization circulate freshly oxygenated blood through the "head" region first, and sec ondarily to the rest of the body

Invertebrates vary considerably in their oxygen requirements. In general, active animals consume more oxygen than sedentary ones. In slow moving and sed entary invertebrates, oxygen consumption and utilization are quite low. For example, no more than 20% oxygen withdrawal from the gas exchange water current has ever been demonstrated in sessile sponges, b i valves, or tunicates. The amount of oxygen available to an organism varies greatly in different environments. The concentration of oxygen in dry air at sea level is uniformly about 210 ml/liter, whereas in water it ranges from near zero to about 10 ml/liter. This variation in aquatic environments is due to such factors as depth, surface turbulence, photosynthetic activity, temperature, and salinity (oxygen concentrations drop as temperature and salinity increase). With the exception of certain areas prone to oxygen depletion (e.g., muds rich in organic detritus), most habitats provide adequate sources of oxygen to sustain animal life. Also, the relatively low capacity of body fluids to carry oxygen in solution is greatly increased by binding oxygen with complex organic compounds called respiratory pigments.

Respiratory pigments differ in molecular architecture and in their affinities for oxygen, but all have a metal ion (usually iron, sometimes copper) with which the oxygen combines. In most invertebrates, these pigments occur in solution within the blood or other body fluid, but in some invertebrates (and virtually all vertebrates), they may be in specific blood cells. In general, the pigments respond to high oxygen concentrations by "loading" (combining with oxygen), and to low oxygen concentrations by "unloading" or dissociating from oxygen (releasing oxygen). The loading and unloading qualities are different for various pigments in terms of their relative saturations at different levels of oxygen in their immediate surroundings, and are generally expressed in the form of dissociation curves. Respiratory pigments load at the site of gas exchange, where environmental oxygen levels are high relative to the body fluid, and unload at the cells and tissues, where surrounding oxygen levels are low relative to the body fluid. In addition to simply carrying oxygen from the loading to the unloading sites, some pigments may carry reserves of oxygen that are released only when tissue levels are unusually low. Other factors, such as temperature and carbon dioxide concentration, also influence the oxygen carrying capacities of respiratory pigments

Hemoglobin is among the most common respiratory pigments in animals. There are actually a number of different hemoglobins. Some function primarily for transport, whereas others store oxygen and then release it during times of low environmental oxygen availability. Hemoglobins are reddish pigments containing iron as the oxygen-binding metal. They are found in a variety of invertebrates and, with the exception of a few fishes, in all vertebrates. Among the major groups of invertebrates, hemoglobin occurs in many annelids, some crustaceans, some insects, and a few molluscs and echinoderms. Interestingly, hemoglobin is not restricted to the Metazoa; it is also produced by some protists, certain fungi, and in the root nodules of leguminous plants. Among animals, hemoglobin may be carried within red blood cells (erythrocytes), in coelomic cells called hemocytes (in a few echinoderms), or it may simply be dissolved in the blood or coelomic fluid.

Hemocyanins are the most commonly occurring respiratory pigments in molluscs and arthropods, and they occur only in members of these two phyla. Among arthropods, hemocyanin occurs in chelicerates, a few myriapods, and the "higher Crustacea." There is indirect evidence that it also occurred in trilobites. Hemocyanin has been found in most classes of molluscs. Although hemocyanins, like hemoglobins, are proteins, they display significant structural differences, contain copper rather than iron, and tend to have a bluish color when oxygenated. The oxygen binding site on a hemocyanin molecule is a pair of copper atoms linked to amino acid side chains. Unlike most hemoglobins, hemocyanins tend to release oxygen easily and provide a ready source of oxygen to the tissues as long as there is a relatively high concentration of available environmental oxygen. Hemocyanins are always found in solution, never in cells, a characteris tic probably related to the necessity for rapid oxygen unloading. Hemocyanins often give a bluish tint to the hemolymph of arthropods, although the presence of

TABLE 4.1 Properties of oxygen carrying respiratory p gments

Pigment	Molecular weight	Meta	Ratio of metal to O_2	Metal associate
Hemoglobin	65,000	Fe	1:1	Porphynn
Hemerythrin	40,000-108,000	Fe	2:1	Protein chains
Hemocyanin	40,000-9,000,000	Cu	2:1	Protein chains
Chlorocruorin	3 000,000	Fe	1:1	Porphyrin

carotenoid pigments (beta carotene and related mole cules) commonly impart a brown or orange coloration.

Two other types of respiratory pigments occur incidentally in certain invertebrates; these are **hemerythrins** and **chlorocruorins**, both of which contain iron. The former is violet to pink when oxygenated; the latter is green in dilute concentrations but red in high concentrations. Chlorocruorins generally function as efficient oxy gen carriers when environmental levels are relatively high; hemerythrins function more in oxygen storage. Chlorocruorin is structurally similar to hemoglobin and may have been derived from it Chlorocruorin occurs in several families of polychaete worms; hemerythrin is known from sipunculans, at least one genus of poly chaetes, and some priapulans and brachiopods.

Table 4.1 gives some of the basic properties of oxygen-carrying pigments. There seems to be no obvious phylogenetic rhyme or reason to the occurrence of these pigments among the various taxa. Their sporadic and inconsistent distribution suggests that some of them may have evolved more than once, through parallel or convergent evolution. Respiratory pigments are rare among insects and are known only from the occurrence of hemoglobin in chironomid midges, some notonectids, and certain parasitic flies of the genus *Gastrophilus*. The absence of respiratory pigments among the insects reflects the fact that most of them do not use the blood as a medium for gas transport, but employ extensive tracheal systems to carry gases directly to the tissues. In those insects without well de veloped tracheae, oxygen is simply carried in solution in the hemolymph.

Respiratory pigments raise the oxygen-carrying capacity of body fluids far above what would be achieved by transport in simple solution. Similarly, carbon dioxide levels in body fluids (and in sea water) are much higher than would be expected strictly on the basis of its solubility. The enzyme carbonic anhydrase greatly accelerates the reaction between carbon dioxide and water, forming carbonic acid:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$

Furthermore, carbonic acid ionizes to hydrogen and bicarbonate ions, so a series of reversible reactions takes place:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

By "tying up" CO_2 in other forms, the concentration of CO_2 in solution is lowered, thus raising the overall CO_2-carrying capacity of the blood. This set of reactions responds to changes in pH, and in the presence of appropriate cations (e.g., Ca^{2+} and Na^+) it shifts back and forth, serving as a buffering mechanism by regulating hydrogen ion concentration.

Nervous Systems and Sense Organs

All living cells respond to some stimuli and conduct some sort of "information," at least for short distances. Thus, even when no real nervous system is present the condition found in protists and sponges—coordination and reaction to external stimulation do occur. The regular metachronal beating of cilia in ciliate protists and the responses of certain flagellates to varying light intensities are examples. In addition, most protists are known to respond to gradients of various environmental factors by moving to or away from areas of high concentration. For example, when subjected to condi tions of low oxygen concentration (hypoxia), paramecia move to regions of lower water temperature, thus lowering their metabolic rate and presumably their oxygen need. But the integration and coordination of bodily activities in Metazoa are in large part due to the processing of information by a true nervous system. The functional units of nervous systems are **neurons**: cells that are specialized for high-velocity impulse conduction.

The generation of an impulse within a true nervous system usually results from a stimulus imposed on the nervous elements. The source of stimulation may be external or internal. A typical pathway of events occurring in a nervous system is shown in Figure 4.27. A stimulus received by some receptor (e.g., a sense organ) generates an impulse that is conducted along a **sensory nerve (afferent nerve)** via a series of adjacent neurons to some coordinating center or region of the system. The information is processed and an appropriate response is "selected." A **motor nerve (efferent nerve)** then conducts an impulse from the central processing center to an effector (e.g , a muscle), where the response occurs. Once an impulse is initiated within the system, the mechanism of conduction is essentially

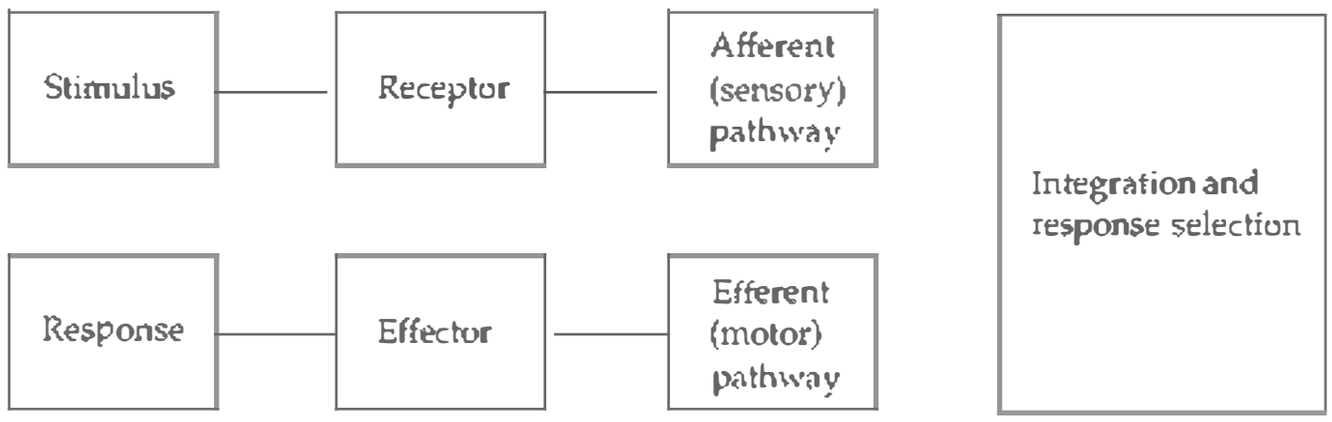

Figure 4.27 A generalized pathway within the nervous system. A stimulus init ates an mpulse w th n some sensory structure (the receptor); the impu se is then transferred to some integrative port on of the nervous system via sensory nerves. Following response selection, an impulse is generated and transferred a ong motor nerves to an ef ector (e g., muscle), where the appropr ate response is elicited.

the same in all neurons, regardless of the stimulus. The wave of depolarization along the length of each neuron and the chemical neurotransmitters crossing the synaptic gaps between neurons are common to virtually all nervous conduction. How then is the informa tion interpreted within the system for response selection? The answer to this question involves three basic considerations.

First is the occurrence of a point called a threshold, which corresponds to the minimum intensity of stimulation necessary to generate an impulse Receptor sites consist of specialized neurons whose thresholds for various kinds of stimuli are drastically different from one another because of structural or physiological qualit es. For example, a sense organ whose threshold for light stimulation is very low (compared with other potential stimuli) functions as a light sensor, or photo receptor. In any such specialized sensory receptor, the condition of differential thresholds essentially screens incoming st muli so that an impulse normally is generated by only one kind of information (e.g , light, sound, heat, or pressure). Second is the nature of the receptor itself. Receptor units (e.g., sense organs) are generally constructed in ways that permit only certain stimuli to reach the impulse generating cells. For example, the light sensitive cells of the human eye are located be neath the eye surface, where stimuli other than light would not normally reach them.

And third, the overall "wiring" or circuitry of the entire nervous system is such that impulses received by the integrative (response selecting) areas of the sys tem from any particular nerve will be interpreted according to the kind of st mulus for which that sensory pathway is specialized. For example, all impulses coming from a photoreceptor are understood as being light induced. Threshold and circuitry can be demonstrated by introducing false information into the system by stimulating a specialized sense organ in an inappropriate manner: if photoreceptors in the eye are stimulated by electricity or pressure, the nervous system will interpret this input as light. Remember that an impulse can be generated in any receptor by nearly any form of stimulation if the stimulus is intense enough to exceed the relevant threshold. A blow to the eye often results in "seeing stars," or flashes of light, even when the eye is closed. In such a situation, the photoreceptor's threshold to mechanical stimulation has been reached. By the same token, the application of extreme cold to a heat receptor may feel hot.

Nervous systems in general operate on the principles outlined above. However, this description applies largely to nervous systems that have structural centralized regions. Following a discussion below of the basic types of sense organs (receptor units), we discuss centralized and noncentralized nervous systems and their relationships to general body architecture.

Sense Organs

Invertebrates possess an impressive array of receptor structures through which they receive information about their internal and external environments. An animal's behavior is in large part a function of its responses to that information. These responses often take the form of some sort of movement relative to the source of a particular stimulus. A response of this nature is called a **taxis** and may be positive or negative depending on the reaction of the animal to the stimulus. For example, many animals tend to move away from bright light and are thus said to be negatively phototactic.

The activities of receptor units represent the initial step in the usual functioning of the nervous system; they are a critical link between the organism and its surroundings. Consequently, the kinds of sense organs present and their placement on the body are intimately related to the overall complexity, mode of life, and general body plan of any animal. The following general review provides some concepts and terminology that serve as a basis for more detailed coverage in later chapters. The first five categories of sense organs may all be viewed as mechanoreceptors, in that they respond to mechanical stimuli (e.g., touch, vibrations, and pressure). The last three are sensitive to nonmechanical input (e g., chemicals, light, and temperature). In addition, a few invertebrates have been shown to possess a magnetic compass. For example, during their migrations between North America and central Mexico, monarch butterflies probably navigate using a combination of the sun and the inclination angle component of the Earth's magnetic field to guide their flights, as has been shown for most vertebrate migrators.

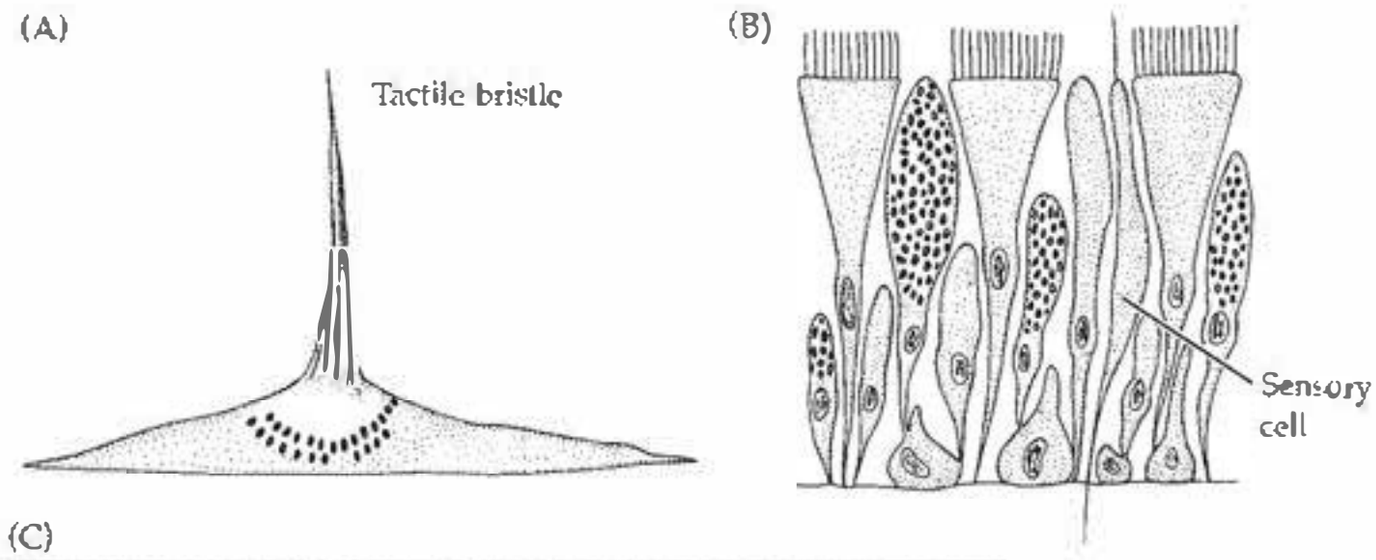

Figure 4.28 Some invertebrate tactile receptors. (A) Tactile organ of *Sagitta bipunctata* (an arrow worm, phylum Chaetognatha). (B) A sensory epithelial cell of a nemertean worm. (C) Long, touch-sensitive setae (and stout grasping setae) on the leg of the isopod, *Politolana* (SEM).

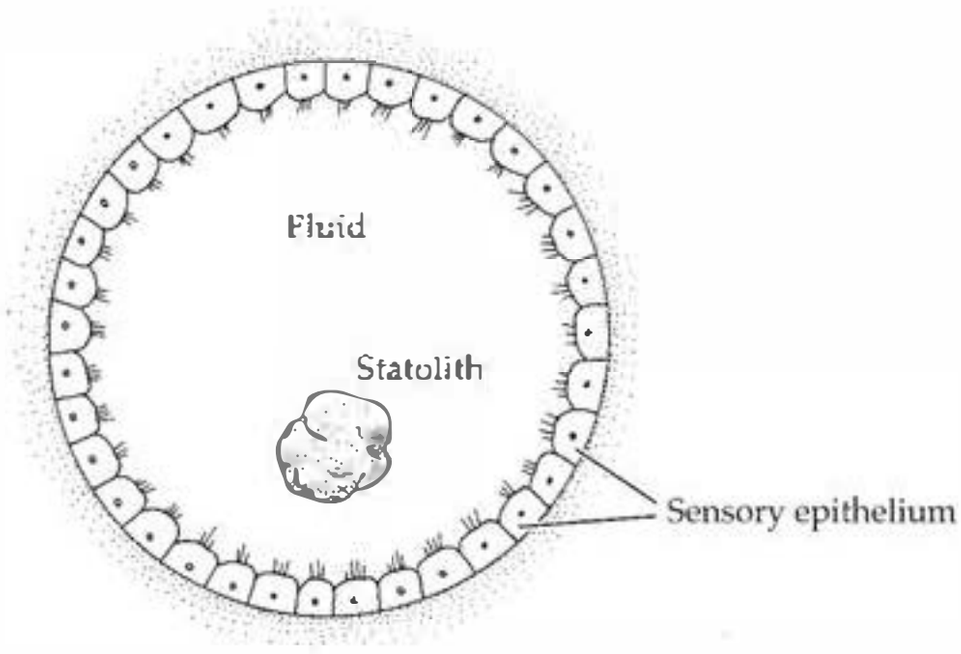
Tactile receptors Touch or tactile receptors are generally derived from modified epithelial cells associated with sensory neurons. The nature of the epithelial modifications depends a great deal on the structure of the body wall. For instance, the form of a touch receptor in an arthropod with a rigid exoskeleton must be different from that in a soft-bodied cnidarian. Most such receptors, however, involve projections from the body surface, such as bristles, spines, setae, tubercles, and assorted bumps and pimples (Figure 4.28). Objects in the environment with which the animal makes contact move these receptors, thereby creating mechanical deformations that are imposed upon the underlying sensory neurons to initiate an impulse.

Virtually all animals are touch-sensitive, but their responses are varied and often integrated with other sorts of sensory input. For example, the gregarious nature of many animals may involve a positive response to touch (positive thigmotaxis) combined with the chemical recognition of members of the same species. Some touch receptors are highly sensitive to mechanically induced vibrations propagated in water, loose sediments, through solid substrata, or other materials. Such vibration sensors are common in certain tube-dwelling polychaetes that retract quickly into their tubes in response to movements in their surroundings. Some crustacean ambush-predators are able to detect the vibrations induced by nearby potential prey animals, and web-building spiders quickly and accurately sense prey in their webs through vibrations of the threads. Some spiders have highly sensitive tactile setae on their appendages, called trichobothria, that sense airborne vibrations of prey, such as wing beats and perhaps even some sound frequencies.

Georeceptors Georeceptors respond to the pull of gravity, giving animals information about their orientation relative to "up and down." Most georeceptors are structures called statocysts (Figure 4.29). Statocysts usually consist of a fluid-filled chamber containing a solid granule or pellet called a statolith. The inner lining of the chamber includes a touch-sensitive epithelium from which project bristles or "hairs" associated with underlying sensory neurons. In aquatic invertebrates, some statocysts are open to the environment and thus are filled with water. In some of these the statolith is a sand grain obtained from the animal's surroundings. Most statoliths, however, are secreted within closed capsules by the organisms themselves.

Because of the resting inertia of the statolith within the fluid, any movement of the animal results in a change in the pattern or intensity of stimulation of the sensory epithelium by the statolith. Additionally, when the animal is stationary, the position of the statolith within the chamber provides information about the organism's orientation to gravity. The fluid within statocysts of at least some invertebrates (especially certain crustaceans) also acts something like the fluid of the semicircular canals in vertebrates. When the animal moves, the fluid tends to remain stationary—the relative "flow" of the fluid over the sensory epithelium provides the animal with information about its linear and rotational acceleration relative to its environment.



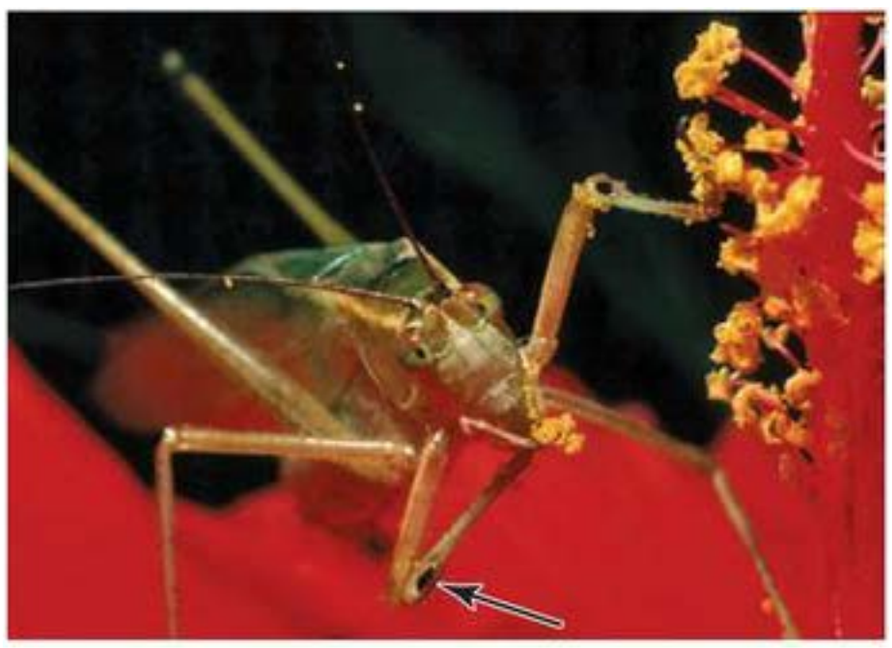


Figure 4.29 A generalized statocyst, or georeceptor (section).

Whether stationary or in motion, animals utilize the input from georeceptors in different ways, depending on their habitat and lifestyle. The information from these statocysts is especially important under conditions where other sensory reception is inadequate. For example, burrowing invertebrates cannot rely on photoreceptors for orientation when moving through the substratum, and some employ statocysts for that purpose Similarly, planktonic animals face orientation problems in their three-dimensional aqueous environment, especially in deep water and at night; many such creatures possess statocysts.

There are a few exceptions to the standard statocyst arrangements described above For example, a number of aquatic insects detect gravity by using air bubbles trapped in certain passageways (e g., tracheal tubes). The bubbles move according to their orientation to the vertical, much like the air bubble in a carpenter's level, and stimulate sensory bristles lining the tube in which they are located.

Proprioceptors Internal sensory organs that respond to mechanically induced changes caused by stretching, compression, bending, and tension are called proprioceptors, or simply stretch receptors. These receptors give the animal information about the movement of its body parts and their positions relative to one another Proprioceptors have been most thoroughly studied in vertebrates and arthropods, where they are associated with appendage joints and certain body extensor muscles. The sensory neurons involved in proprioception are associated with and attached to some part of the body that is stretched or otherwise mechanically affected by movement or muscle tension These parts may be specialized muscle cells, elastic connective tissue fibers, or membranes that span joints. As these structures are stretched, relaxed, and compressed, the sensory endings of the attached neurons are distorted accordingly and thus stimulated. Some of these receptor arrangements can detect not only changes in position but also in static tension.

Phonoreceptors General sensitivity to sound—phonoreception—has been demonstrated in a number of invertebrates (certain annelid worms and a variety of crustaceans), but true auditory receptors are known only in a few groups of insects and perhaps some arachnids and centipedes. Crickets, grasshoppers, and cicadas possess phonoreceptors called tympanic organs (Figure 4 30). A rather tough but flexible tympanum covers an internal air sac that allows the tympanum to vibrate when struck by sound waves. Sensory neurons attached to the tympanum are stimulated directly by the vibrations. Most arachnids possess structures called slit sense organs, which, although poorly studied, are suspected to perform auditory functions; at least they appear to be capable of sensing

F gure 4 30 An arthropod phonoreceptor, or auditory organ, of the fork-tailed katydid, *Scudderia furcata*. Note the position of the right-side tympanum on the t bia of the first walk ng leg.

sound-induced vibrations. Certain centipedes bear so called organs of Tömösváry, which some workers believe may be sensitive to sound.

Baroreceptors The sensitivity of invertebrates to pressure changes baroception is not well understood, and no structures for this purpose have been positively identified. However, behavioral responses to pressure changes have been demonstrated in several pelagic invertebrates including medusae, ctenophores, cephalopods, and copepod crustaceans, as well as in some planktonic larvae. Aquatic insects also sense changes in pressure, and may use a variety of methods to do so. Some intertidal crustaceans coordinate daily migratory activities with tidal movements, perhaps partly in response to pressure as water depth changes.

Chemoreceptors Many animals have a general chemical sensitivity, which is not a function of any definable sensory structure but is due to the general irritability of protoplasm itself. When they occur in sufficiently high concentrations, noxious or irritating chemicals can induce responses via this general chemical sensitivity. In addition, most animals have specific chemoreceptors.

Chemoreception is a rather direct sense in that the molecules stimulate sensory neurons by contact, usually after diffusing in solution across a thin epithelial covering. The chemoreceptors of many aquatic invertebrates are located in pits or depressions, through which water may be circulated by ciliary action. In arthropods, the chemoreceptors are usually in the form of hollow "hairs" or other projections, within which are chemosensory neurons. While chemosensitivity is a universal phenomenon among invertebrates, a wide range of specificities and capabilities exists.

The types of chemicals to which particular animals respond are closely associated with their lifestyles. Chemoreceptors may be specialized for tasks such as

general water analysis, humidity detection, sensitivity to pH, prey tracking, mate location, substratum analysis, and food recognition. Probably all aquatic organisms leak small amounts of amino acids into their environment through the skin and gills as well as in their urine and feces. These released amino acids form an organism's "body odor," which can create a chemical picture of the animal that others detect to identify such characteristics as species, sex, stress level, distance and direction, and perhaps size and individuality. Amino acids are widely distributed in the aquatic environment, where they provide general indicators of biological activity. Many aquatic animals can detect amino acids with much greater sensitivity than our most sophisticated laboratory equipment.

Photoreceptors Nearly all animals are sensitive to light, and most have some kind of identifiable photoreceptors Although members of only a few of the metazoan phyla appear to have evolved eyes capable of image formation (Cnidaria, Mollusca, Annelida, Arthropoda, and Chordata), virtually all animal photoreceptors share structurally similar light receptor molecules that probably predate the origin of discrete structural eyes. Thus, the structural photoreceptors of animals share the common quality of possessing light-sensitive pigments. These pigment molecules are capable of absorbing light energy in the form of photons, a process necessary for the initiation of any light-induced, or photic, reaction. The energy thus absorbed is ultimately responsible for stimulating the sensory neurons of the photoreceptor unit.

Beyond this basic commonality, however, there is an incredible range of variation in complexity and capability of light-sensitive structures Arthropods, molluscs, and some polychaete annelids possess eyes with extreme sensitivity, good spatial resolution, and, in some cases, multiple spectral channels. Most classifications of photoreceptors are based upon grades of complexity, and the same categorical term may be applied to a variety of nonhomologous structures, from simple pigment spots (found in protists) to extremely complicated lensed eyes (found in squids and octopuses). Functionally, the capabilities of these receptors range from simply perceiving light intensity and direction to forming images with a high degree of visual discrimination and resolution.

Certain protists, particularly flagellates, possess subcellular organelles called **stigmata**, which are associated with simple spots of lightsensitive pigment (Figure 4.31A). The simplest metazoan photoreceptors are unicellular structures scattered over the epidermis or concentrated in some area of the body. These are usually called eyespots. Multicellular photoreceptors may be classified into three general types, with some subdivisions. These types include **ocelli** (sometimes called simple eyes or eyespots), compound eyes (found in many arthropods), and complex eyes (the "camera" eyes of cephalopod molluscs and vertebrates). In multicellular ocelli, the light sensitive (retinular) cells may face outward; these ocelli are then said to be direct. Or the light-sensitive cells may be inverted. The inverted type is common among flatworms and nemerteans and is made up of a cup of reflective pigment and retinular cells (Figure 4.31B). The light-sensitive ends of these neurons face into the cup. Light entering the opening of the pigment cup is reflected back onto the retinular cells. Because light can enter only through the cup opening, this sort of ocellus gives the animal a good deal of information about light direction as well as variations in intensity.

Compound eyes are composed of a few to many distinct units called **ommatidia** (Figure 4.31C). Although eyes of multiple units occur in certain annelid worms and some bivalve molluscs, they are best developed and best understood among the arthropods. Each ommatidium is supplied with its own nerve tract leading to a large optic nerve, and apparently each has its own discrete field of vision. The visual fields of neighboring ommatidia overlap to some degree, with the result that a shift in position of an object within the total visual field causes changes in the impulses reaching several ommatidial units; based in part on this phenomenon, compound eyes are especially suitable for detecting movement. Compound eyes are described in more detail in Chapter 20.

The complex eyes of squids and octopuses (Figure 4.31D) are probably the best image-forming eyes among the invertebrates. Cephalopod eyes are frequently compared with those of vertebrates, but they differ in many respects. The eye is covered by a transparent protective cornea. The amount of light that enters the eye is controlled by the iris, which regulates the size of the slitlike pupil. The lens is held by a ring of ciliary muscles and focuses light on the retina, a layer of densely packed photosensitive cells from which the neurons arise The receptor sites of the retinal layer face in the direction of the light entering the eye. This direct eye arrangement is quite different from the indirect eye condition in vertebrates, where the retinal layer is inverted. Another difference is that in many vertebrates, focusing is accomplished by the action of muscles that change the shape of the lens, whereas in cephalopods it is achieved by moving the lens back and forth with the ciliary muscles and by compressing the eyeball.

A good deal of work suggests that metazoan photoreceptors evolved primarily along two lines. On one hand are photoreceptor units derived from or closely associated with cilia (e.g., in cnidarians, echinoderms, and chordates). These types of eyes are called **ciliary** eyes. On the other hand are photoreceptors derived from microvilli or microtubules and referred to as **rhabdomeric** eyes (e.g., in flatworms, annelids, arthropods, and molluscs). All animal photoreceptors may

share a deep developmental homology with the *Pax-6* gene, which is known to initiate eye development (even structurally non-homologous eyes) in numerous distantly related phyla of both Protostomia and Deuterostomia.

Thermoreceptors The influence of temperature changes on all levels of biological activity is well documented. Every student of general biology has learned about the basic relationships between temperature and rates of metabolic reactions. Furthermore, even the casual observer has noticed that many organisms' activity levels range from lethargy at low temperatures to hyperactivity at elevated temperatures, and that thermal extremes can result in death. The problem is determining whether the organism is simply responding to the effects of temperature at a general physiological level, or whether discrete thermoreceptor organs are also involved.

There is considerable circumstantial evidence that at least some invertebrates are capable of directly sensing differences in environmental temperatures, but actual receptor units are for the most part unidentified. A number of insects, some crustaceans, and the horseshoe crab (*Limulus*) apparently can sense thermal variation. The only nonarthropod invertebrates that have received much attention in this regard are certain leeches, which apparently are drawn to warm-blooded hosts by some heat-sensing mechanism. Other ectoparasites (e.g., ticks) of warm-blooded vertebrates may also be able to sense the "warmth of a nearby meal," but little work has been done on this subject.

Independent Effectors

Independent effectors are specialized sensory response structures that not only receive information from the environment but also elicit a response to the stimulus directly, without the intervention of the nervous system per se. In this sense, independent effectors are like closed circuits. As discussed in later chapters,

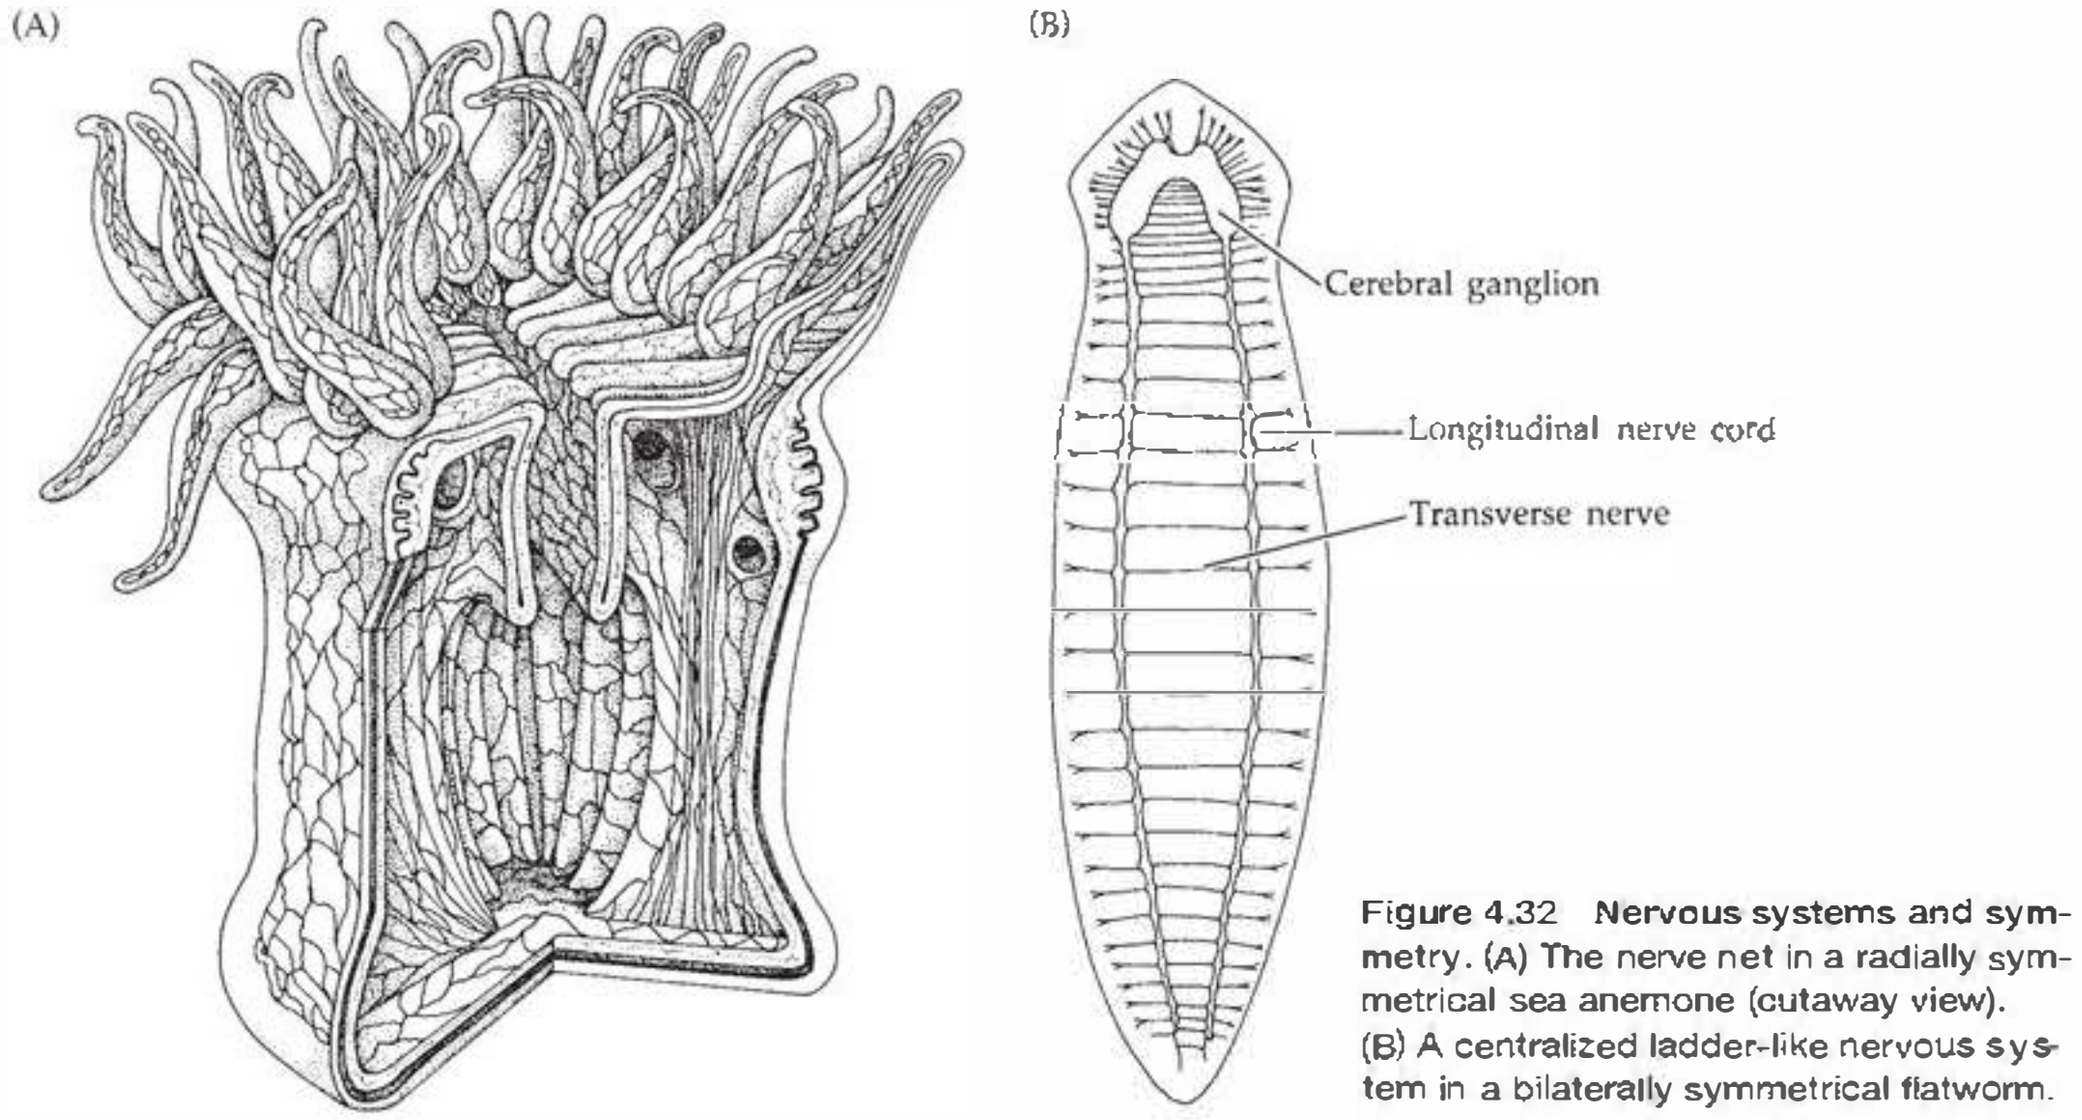

Figure 4.32 Nervous systems and symmetry. (A) The nerve net in a radially symmetrical sea anemone (cutaway view). (B) A centralized ladder-like nervous system in a bilaterally symmetrical flatworm.

the stinging capsules (nematocysts) of cnidarians and the adhesive cells of ctenophores are, at least under most circumstances, independent effectors.

Bioluminescence

Bioluminescence, the production of light by living creatures, occurs in a great variety of organisms in the sea and in some land animals, but it is, curiously, rare in freshwaters. On land, it is seen in a number of beetle groups, as well as some flies and springtails, centipedes and millipedes, a few earthworms, and at least one snail (as well as some fungi). In freshwater it has been reported from only a few insect larvae and a freshwater limpet. In the sea, bioluminescence plays a significant role in animal communication, and it has been recorded from various protists, cnidarians, ctenophores, chaetognaths, annelids, molluscs, numerous arthropods, echinoderms, hemichordates, tunicates, at least one nemertean, and, of course, numerous fishes (as well as bacteria and fungi). Most bioluminescence commonly seen in the sea is produced by dinoflagellates emitting rapid (one-tenth of a second) flashes. But the patient nighttime observer will also discover that flashes of light are produced by some species of medusae, ctenophores, copepods, benthic ostracods, brittle stars, sea pansies and sea pens, chaetopterid and syllid polychaetes, limpets, clams, tunicates, and others.

Luminescence is the emission of light without heat. It involves a special type of chemical reaction in which the energy, instead of being released as heat as occurs in most chemical reactions, is used to excite a product molecule that releases energy as a photon. In all cases, the reaction involves the oxidation of a substrate called **luciferin**, catalyzed by an enzyme called **luciferase**. The structures of these chemicals differ among taxa, but the reaction is similar. The color of light varies from deep blue (shrimp and dinoflagellates) to blue-green or green (certain millipedes, ostracods, and tunicates), to yellow and even red (fireflies). Bioluminescence serves several functions, including offense, defense, prey attraction, and intraspecific communication. In some cases, the luminescent organs of metazoans (particularly fishes) are not intrinsic but are symbiotic colonies of microorganisms.

Nervous Systems and Body Plans

The nervous system is always receiving information via its associated receptors, processing this information, and eliciting appropriate responses. We limit our discussion at this point to those conditions in which distinct systems of identifiable neurons exist, leaving the special situations in protists and sponges for later chapters.

The structure of the nervous system of any animal is related to its body plan and mode of life. Consider first a radially symmetrical animal with limited powers of locomotion, such as a planktonic jellyfish or a sessile sea anemone. In such animals the major receptor organs are more or less regularly (and radially) distributed around the body; the nervous system itself is a noncentralized, diffuse meshwork generally called a **nerve net** (Figure 4.32A). Radially symmetrical animals tend to be able to respond equally well to stimuli coming

from any direct.on a useful ability for creatures with either sessile or freefloat.ng lifestyles. Interestingly, at least in cnidarians, there are both polarized and non polarized synapses within the nerve net Impulses can travel in either direction across the nonpolarized synapses because the neuronal processes on both sides are capable of releasing synaptic transmitter chemicals. This capability, coupled with the gridlike form of the nerve net, enables impulses to travel in all directions from a point of stimulation. From this brief description, it might be assumed that such a simple and "unorganized" nervous system would not provide enough integrated information to allow complex behaviors and coordination. In the absence of a structurally recogniz able integrating center, the nerve net does not fit well with our earlier description of the sequence of events from stimulus to response. But many cnidarians are in fact capable of fairly int icate behavior, and the system works, often in ways that are not yet fully understood. In any case, symmetry, sense organ distribution, ner vous system organization, and lifestyles are clearly correlated to one another.

The tremendous evolutionary success of bilateral symmetry and unidirectional locomotion must have depended in large part on associated changes in the or ganization of the nervous system and the distribution of sense organs. The evolutionary trend among animals has been to centralize and concentrate the major coordinating elements of the nervous system. This central nervous system is usually made up of an anteriorly located neuronal mass (ganglion) from which arise one or more longitudinal nerve cords that often bear addi tional ganglia (Figure 4 32B). The anterior ganglion is referred to by a variety of names. Many authors have abandoned the term brain for such an organ because of the multifaceted implications of that word and adopt the more neutral term cerebral ganglion (or cerebral ganglia) for the general case. In many instances, a term of its relative position to some other organ is applied. For example, the cerebral ganglion commonly lies dor sal to the anterior portion of the gut and is thus a supraenteric (or supraesophageal, or suprapharyngeal) ganglion.

In addition to the cerebral ganglion, most bilaterally symmetrical animals have many of the major sense organs placed anteriorly. The concentration of these organs at the front end of an animal is called cephalization the formation of a head region. Even though cephalization may seem an obvious and predictable outcome of bilaterality and mobility, it is nonetheless extremely important. It simply would not do to have information about the environment gathered by the trailing end of a motile animal, lest it enter adverse and potentially dangerous conditions unawares. Hunting, tracking, and other forms of food location are greatly facilitated by having the appropriate receptors placed anteriorly—toward the direction of movement.

Longitudinal nerve cords receive information through peripheral sensory nerves from whatever sense organs are placed along the body, and they carry impulses from the cerebral ganglion to peripheral motor nerves to effector sites. Additionally, nerve cords and peripheral nerves often serve animals in reflex actions and in some highly coordinated activities that do not depend on the cerebral ganglion. The most primitive centralized nervous system may have been similar to that seen today in xenacoelomorph worms and some free living flatworms, where pairs of longitudinal cords may attached to one another by transverse connectives in a ladder-like fashion (Figure 4 32B). Among those Metazoa that have developed active lifestyles (e.g., errant polychaetes, most arthro pods, cephalopod molluscs, vertebrates), the nervous system has become increasingly centralized through a reduction in the number of longitudinal nerve cords. However, a number of invertebrates (e g , ectoprocts, tunicates, echinoderms) have secondarily taken up sedentary or sessile modes of existence. Within these groups there has been a corresponding decentralization of the nervous system and a general reduction in and dispersal of sense organs.

Hormones and Pheromones

We have stressed the significance of the integrated nature of the parts and processes of living organisms and have discussed the general role of the nervous system in this regard. Organisms also produce and distribute within their bodies a variety of chemicals that regulate and coordinate biological activities. This very broad description of what may be called chemical coordinators obviously includes almost any substance that has some effect on bodily functions. One special category of chemical coordinators is the **hormones**. This term r e fers to any chemicals that are produced and secreted by some organ or tissue, and are then carried by the blood or other body fluid to exert their influence elsewhere in the body. In vertebrates, we associate this type of phenomenon with the endocrine system, which includes well known glands as production sites. For our purposes we may subdivide hormones into two types. First are endocrine hormones, which are produced by more or less isolated glands and released into the circulatory fluid. Second are neurohormones, which are produced by special neurons called neurosecretory cells.

Much remains unknown concerning hormones in invertebrates. Most of our information comes from studies on insects and crustaceans, although hormonal activity has been demonstrated in a few other taxa and is suspected in many others. Among the arthropods, hormones are involved in the control of growth, molting, reproduction, eye pigment migration, and probably other phenomena; in at least some other taxa (e.g.,

annelids), hormones influence growth, regeneration, and sexual maturation.

Hormones do not belong to any particular class of chemical compounds, nor do they all produce the same effects at their sites of action: some are excitatory, some are inhibitory. Because endocrine hormones are carried in the circulatory fluid, they reach all parts of an animal's body. The site of action, or target site, must be able to recognize the appropriate hormone(s) among the myriad other chemicals in its surroundings. This recognition usually involves an interaction between the hormone and the cell surface at the target site. Thus, under normal circumstances, even though a particular hormone is contacting many parts of the body, it will elicit activity only from the appropriate target organ or tissue that recognizes it.

In a general sense, pheromones are substances that act as "interorganismal hormones." These chemicals are produced by organisms and released into the environment, where they have an effect on other organisms. Most pheromone research has been on intraspecific actions, especially in insects, where activities such as mate attraction are frequently related to these airborne chemicals. We may view intraspecific pheromones as coordinating the activities of populations, just as hormones help coordinate the activities of individual organisms. There is also a great deal of evidence for the existence of interspecific pheromones. For example, some predatory species (e.g., some starfish) release chemicals into the water that elicit extraordinary behavioral responses on the part of potential prey species, generally in the form of escape behavior. We discuss examples of various pheromone phenomena for specific animal groups throughout the book.

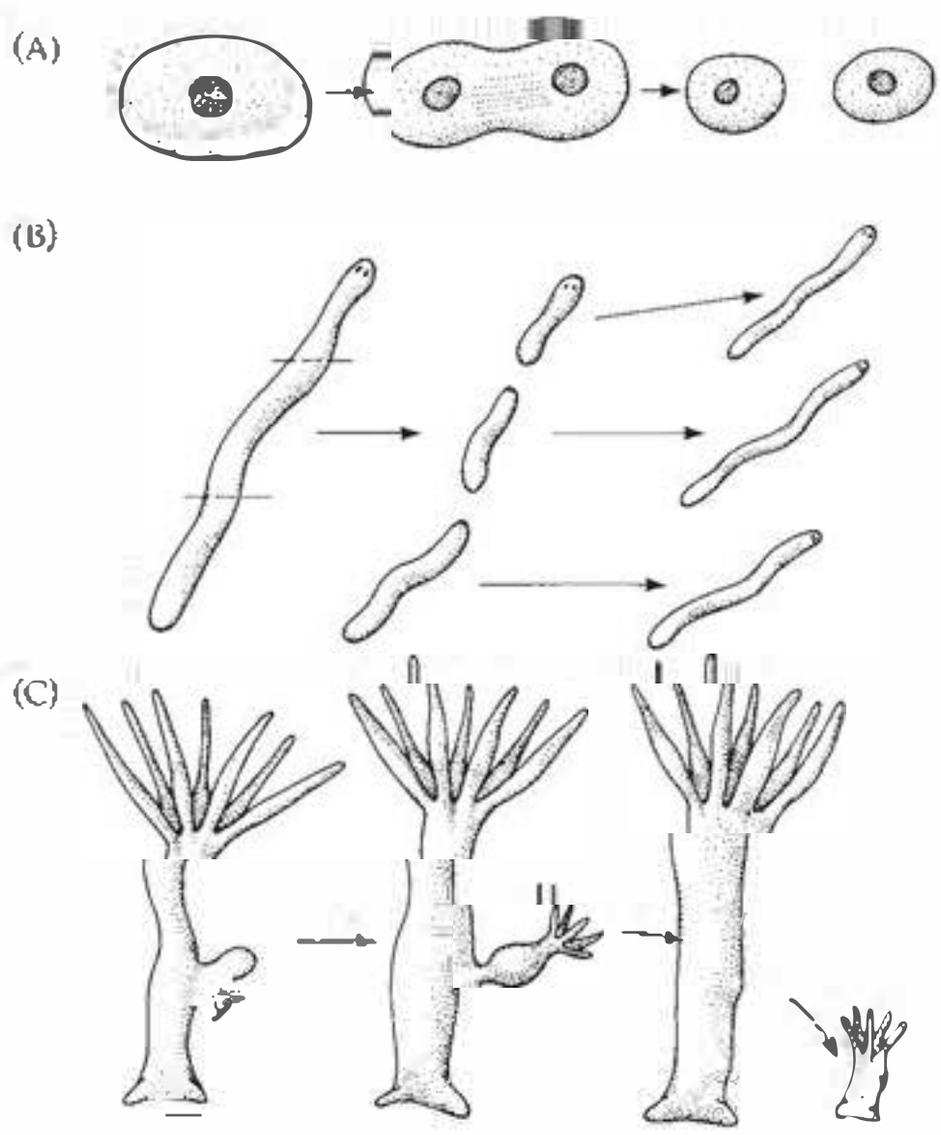

Figure 4.33 Some common asexual reproductive processes. (A) Simple mitotic binary fission; this process occurs in most protists. (B) Fragmentation, followed by regeneration of lost parts. This process occurs in a number of vermiform invertebrates. (C) Budding may produce separate solitary individuals, as it does in *Hydra* (shown here); or it may produce colonies (see Figure 4.34).

Reproduction

The biological success of any species depends upon its members staying alive long enough to reproduce themselves. The following account includes a discussion of the basic methods of reproduction among invertebrates and leads to the account of embryology and developmental strategies provided in Chapter 5.

Asexual Reproduction

Asexual reproductive processes do not involve the production and subsequent fusion of haploid cells, but rely solely on vegetative growth through mitosis. Cell division itself is a common form of asexual reproduction among the protists, and many invertebrates engage in various types of body fission, budding, or fragmentation, followed by growth to new individuals (Figure 4.33). These asexual processes depend largely on the organism's "reproductive exploitation" of its ability to regenerate (regrow lost parts). Even wound healing is a form of regeneration, but many animals have far more dramatic capabilities. The replacement of a lost appendage in familiar animals such as starfish and crabs is a common example of regeneration. However, these regenerative abilities are not "reproduction" because no new individuals result, and their presence does not imply that an animal capable of replacing a lost leg can necessarily reproduce asexually. Examples of organisms that possess regenerative abilities of a magnitude permitting asexual reproduction include protists, sponges, many cnidarians (corals, anemones, and hydroids), many colonial animals, and certain types of worms.

In many cases asexual reproduction is a relatively incidental process and is rather insignificant to a species' overall survival strategy. In others, however, it is an integral and even necessary step in the life cycle. There are important evolutionary and adaptive aspects to asexual reproduction. Organisms capable of rapid asexual reproduction can quickly take advantage of favorable environmental conditions by exploiting temporarily abundant food supplies, newly available living space, or other resources. This competitive edge is frequently evidenced by extremely high numbers of asexually produced individuals in disturbed or unique habitats, or in other unusual conditions. In addition, asexual processes are often employed in the production

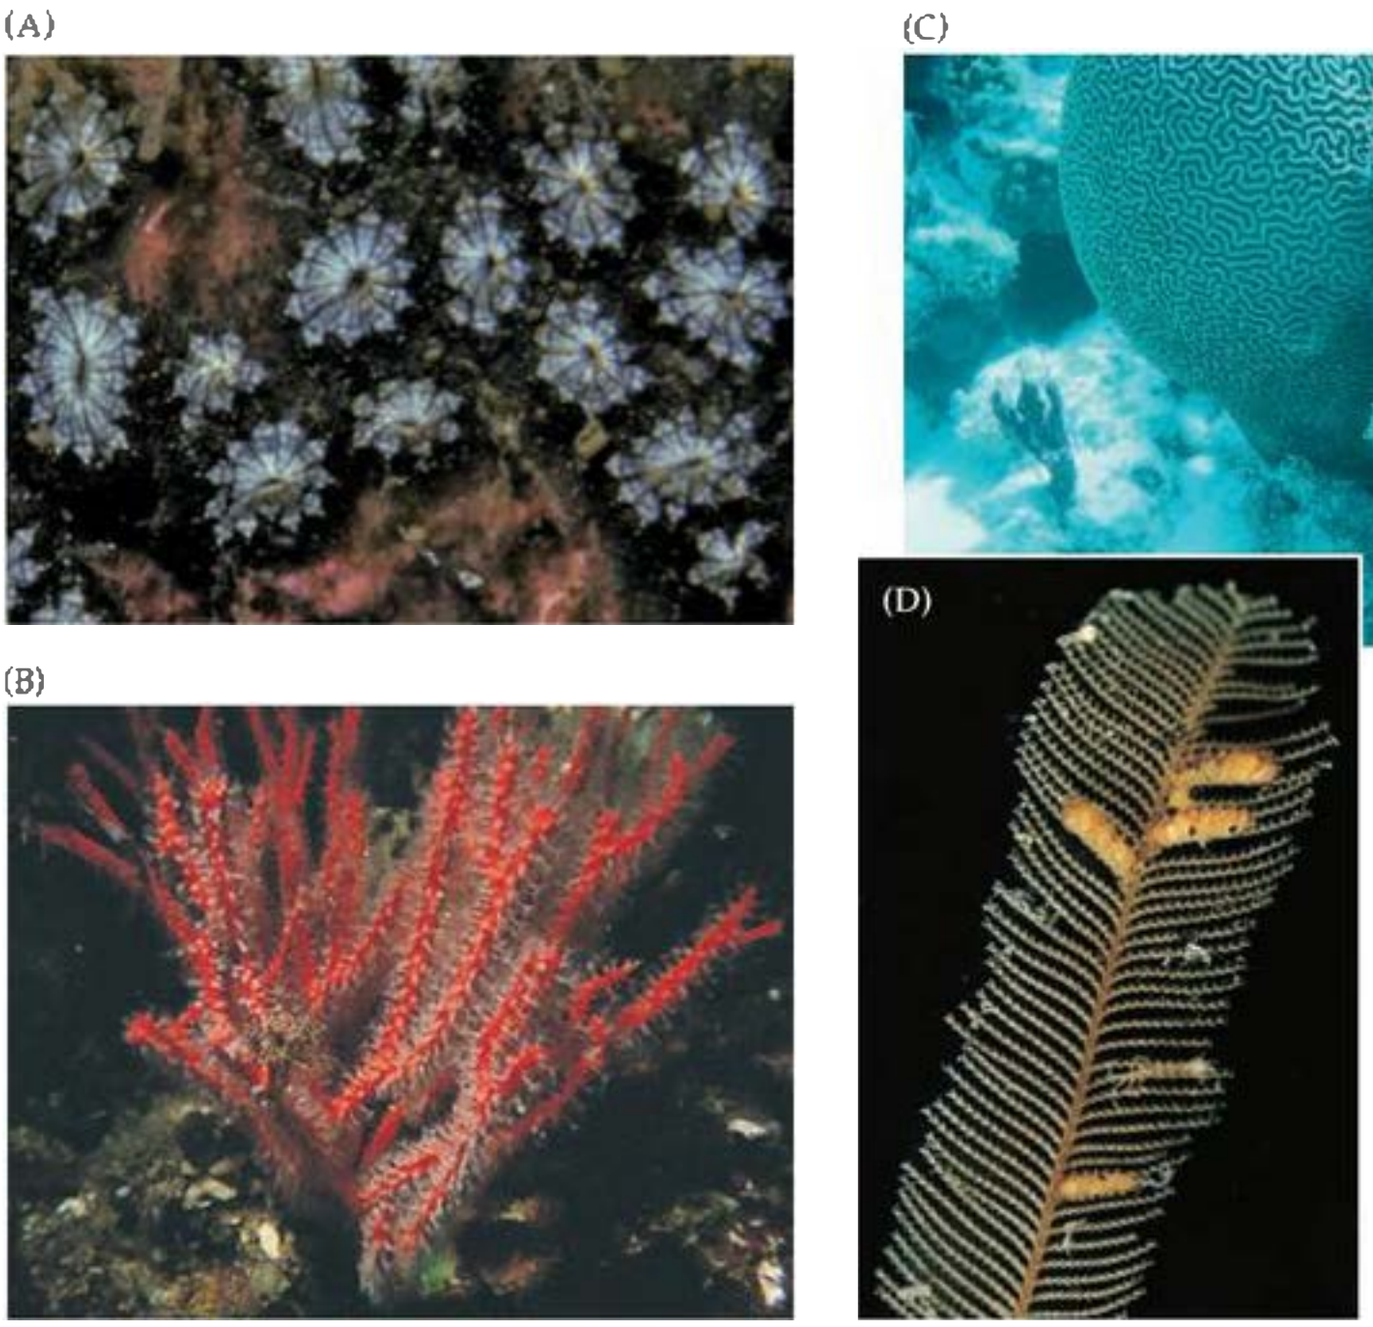

Figure 4.34 Representative inver- tebrate colon es. (A) *Botryllus*, a colonial ascidian. (B) *Lophogorgia*, a colonial gorgonian. (C) Three species of coral. (D) *Aglaophenia*, a colonial hydro d.

of resistant cysts or overwintering bodies, which are capable of surviving through periods of harsh environmental conditions. When favorable conditions return, these structures grow to new individuals.

A word about colonies A frequent result of asexual reproduction, particularly some forms of budding, is the formation of colonies. This phenomenon is espe cially common in certain taxa (e.g., cnidarians, ascid ians, bryozoans) (Figure 4.34). The term colony is not easy to define. It may initially bring to mind ant or bee colonies, or even groups of humans; but these examples are more appropriately viewed as social units rather than as colonies, at least in the context of our discus sions. For our purposes, we define colonies as associations in which the constituent individuals are not completely separated from each other, but are organically connected together, either by living extensions of their bodies, or by material that they have secreted. While occasional mixed colonies may exist (usually due to fusion of two separate colonies, as in some tunicates), most colonies are composed of genetically identical individuals. We describe the nature of numerous examples of colonial life in later chapters.

The formation of colonies not only may enhance the benefits of asexual reproduction in general, but also produces overall functional units that are much greater in size than mere individuals; thus this growth habit may be viewed as a partial solution to the surface-to-volume dilemma. Increased functional size through colonialism can result in a number of advantages for animals it can increase feeding efficiency, facilitate the handling of larger food items, reduce chances of predation, increase the competitive edge for food, space, and other resources, and allow groups of individuals within the colony to specialize for different funct ons.

Sexual Reproduction

Although reproduction is critical to a species' survival, it is the one major physiological activity that is not essential to an individual organism's survival. In fact, when animals are stressed, reproduction is usually the first activity that ceases. Sexual reproduction is especially energy costly, yet it is the characteristic mode of reproduction among multicellular organisms.[6]

Given the advantages of asexual reproduction, one might wonder why all animals do not employ it and abandon sexual activities entirely. The most frequently given explanation for the popularity of sexual reproduction (aside from anthropomorphic views, of course) focuses on the long-term benefits of genetic

[6] In thinking of animals, we typically view "sex" and "reproduc tion" as one in the same. However, at the cellular level these two processes are opposites: reproduction is the division of one cell to form two, whereas the sexual process incudes two cells fusing to form one

variation. Recombination allows for the maintenance of high genetic heterozygosity in individuals and high polymorphism in populations. Through regular meiosis and recombination, a level of genetic variation is maintained generation after generation, within and among populations; thus species are thought to be more "genetically prepared" for environmental changes, including both shifts in the physical environment and the changing milieu of competitors, predators, prey, and parasites.

Although this advantage must surely be real, does it satisfactorily explain the role of sex in short-term selection (i.e., generation by generation)? Presumably even in the short term an advantage lies in the maintenance of genetic variability. That is, genetic variability in both individuals and populations may increase their chances of adapting to environmental fluctuations, predators, parasites, and disease. In 1973, Leigh Van Valen proposed the idea that in order just to "keep up" with changing environments, populations must continually access new and different gene combinations through the process of natural selection—a notion called the "red queen hypothesis" after the Red Queen in Alice in Wonderland, who commanded her courtiers to run continuously just to stay in the same place.

Sexual reproduction involves the formation of haploid cells through meiosis and the subsequent fusion of pairs of those cells to produce a diploid zygote (Figure 4.35). The haploid cells are gametes—sperm and eggs—and their fusion is the process of fertilization, or syngamy. (Exceptions to these general terms and processes are common among protists as discussed in Chapter 3.) The production of gametes is accomplished by the gonads—ovaries in females and testes in males—or their functional equivalents. The gonads are frequently associated with reproductive systems that may include various arrangements of ducts and tubes, accessory organs such as yolk glands or shell glands,

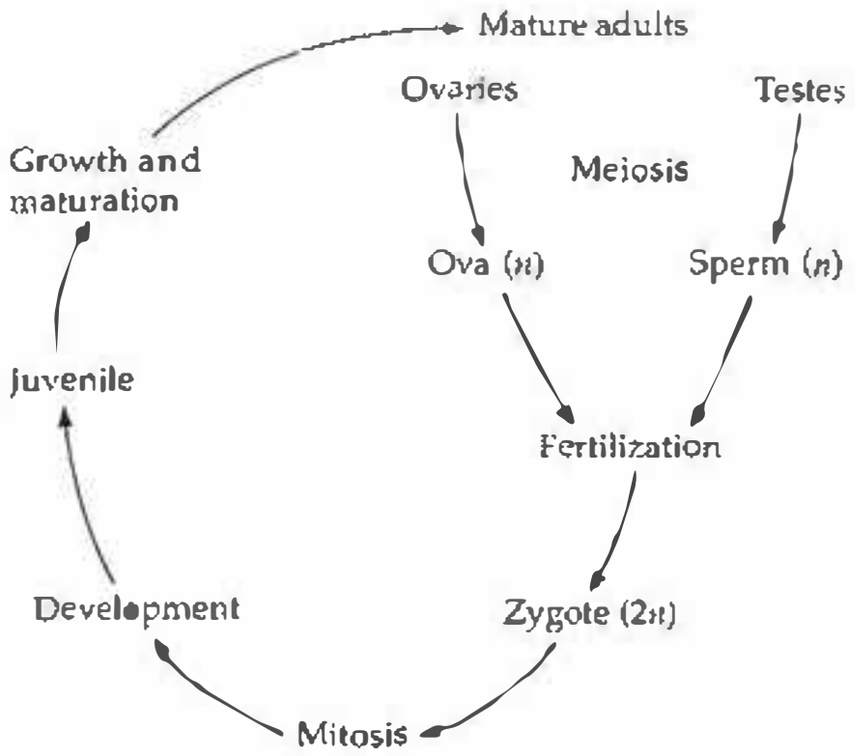

Figure 4.35 A generalized metazoan life cycle.

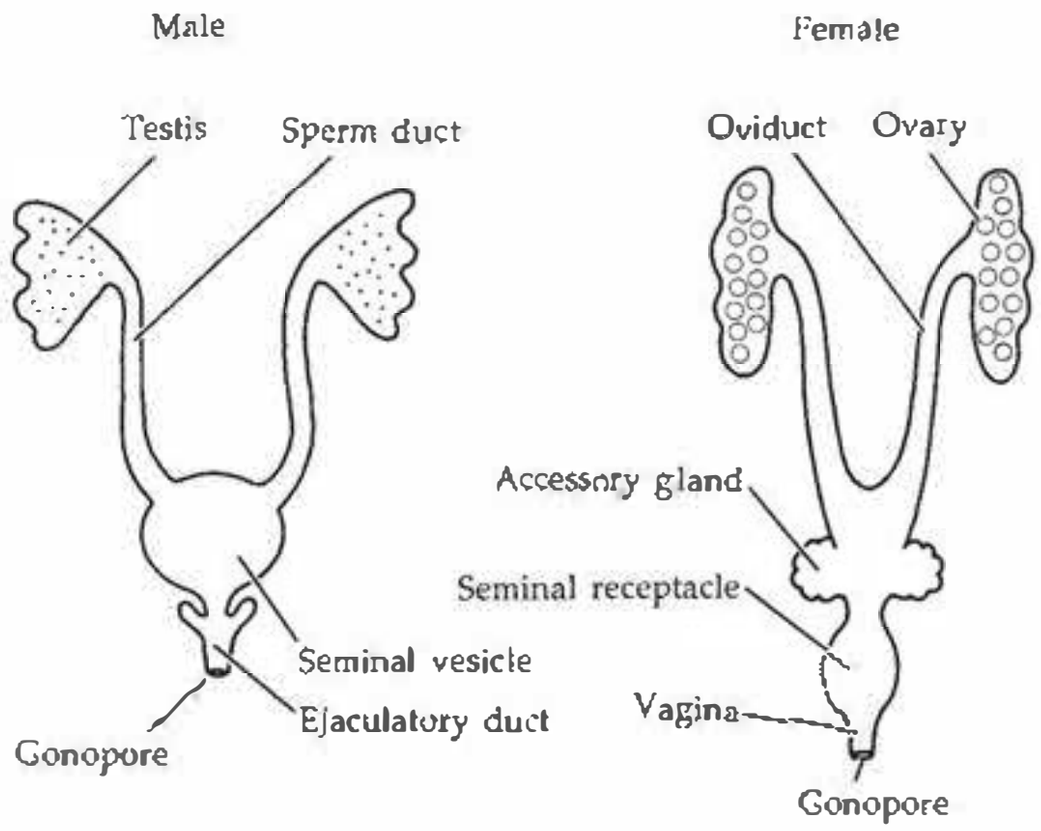

Figure 4.36 Schematic and generalized male and female reproductive systems. See text for explanation.

and structures for copulation. The different levels of complexity of these systems are related to the developmental strategies used by the organisms in question, as discussed in Chapter 5 and described in the coverage of each phylum. The variation in such matters is immense, but at this point we introduce some basic terminology of structure and function.

Many invertebrates simply release their gametes into the water in which they live (**broadcast spawning**), where external fertilization occurs. In such animals the gonads are usually simple, often transiently occurring structures associated with some means of getting the eggs and sperm out of the body. This release is accomplished through a discrete plumbing arrangement (coelomoducts, metanephridia, or gonoducts—sperm ducts and oviducts), or by temporary pores in or rupture of the body wall. In such animals, synchronous spawning is critical, and marine species rely largely on this synchrony and the water currents to achieve fertilization. Water temperature, light, phytoplankton abundance, lunar cycle, and the presence of conspecifics have all been implicated in synchronized spawning events of invertebrates.

On the other hand, invertebrates that pass sperm directly from the male to the female, where fertilization occurs internally, must have structural features to facilitate such activities. Figure 4.36 illustrates stylized male and female reproductive systems. A general scenario leading to internal fertilization in such systems is as follows. Sperm are produced in the testes and transported via the **sperm duct** to a precopulatory storage area called the **seminal vesicle**. Prior to mating, many invertebrates incorporate groups of sperm cells into sperm packets, or **spermatophores**. Spermatophores provide a protective casing for the sperm and facilitate

transfer with minimal sperm loss. In addition, many spermatophores are themselves motile, acting as inde pendent sperm carriers. Some sort of male copulatory or intromittent organ (e g., penis, cirrus, gonopod) is inserted through the female's gonopore and into the vagina. Sperm are passed through the male's ejaculato ry duct directly, or by way of a copulatory organ, into the female system, where they are received and often stored by a seminal receptacle.

In the female, eggs are produced in the ovaries and transported into the region of the oviducts. Sperm eventually travel into the female's reproductive tract, where they encounter the eggs; fertilization often takes place in the oviducts Among invertebrates, the sperm may move by flagellar or ameboid action, or by loco motor structures on the spermatophore packet; they may be aided by ciliary action of the lining of the fe- male reproductive tract. Various accessory glands may be present both in males (such as those that produce spermatophores or seminal fluids) and in females (such as those that produce yolk, egg capsules, or shells). This simple sequence is typical (although with many elaborations) of most nvertebrates that rely on internal fertilization.

Animals in which the sexes are separate, each individual being either male or female, are termed gonochoristic, or dioecious However, many invertebrates are hermaphroditic, or monoecious: each animal con tains both ovaries and testes and thus is capable of producing both eggs and sperm (though not necessarily at the same time).[7] Although self-fertilization may seem to be a natural advantage in this condition, such is not the case. In fact, with some exceptions, self fertilization in hermaphrodites is usually prevented. Fertilizing one's self would be the ultimate form of inbreeding and would presumably result in a dramatic decrease in potential genetic variation and heterozygosity. The rule for many hermaphroditic invertebrates is mutual cross fertilization, wherein two individuals function alternately or simultaneously as males and exchange sperm, and then use the mate's sperm to fertilize their own eggs. The real advantage of hermaphroditism now becomes clear: a single sexual encounter results in the impregnation of two individuals, rather than only one as in the gonochoristic condition.

A common phenomenon among hermaphroditic invertebrates is **protandric hermaphroditism**, or sim ply **protandry** (Greek *proto*, "first"; *andro*, "male"), where an individual is first a functional male, but later in life changes sex to become a functional female. The less common reverse situation, female first and then male, is called **protogynic hermaphroditism**, or simply protogyny (Greek *gynos*, "female"). At least some in- vertebrates alternate regularly between being function- al males and females, as explained by Jerome Tichenor (*Poems in Contempt of Progress*, 1974):

> *Consider the case of the oyster,*
> *Which passes its time in the moisture;*
> *Of sex alternate,*
> *It chases no mate,*
> *But lives in self-contained cloister*

In addition to the clever oysters immortalized by Professor Tichenor, some other taxa in which the hermaph- roditic condition is common include barnacles, arrow worms (Chaetognatha), flatworms, clitellate annelids, tunicates, many advanced gastropods, and cymothoid isopods (Crustacea).

The sexual conditions of colonial animals include myriad variations on the themes described above. Colonies may include only one sex, both sexes, or the individuals may be hermaphroditic.

Parthenogenesis

Parthenogenesis (Greek *partheno*, "virgin"; *genesis*, "birth") is a special reproductive strategy in which unfertilized eggs develop into viable adult individuals. Parthenogenetic species are known in many inver- tebrate (and vertebrate and plant) groups, including gastrotrichs, rotifers, tardigrades, nematodes, gastro pods, certain insects, and various crustaceans. The taxonomic distribution of parthenogenesis is spotty; it is rare to find a whole genus, let alone any higher taxon, that is wholly parthenogenetic. Some higher taxa that are largely parthenogenetic (e.g., aphids, cladocerans) are cyclically parthenogenetic, and they punctuate their life histories with sex.[8] There are also a number of protist higher taxa for which sex has yet to be described. Among the invertebrates, partheno- genesis usually occurs in small bodied species that are parasites, or are free-living but inhabit extreme or highly variable habitats such as temporary freshwater ponds. There is a general trend for parthenogenesis to become more prevalent as one moves toward higher lat tudes or into harsher environments. Overall, it ap- pears that parthenogenetic taxa arise from time to time and succeed in the short run due to certain immediate advantages, but in the long run they might be con- demned to extinction through competition with their sexual relatives.

---

[7] Hermaphoditus, the beautiful son of Hermes and Aphrodite, was united with a water nymph at the Carian fountain. Thus his body became both male and female.

[8] A number of fishes and amphibians are parthenogenetic, but none seems to have overcome the need for their egg to be penetrated by a sperm in order to nitiate development. The parthenogenetic females usually mate with a male of another species, providing sperm that trigger development (a behavior called pseudogamy). A few lizards apparently have no need for a sperm to trigger parthenogenetic development No partheno genetic wild birds or mammals have been documented.

In most species that have been studied, parthenogenetic periods alternate with periods of sexual reproduction. In temperate freshwater habitats, parthenogenesis often occurs during summer months, with the population switching to sexual reproduction as winter approaches. In some species, parthenogenesis takes place for many generations, or several years, eventually to be punctuated by a brief period of sexual reproduction. In some rotifers, parthenogenesis predominates until the population attains a certain critical size, at which time males appear and a period of sexual reproduction ensues. Cladocerans switch from parthenogenesis to sexual reproduction under a number of conditions, such as overcrowding, adverse temperature, food scarcity, or even when the nature of the food changes. Many parasitic species alternate between a free-living sexual stage and a parasitic parthenogenetic one; this arrangement is seen in some nematodes, thrips (Thysanoptera), gall wasps, aphids, and certain other hemipterans

One of the most interesting examples of parthenogenesis occurs in honeybees; in these animals the queen is fertilized by one or more males (drones) at only one period of her lifetime, in her "nuptial flight." The sperm are stored in her seminal receptacles. If sperm are released when the queen lays eggs, fertilization occurs and the eggs develop into females (queens or workers). If the eggs are not fertilized, they develop parthenogenetically into males (drones).

The question of the existence or prevalence of purely parthenogenetic species has been debated for decades. Many species once thought to be entirely parthenogenetic have proved, upon closer inspection, to alternate between parthenogenesis and brief periods of sexual reproduction. In some species purely parthenogenetic populations apparently exist only in some localities. In other species, parthenogenetic lineages have been traced to sexual ancestral populations occupying relictual habitats. Nevertheless, for some parthenogenetic animals, males have yet to be found in any population, and these may indeed be purely clonal species. One cannot help but wonder how long such species can exist in the face of natural selection without the benefits of any genetic exchange. One would predict that, as with any form of asexual reproduction, obligatory parthenogenesis would eventually lead to genetic stagnation and extinction. There may, however, be some as yet unexplained genetic mechanisms to avoid this, because some parthenogenetic animals (e g, some earthworms, insects, and lizards) are capable of inhabiting a wide range of habitats. Presumably they either have a significant level of genetic adaptability or possess "general purpose genotypes"

CHAPTER 5

Introduction to the Animal Kingdom

Development, Life Histories, and Origin

The process by which unicellular zygotes transform themselves into multicellular individuals and eventually into reproducing adults, is called ontogeny. At the core of metazoan ontogeny is embryogenesis—the growth and development of the embryo. The embryo is that stage of an organism between fertilization and birth. It is the principal phase of life history that mediates between genotype and phenotype.

As we saw in Chapter 4, the cells of animals are organized into functional units, generally as tissues and organs, with specific roles that support the whole animal. These different cell types are interdependent and their activities are coordinated in predictable patterns and relationships. The tissues and organs develop through a series of events early in an organism's embryogeny. The embryonic tissues, or germ layers, form the framework upon which metazoan body plans are constructed. Thus, the cells of animals (Metazoa) are specialized, interdependent, coordinated in function, and develop through a genetically-orchestrated tissue layering process during embryogeny—a combination of features that is absent among the protists.

The influence of yolk on early zygotic divisions, as well as on the differentiation of embryonic tissues, is one of the most well-established principles of zoology. So it is not surprising that a large body of detailed descriptive research on animal embryos has accumulated, leading to a strong focus on structure and physical processes in the field of developmental biology. Because particular developmental schemes characterize different animal lineages, developmental biology has compiled detailed descriptions of cell divisions, cell fates, embryonic germ layers, and larval or adult structures in the search for shared evolutionary patterns among animal phyla. Among the most detailed studies in biology are the meticulous accounts of early metazoan development by Wilhelm Roux, Hans Driesch, Edmund Beecher Wilson, Hans Spemann, and others. The apparent tendency for progressive stages of embryonic development to reveal the evolutionary history of animals is what inspired Ernst Haeckel, Karl von Baer, Walter Garstang, and others to formulate their versions of the recapitulation hypothesis, or "biogenetic law" (see the end of this chapter). And, despite some ongoing philosophical debate, from a morphological perspective ontogeny does appear to recapitulate many aspects of animal phylogeny.

However, the recent emergence of *molecular* developmental biology has changed some longstanding embryological principles in subtle and compelling ways. Haeckel's biogenetic law is no longer seen to govern the development of metazoan embryos in the ways embryologists once thought that it did. Taxon specific patterns, and deviations of those patterns in animal development, have revealed more complicated interactions than could ever have been anticipated from morphological descriptions alone. For these reasons, developmental biology can no longer consist primarily of descriptions of ova, early cell division, the formation of increasingly complex balls of cells and cell layers, although these classic patterns are still a major part of this field. A modern approach to the study of animal development includes molecular as well as morphological studies.

Evolutionary Developmental Biology—EvoDevo

Molecular genetics has had an explosive impact on the study of developmental biology and animal phylogenetics and evolution. "EvoDevo," the catchy abbreviation for the field of evolutionary developmental biology, is used for the burgeoning field of comparative developmental genetics the evolutionary study of the spatial and temporal expression of genes that control body architecture among metazoans. Much of EvoDevo focuses on the roles of transcription factors (TFs), which are the products of the genes involved in controlling early development. These genes and TFs define the primary embryonic body axes (e.g , the anterior–posterior and dorsal–ventral axes), the directionality of structures developing along these axes, and the appearance of particular structures or organizations such as body cavities, segments, or appendages. EvoDevo investigates the genetic underpinnings of nearly every process described within classical studies of developmental biology. The focus of developmental biology has thus shifted, from the ontogenetic study of animal structural organization, to the comparative ontogenetic study of gene functions and their roles in body organization.

As genomic methods become less expensive and more widely explored, the number of animal species whose full or partial genomic sequences are known is dramatically increasing. Each year, new "model organisms" in the genetic sense are identified, and as the number of species considered within these frameworks grows, opportunities for evolutionary comparison of the different patterns and mechanisms become increasingly possible. The use of developmental genomics has therefore become more than the mere determination of whether ontogeny recapitulates phylogeny, an idea that is now seen to be an oversimplification. Instead, the comparison of developmental similarities and differences, as well as how the differences are played out, has led to a much more subtle and discerning understanding of how animals are organized and how that organization unfolds within individual lifespans. Although the breadth of these changes is beyond the scope of this book, some general patterns are now apparent and we summarize these briefly below.

Developmental Tool Kits

If animals arose from among the Protista, a basic set of genetic factors are likely to have existed in that ancestry that supported multicellularity (which arose several times in the Eukaryota), facilitated its expression, and allowed these traits to be favored by selection. Likely genetic factors may have included a tendency for cells to aggregate rather than disperse after mitosis, the biochemical ability for cells to remain together as a group, and the movement or differentiation of cells bearing one set of specializations in response to proximity with cells bearing another set of specializations.

The possibility that such traits existed implies they were mediated in some way by the transcription products of genes borne by the protistan ancestors of animals. Sets of functional genes that control ontogenetic processes have been called developmental tool kits, and with respect to the evolution of multicellularity, they are likely to have been associated with three processes: (1) the adhesion of cells to one another, (2) the transduction of biochemical signals within and between cell types (i.e., cell signaling pathways), and (3) differentiation of cells from primordial to specialized states

The transition to multicellularity from a unicellular state was a fundamental event in metazoan evolution. However, until recently, there were few avenues available for investigating this transition. The possibility that developmental tool kits underlying multicellularity existed at the origin of the Metazoa suggests that recognizable homologous gene sequences in different species, or orthologs, and their transcription factors might be found in predictable ways within the ancestors of metazoans, as well as throughout the metazoans themselves.

The structural organization of choanoflagellates (see Chapter 3), as well as their similarity to metazoans such as sponges, have made these creatures compelling candidates as metazoan ancestors, and molecular phylogenetic methods have allowed this hypothesis to be directly tested. Many analyses of nuclear and mitochondrial genes from diverse metazoan lineages strongly support the idea of animals and choanoflagellates having a common ancestor, and as predicted, a majority of choanoflagellate expressed genes have homologous sequences (orthologs) in animal genotypes. Noteworthy too are observations that choanoflagellates

express a surprising diversity of adhesion and cell signaling homologues Thus, by identifying genes shared among animals and their apparent most recent common ancestor, tests of specific developmental hypotheses regarding genome evolution in early animals have become increasingly possible. However, things aren't always as easy as they seem.

The Relationship Between Genotype and Phenotype

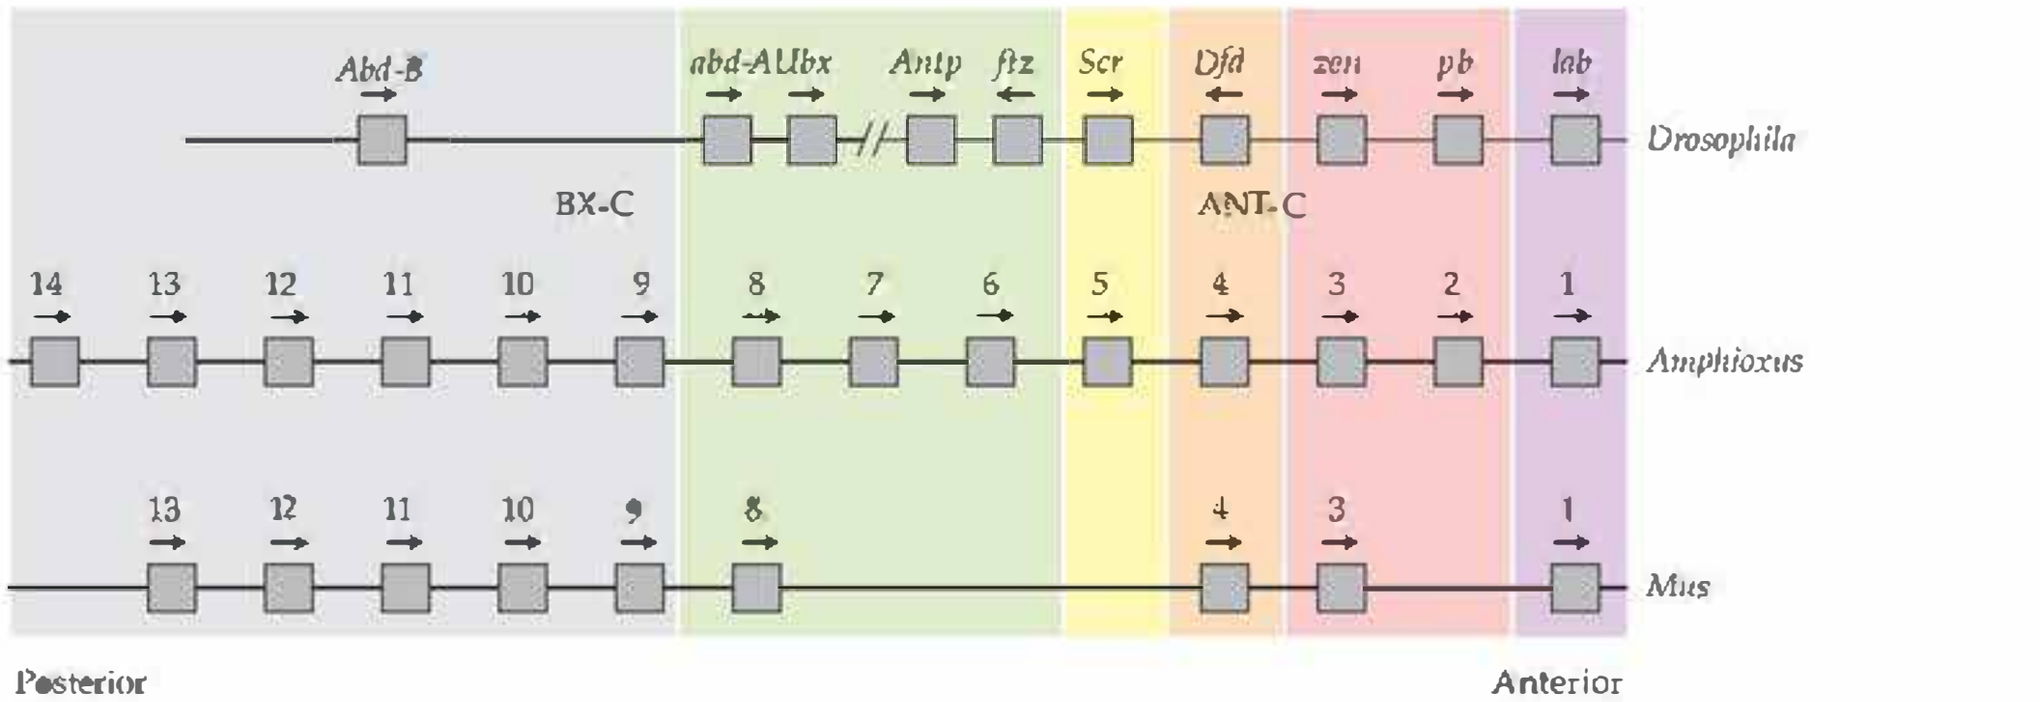
A search for genetically conserved tool kits underlying particular events or morphological landmarks in animal development seems exciting indeed. Unfortunately, evidence now suggests that a direct correspondence between genotype and phenotype in metazoan development is rare things are usually more complicated. Early studies were lured in this direction by the striking degree to which **Hox clusters** (groups of homeotic genes that control the body plan and limb organization of developing embryos along their anterior–posterior axis) seemed to exhibit organizational and functional consistency throughout the Metazoa. The discovery in the late 1970s that animals as diverse as vertebrates and arthropods had structurally and functionally related Hox genes led to the assumption that all animals would contain similar gene clusters. And some gene sequences, including Hox clusters and other similar genes, confirmed this assumption. The developmental gene *Brachyury* (*bra*) is a good example. The transcription products of *bra* define the midline of bilaterians, and the gene also is expressed in the notochord of species belonging to the phylum Chordata. Its expression pattern confirms the homologies suggested by morphology, in that its expression in the notochord of chordates provides an example of a homologous gene with a homologous function in a homologous morphological character the notochord (which is a synapomorphy of the phylum).

The use of gene sequences and gene products for phylogenetic analysis has proven to be more complicated than expected. For example, Hox genes that are apparently homologous in their sequences may not be identical or even necessarily similar in their expression in different taxa, even among closely related taxa. Gene sequence homology, it seems, does not guarantee that the specific functions of the genes will be similar And, Hox genes have been found to be linearly arranged only in certain taxa, despite their near representation in most review papers and textbooks (Figure 5 1).

Despite their presumed role as an evolutionary "magic bullet," developmental genes now seem every bit as likely as morphological characters are to exhibit homoplasy (e.g , convergent evolution). While developmental genetic programs may at first appear to contain phylogenetic information, observed patterns are likely to represent patterns shaped by the needs of the developmental program in different lineages. Because such difficulties are widespread, using particular genes to establish homology in different metazoan lineages can be challenging.

The Evolution of Novel Gene Function

New functional roles appear to routinely evolve in developmental genetic systems. Developmental genes, despite being under strong stabilizing selection to perform precise functions, can evolve in unexpected ways. This tendency is called **developmental system drift** or DSD. The existence of DSD can be useful for tracking the evolution of particular structures (e.g , visual elements) but can cause confusion because DSD itself often leads to morphological divergences.



DSD appears to occur in two ways. First, a gene that performs a function in one taxon may be co-opted for another use in a different taxon. The process often begins with gene **duplication**, when replication errors create multiple copies of functional genes. Redundancy in regulatory function allows continuation of normal metabolism, but also allows duplicated gene products to be used elsewhere. For example, the gene *Pax6* is expressed in a range of both eyed and eyeless bilaterians suggesting that this patterning gene has been co-opted for multiple functions in the regulation of eye development.

A second DSD mechanism occurs when differences in gene expression arise due to genetic interactions, or epistasis, occurring within different genetic backgrounds. Identical sequences can produce different phenotypic effects in different species, or even among members of the same species. Although the magnitude of these effects can become increasingly pronounced as species divergence increases, the complexities of epistatic interactions are seldom predictable.

Gene Regulatory Networks

A major contribution of genomic analyses to developmental biology is the conclusion that individual genes do not control cellular or development function. That is, there is no one gene "for" a particular phenotype or structure. Instead, groups of genes, usually called **gene regulatory networks**, are responsible for producing functional traits. Four major groups of these regulatory clusters exist: (1) cell differentiation networks, which appear to allow groups of cells to differentiate in particular ways; (2) subcircuits, developmental gene networks that are repeatedly used in general cell function; (3) switches, regulatory gene networks that turn cell functions off or on to regulate the timing of particular developmental events; and (4) kernels, complex and tightly conserved gene networks designed to specify the fields of cells from which particular body parts will eventually arise.

Because kernels appear to be the type of network most important for organizing lineage-specific

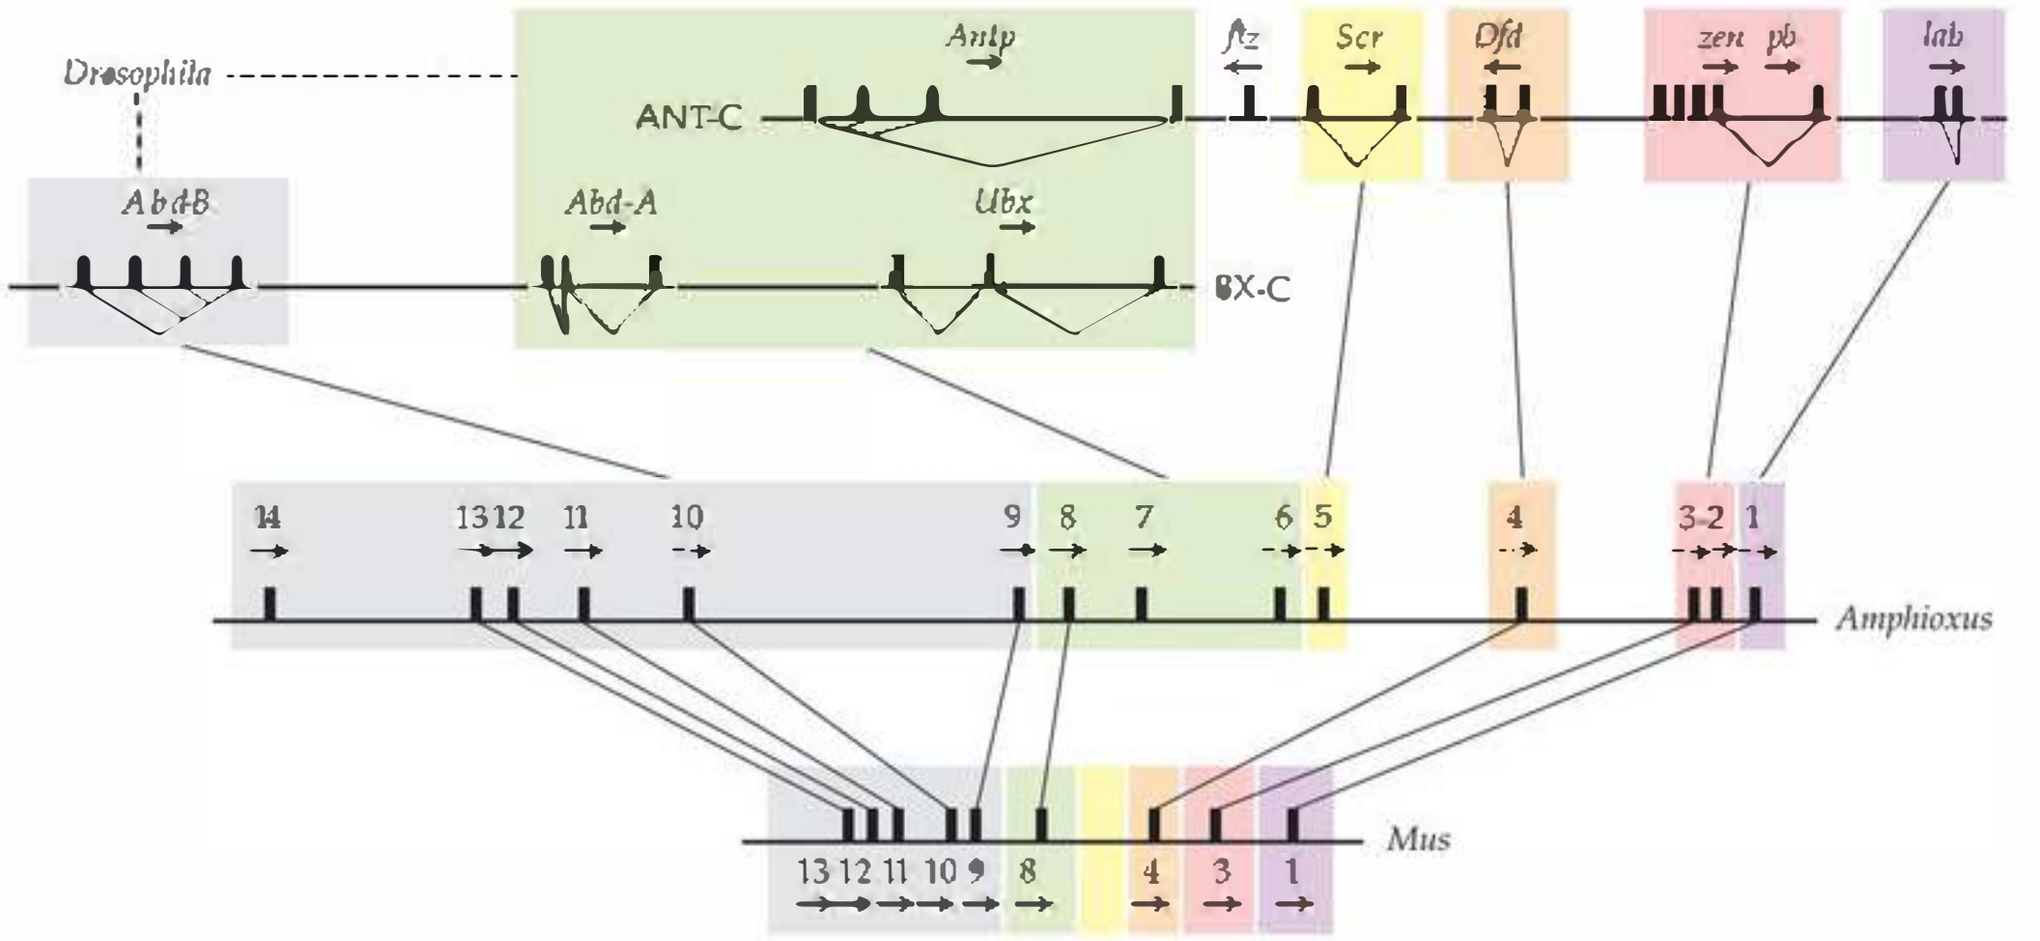


Figure 5.1 Representations of Hox genes in textbooks are often oversimplified and thus can lead to erroneous views of metazoan phylogenetic relationships. In this figure, the horizontal lines represent chromosomes. The colored boxes represent Hox gene "clusters," those genes that are related in their sequences and thus appear to be derived from a common ancestral Hox gene, in an insect (*Drosophila*), a cephalochordate (*Amphioxus*), and a vertebrate (mouse, *Mus*). The arrows represent gene orientation, that is, the direction in which transcription of the DNA coding strand proceeds. (A) Hox "clusters" 1 through 14 as they are often represented in textbooks and some scientific articles. In such oversimplified representations, Hox genes, including BX-C (the bithorax complex of *Drosophila* that controls development of abdominal and posterior thoracic segments) and ANT-C (the antennipedia complex of *Drosophila* that controls the formation of legs) are incorrectly shown as being located in close proximity, with clusters that are similar in nucleotide sequence length, and with gene clusters that are arranged in a linear order on chromosomes. (B) A more accurate representation of Hox clusters as they actually exist within *Drosophila*, *Amphioxus* and *Mus*, shown to scale with regard to the actual size of the genes (the number of nucleotides involved including non-coding sequences), the relative distances between the genes (the degree to which genes form "clusters"), and clearer spatial and gene orientation arrangements of Hox elements with respect to one another on the chromosome. Note that in *Drosophila*, the BX-C and ANT-C complexes are "split" (spatially separated as indicated by the dashed line) on chromosome III, compared with less spatially dispersed arrangements characteristic of chordates (*Amphioxus* and *Mus*). Note also that while *Drosophila* gene orientations are variable (indicated by arrows), they are consistently unidirectional in *Amphioxus* and *Mus*. While Hox clusters in chordates (*Amphioxus* and *Mus*) tend to be more spatially condensed than in other metazoans, they are especially "organized" in this way in vertebrates (e.g., *Mus*). Accurate physical representations of Hox genes are needed to inform the discussion on the structural and functional evolution of Hox clusters.

development (e.g., there are likely to be bilaterian, protostome, spiralian, and ecdysozoan kernels) these are considered most likely useful for phylogenetic analyses of the kind originally conceived of for Hox clusters. Nevertheless, it is still possible for gene regulatory networks to undergo substantial evolution within lineages. Thus, as with all such analyses, care must be used in choosing which networks to include.

Eggs and Embryos

The physical (and physiological) attributes that distinguish the Metazoa are the result of their embryonic development. Stated differently, adult phenotypes result from specific sequences of developmental stages. Therefore, both animal unity and diversity are as evident in patterns of development as they are in the body architecture of adults. The patterns of development discussed below reflect this unity and diversity, and serve as a basis for understanding the sections on embryology in later chapters.

Eggs

Biological processes in general are cyclical. Successive generations illustrate this generality, as the term "life cycle" implies, and where the description of a process begins is only a matter of convenience. Here, we begin with the egg, or **ovum**, a single remarkable cell capable of developing into a new individual. Once fertilized, all of the different cell types of an adult animal are derived during embryogenesis from this single totipotent entity. A fertilized ovum contains not only the genetic information necessary to direct development but also some quantity of nutrient material called **yolk**, which sustains the early stages of life.

Eggs are polarized along an animal–vegetal axis. This polarity may be apparent in the egg itself, or it may be recognizable as development proceeds. The vegetal pole is associated with the formation of nutritive organs (e.g., the digestive system), whereas the animal pole produces other regions of the embryo. Animal ova are categorized primarily by the amount and location of yolk within the cell (Figure 5.2), two factors that greatly influence certain aspects of development. Isolecithal eggs contain a relatively small amount of yolk that is more or less evenly distributed throughout the cell. Ova in which the yolk is concentrated at one end (toward the vegetal pole) are termed telolecithal eggs; those in which the yolk is concentrated in the center are called centrolecithal eggs.

The actual amount of yolk in telolecithal and centrolecithal eggs is highly variable. Yolk production (vitellogenesis) is typically the longest phase of egg production, although its duration varies by orders of magnitude among species. Rates of yolk production depend on the specific vitellogenic mechanism used. In general, opportunistic (so-called *r*-selected) species have evolved vitellogenic pathways for the rapid conversion of food into egg production, while more specialist (so-called *K*-selected) species utilize slower pathways.

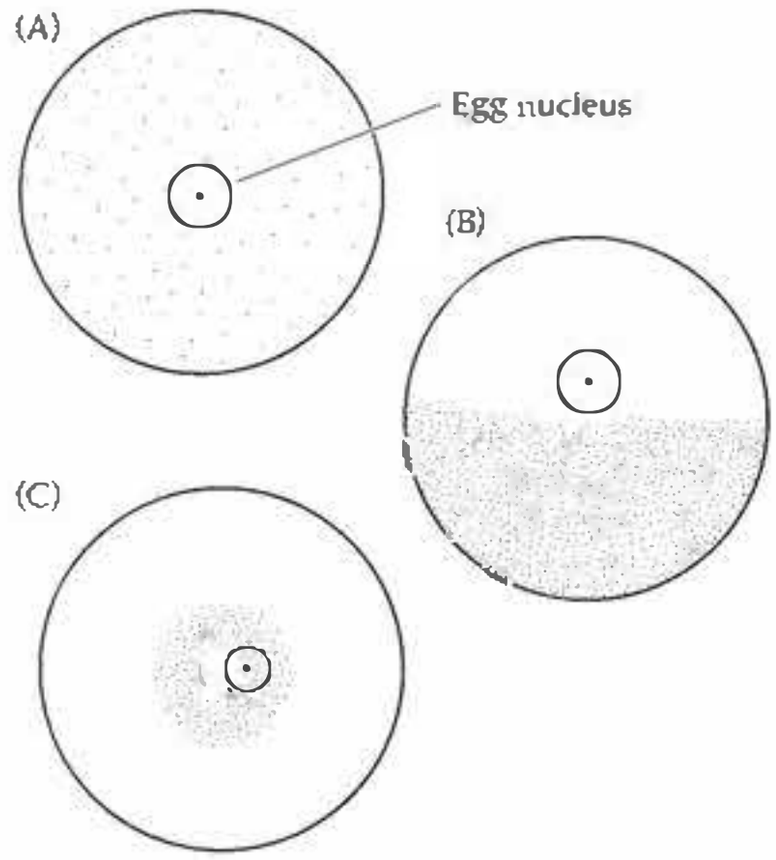

Figure 5.2 Types of ova. Stippling denotes the distribution and relative concentration of yolk within the cytoplasm. (A) An isolecithal ovum has a small amount of yolk distributed evenly. (B) The yolk in a telolecithal ovum is concentrated toward the vegetal pole. The amount of yolk in such eggs varies greatly. (C) A centrolecithal ovum has yolk concentrated at the center of the cell.

Cleavage

The penetration of an ovum by a sperm cell and the subsequent fusion of the male and female nuclei initiate the transformation of an ovum into a zygote or fertilized egg. The initial cell divisions of a zygote are called cleavage, and the resulting cells are called blastomeres. Certain aspects of the pattern of early cleavage are determined by the amount and placement of yolk, whereas other features are inherent in the genetic programming of the particular organism. Isolecithal and weakly to moderately telolecithal ova generally undergo **holoblastic** cleavage. That is, the cleavage planes pass completely through the cell, producing blastomeres that are separated from one another by thin cell membranes (Figure 5.3A). Whenever very large amounts of yolk are present (as in strongly telolecithal eggs), the cleavage planes do not pass readily through the dense yolk, so the blastomeres are not fully separated from one another by cell membranes. This pattern of early cell division is called **meroblastic** cleavage (Figure 5.3B). The pattern of cleavage in centrolecithal eggs is dependent on the amount of yolk and varies from holoblastic to various modifications of meroblastic.

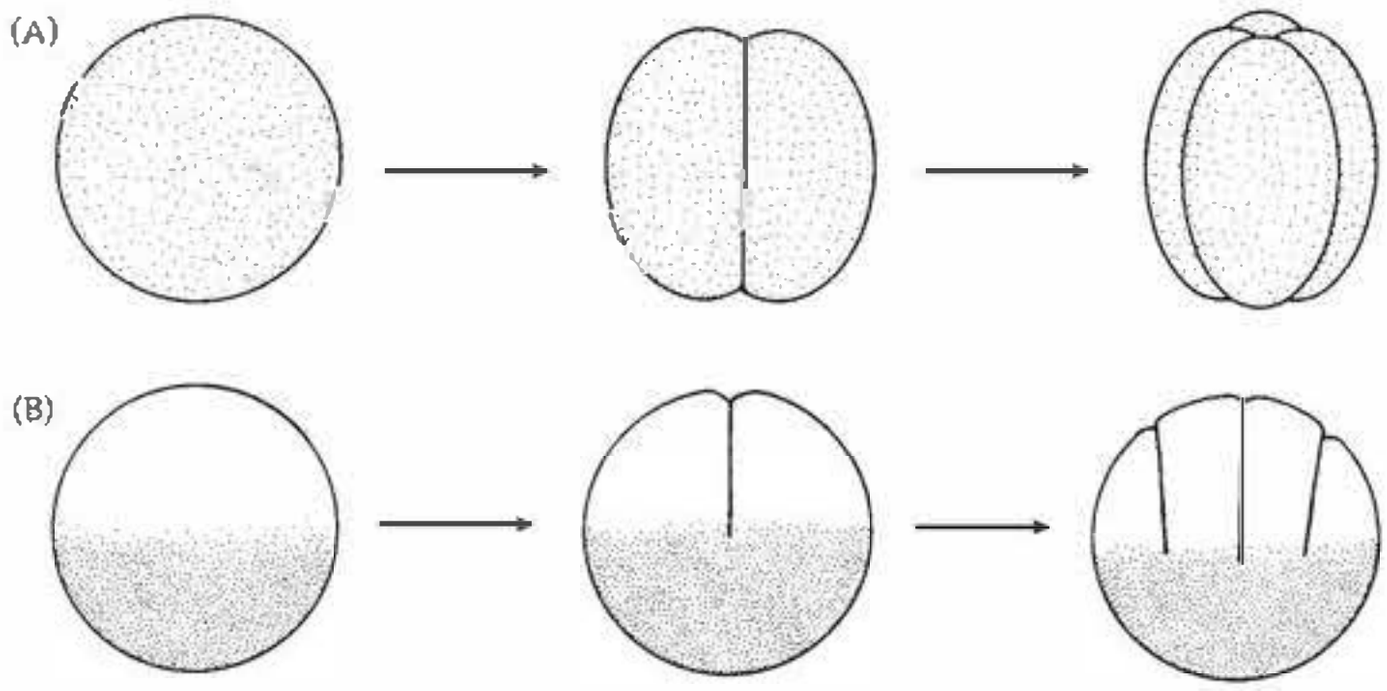

Figure 5.3 Types of early cleavage in developing zygotes. (A) Holoblastic cleavage. The cleavage planes pass completely through the cytoplasm. (B) Meroblastic cleavage. The cleavage planes do not pass completely through the yolky cytoplasm. The stippling represents yolk distribution in the egg and early zygote.

Orientation of Cleavage Planes

A number of terms describe the relationship of cleavage planes to the animal–vegetal axis of the egg and the relationships of the resulting blastomeres, one to another (Figure 5.4). Cell divisions during cleavage may be **equal** or **unequal**, indicating the comparative sizes of groups of blastomeres. The term **subequal** is used when blastomeres are only slightly different in size. When cleavage is distinctly unequal, the larger cells lying at the vegetal pole are called **macromeres.** The smaller cells located at the animal pole are called **micromeres.**

Cleavage planes that pass through or parallel to the animal–vegetal axis produce **longitudinal** (= meridional) divisions; those that pass at right angles to the axis produce **transverse** divisions. Transverse divisions may be equatorial, when the embryo is separated equally into animal and vegetal halves, or simply latitudinal, when the division plane does not pass through the equator of the embryo.

Radial and Spiral Cleavage

Most invertebrates display one of two cleavage patterns defined on the basis of the orientation of the blastomeres about the animal–vegetal axis. These patterns are called radial cleavage and spiral cleavage and are illustrated in Figure 5.5. Radial cleavage involves strictly longitudinal and transverse divisions. Thus, the blastomeres are arranged in rows either parallel or perpendicular to the animal–vegetal axis. The placement of the blastomeres shows a radially symmetrical pattern in polar view. The chapter opening photo shows the 16-cell stage embryo of a radially-cleaving echinoderm (*Lytechinus pictus*), with four large macromeres behind four smaller micromeres (and eight "mesomeres" behind the macromeres).

Spiral cleavage is quite another matter. Although not inherently complex, it can be difficult to describe. The first two divisions are longitudinal, generally equal or subequal. Subsequent divisions, however, displace the blastomeres laterally so that they lie within the furrows between previously divided cells. This condition is a result of the formation of the mitotic spindles at oblique angles rather than parallel to the axis of the embryo; hence the cleavage planes are neither perfectly longitudinal nor perfectly transverse. The division from four to eight cells involves a displacement of the cells near the animal pole in a clockwise (**dextrotropic**) direction (viewed from the animal pole). The next division, from eight to sixteen cells, occurs with a displacement in a counterclockwise (**levotropic**) direction; the

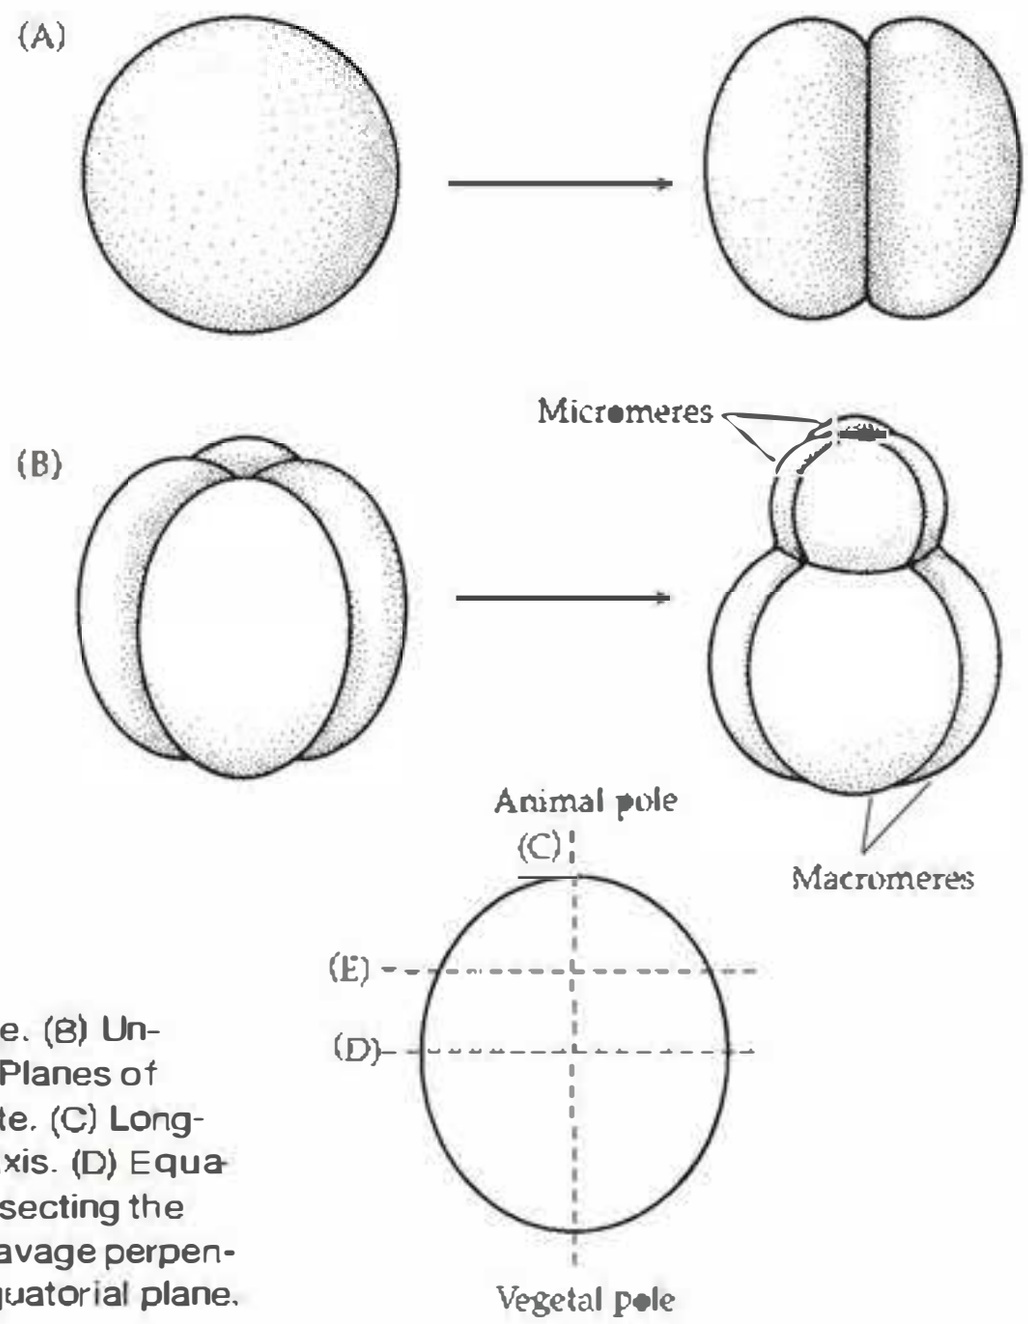

Figure 5.4 Planes of holoblastic cleavage. (A) Equal cleavage. (B) Unequal cleavage produces micromeres and macromeres. (C–E) Planes of cleavage relative to the animal–vegetal axis of the egg or zygote. (C) Longitudinal (= meridional) cleavage parallel to the animal–vegetal axis. (D) Equatorial cleavage perpendicular to the animal–vegetal axis and bisecting the zygote into equal animal and vegetal halves. (E) Latitudinal cleavage perpendicular to the animal–vegetal axis but not passing along the equatorial plane.

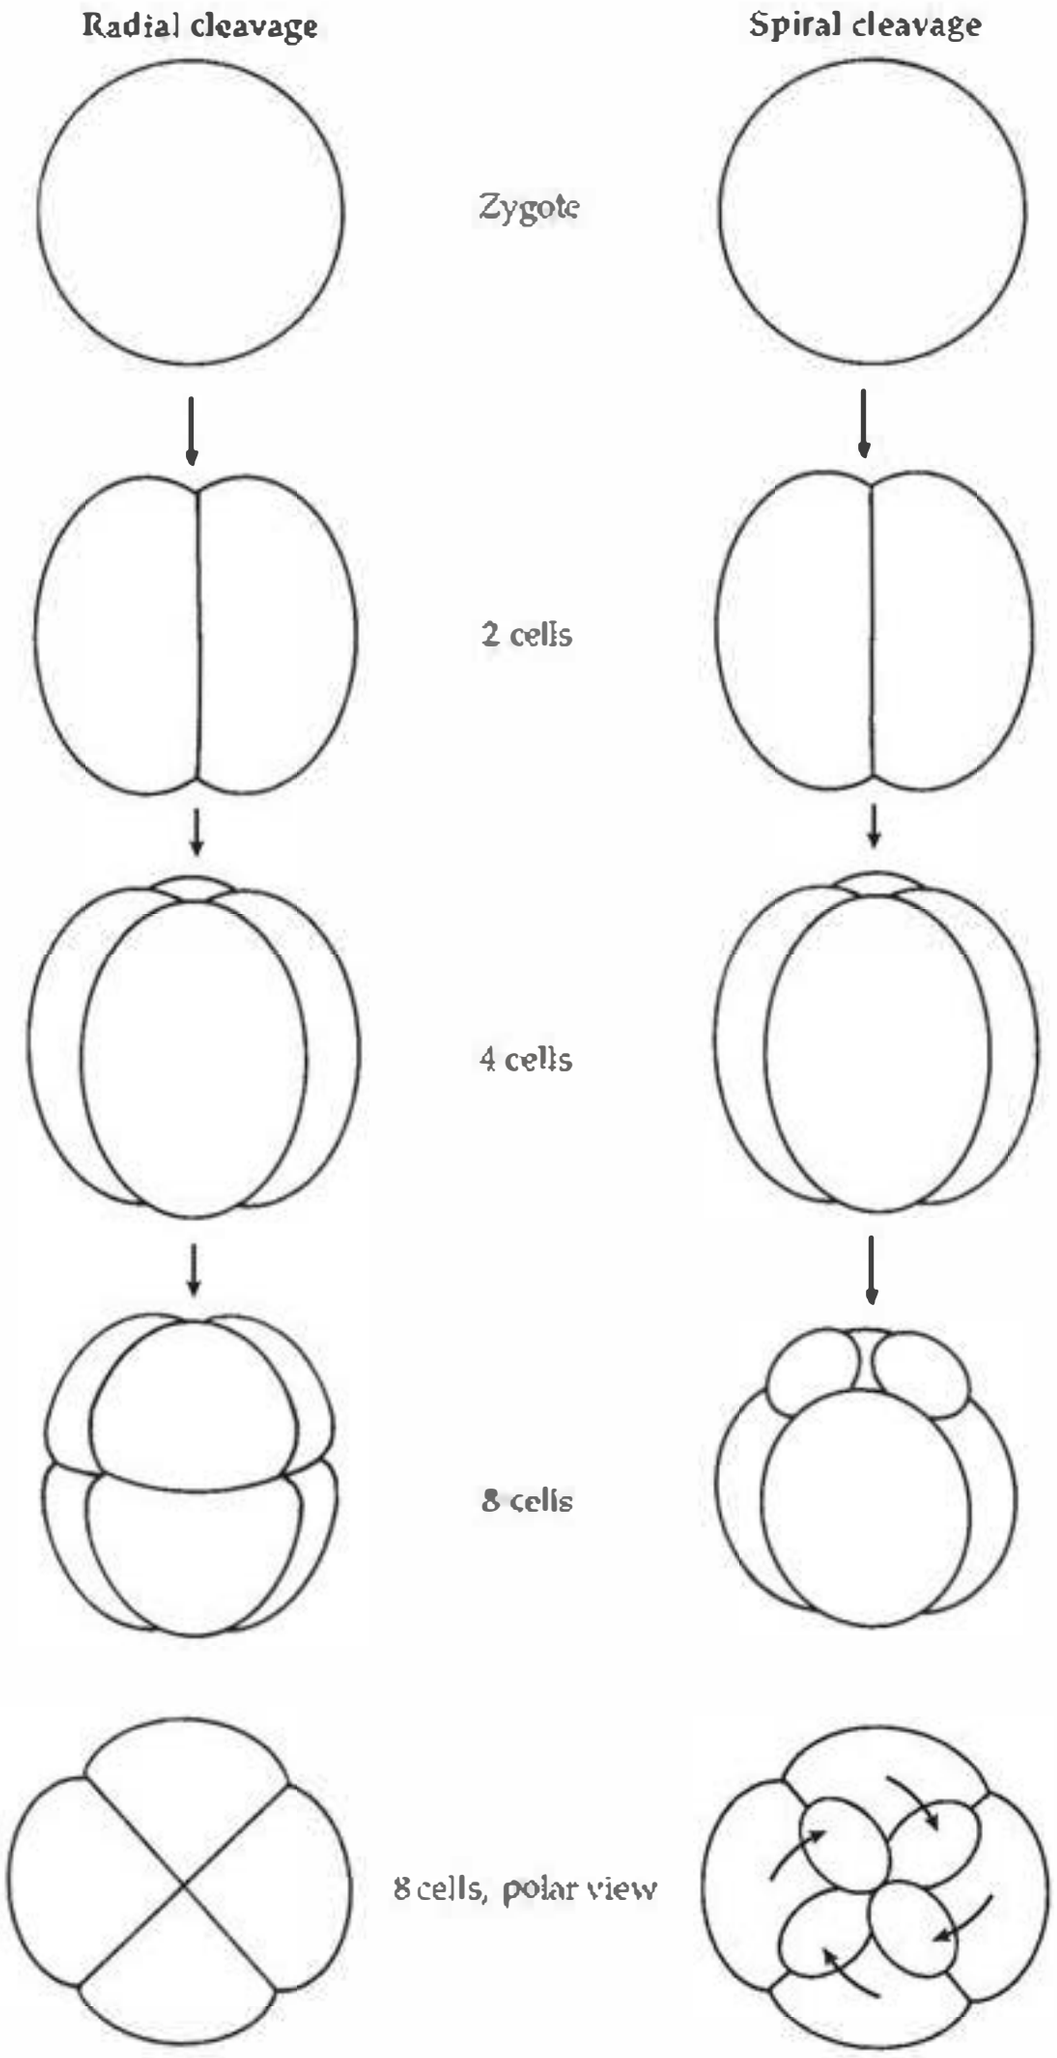

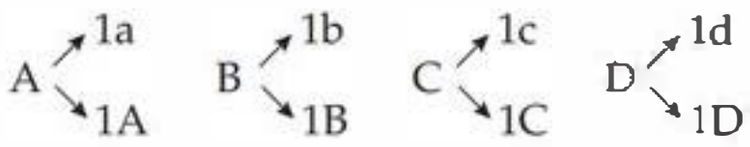

Figure 5.5 Comparison of radial versus spiral cleavage through the 8-cell stage. During radial cleavage, the cleavage planes all pass either perpendicular or parallel to the animal–vegetal axis of the embryo. Spiral cleavage involves a tilting of the mitotic spindles, commencing with the division from 4 to 8 cells. The resulting cleavage planes are neither perpendicular nor parallel to the axis. The polar views of the resulting 8-cell stages illustrate the differences in blastomere orientation.

next is clockwise, and so on—alternating back and forth until approximately the 64-cell stage. We hasten to add that divisions are frequently not synchronous; not all of the cells divide at the same rate. Thus, a particular embryo may not proceed from four cells to eight, to sixteen, and so on, as neatly as in our generalized description.

During his extensive studies on the polychaete worm *Neanthes succinea*, conducted at the Marine Biological Laboratory at Woods Hole, E. B. Wilson (1892) devised an elegant coding system for spiral cleavage, one that allows us to follow the developmental lineage of every embryonic cell. Wilson's system is usually applied to spiral cleavage in order to trace cell fates and compare development among species. Our account of spiral cleavage is a general one, but it provides a point of reference for later consideration of the patterns in different groups of animals.

At the 4-cell stage, following the initial longitudinal divisions, the cells are given the codes of A, B, C, and D, and are labeled clockwise in that order when viewed from the animal pole (Figure 5.6A). These four cells are referred to as a **quartet** of macromeres, and they may be collectively coded as simply Q. The next division is more or less unequal, with the four cells nearest the animal pole being displaced in a dextrotropic fashion, as explained above. These four smaller cells are called the first quartet of micromeres (collectively the 1q cells) and are given the individual codes of 1a, 1b, 1c, and 1d. The numeral "1" indicates that they are members of the first micromere quartet to be produced; the letters correspond to their respective macromere origins. The capital letters designating the macromeres are now preceded with the numeral "1" to indicate that they have divided once and produced a first micromere set (Figure 5.6B). We may view this 8-celled embryo as four pairs of daughter cells that have been produced by the divisions of the four original macromeres as follows:

Note that although the macromeres and micromeres are sometimes similar in size, these terms are nonetheless always used in describing spiral cleavage. Much of the size discrepancy depends upon the amount of yolk present at the vegetal pole in the original egg; this yolk tends to be retained primarily in the larger macromeres.

The division from 8 to 16 cells occurs levotropically and involves cleavage of each macromere and micromere. Notice that the only code numbers that are changed through subsequent divisions are the prefix numbers of the macromeres. These are changed to indicate the number of times these individual macromeres have divided, and to correspond to the number of micromere quartets thus produced. So, at the 8-cell stage, we can designate the existing blastomeres as the 1Q (= 1A, 1B, 1C, 1D) and the 1q (= 1a, 1b, 1c, 1d). The macromeres (1Q) divide to produce a second quartet of micromeres (2q = 2a, 2b, 2c, 2d), and the prefix numeral of the daughter macromeres is changed to "2." The first micromere quartet also divides and now comprises eight cells, each of which is identifiable not only by the letter corresponding to its

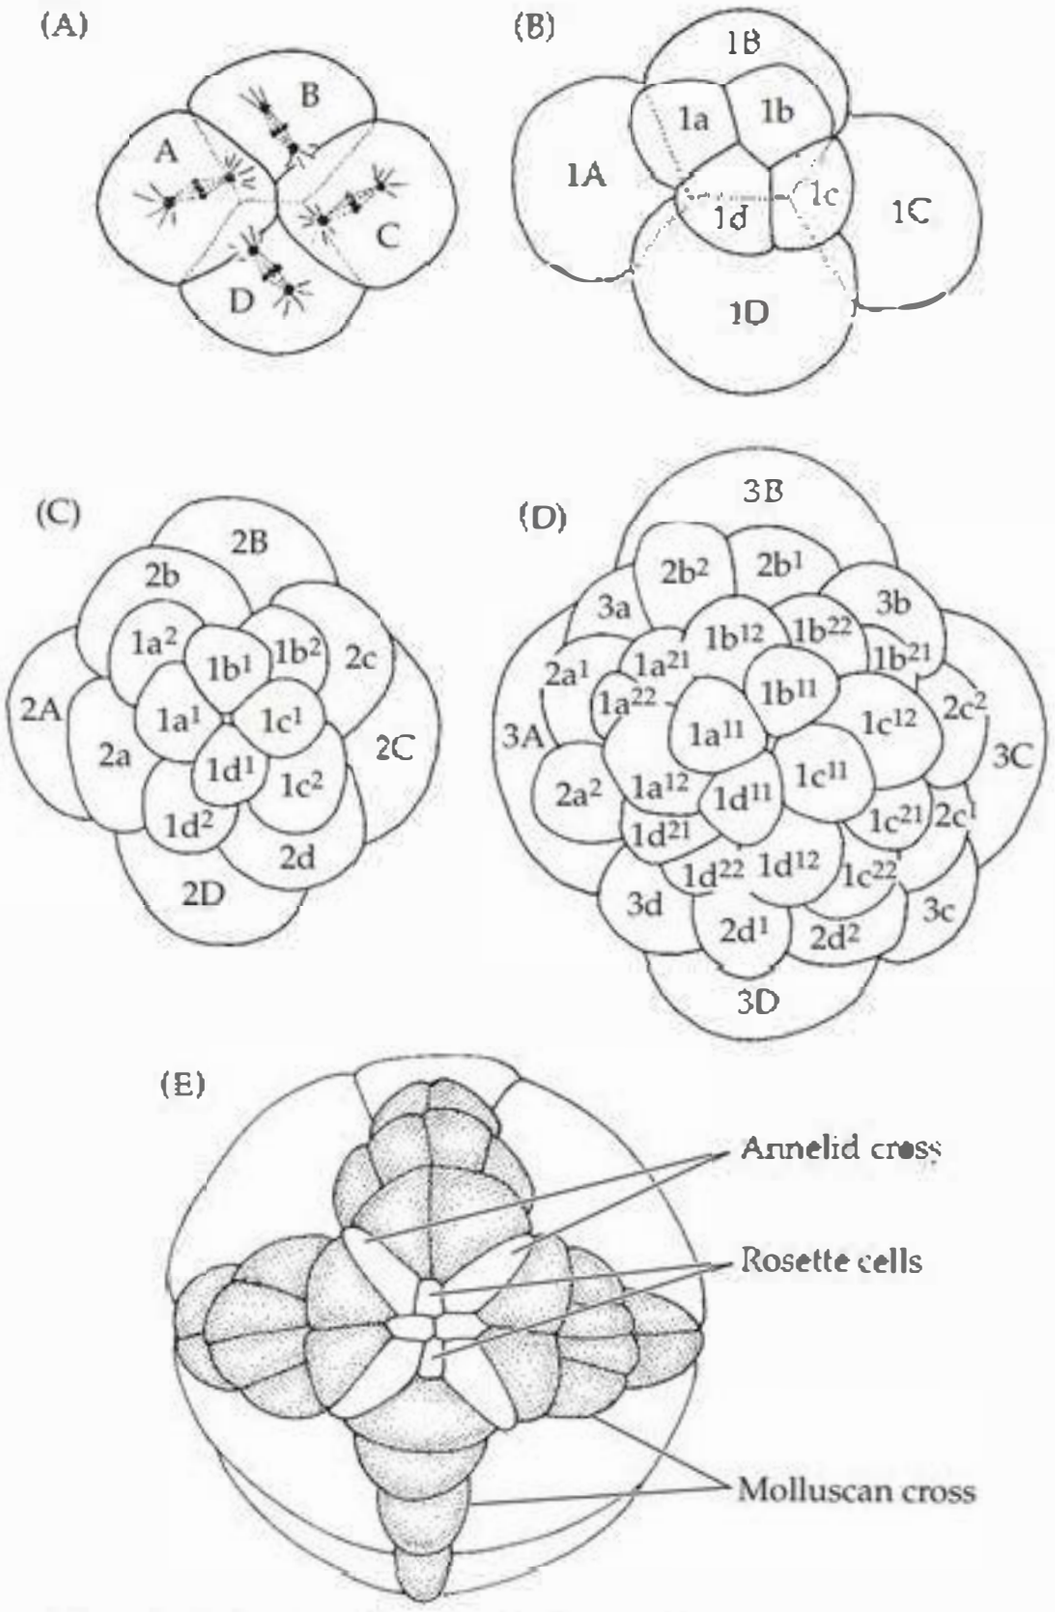

Figure 5.6 Spiral cleavage. (A–D) Spiral cleavage through 32 cells (assumed synchronous) labeled with E. B. Wilson's coding system (all diagrams are surface views from the animal pole). (E) Schematic diagram of a composite embryo at approximately 64 cells showing the positions of the rosette, annelid cross, and molluscan cross.

parent macromere but now by the addition of superscript numerals. For example, the 1a micromere (of the 8-cell embryo) divides to produce two daughter cells coded the 1a1 and the 1a2 cells. The cell that is physically nearer the animal pole of the embryo receives the superscript "1," the other cell the superscript "2." Thus, the 16-cell stage (Figure 5.6C) includes the following cells:

$$\text{Derivatives of the 1q} \begin{cases} 1a^1 & 1b^1 & 1c^1 & 1d^1 \\ 1a^2 & 1b^2 & 1c^2 & 1d^2 \end{cases}$$

$$\text{Derivatives of the 1Q} \begin{cases} 2q = 2a & 2b & 2c & 2d \\ 2Q = 2A & 2B & 2C & 2D \end{cases}$$

The next division (from 16 to 32 cells) again involves dextrotropic displacement. The third micromere quartet (3q) is formed, the daughter macromeres are now given the prefix "3" (3Q), and all of the 12 existing micromeres divide. Superscripts are added to the derivatives of the first and second micromere quartets according to the rule of position as stated above. Thus, the $1b^1$ cell divides to yield the $1b^{11}$ and $1b^{12}$ cells; the $1a^2$ cell yields the $1a^{21}$ and $1a^{22}$ cells; the 2c yields the $2c^1$ and $2c^2$, and so on. Do not think of these superscripts as double-digit numbers (i.e., "twenty-one" and "twenty-two"), but rather as two-digit sequences reflecting the precise lineage of each cell ("two-one" and "two-two").

The elegance of Wilson's system is that each code tells the history as well as the position of the cell in the embryo. For instance, the code $1b^{11}$ indicates that the cell is a member (derivative) of the first quartet of micromeres, that its parent macromere is the B cell, that the original 1b micromere has divided twice since its formation, and that this particular cell rests uppermost in the embryo relative to its sister cells. The 32-cell state (Figure 5.6D) is composed of the following:

$$\text{Derivatives of the 1q} \begin{cases} 1a^{11} & 1b^{11} & 1c^{11} & 1d^{11} \\ 1a^{12} & 1b^{12} & 1c^{12} & 1d^{12} \\ 1a^{21} & 1b^{21} & 1c^{21} & 1d^{21} \\ 1a^{22} & 1b^{22} & 1c^{22} & 1d^{22} \end{cases}$$

$$\text{Derivatives of the 2q} \begin{cases} 2a^1 & 2b^1 & 2c^1 & 2d^1 \\ 2a^2 & 2b^2 & 2c^2 & 2d^2 \end{cases}$$

$$\text{Derivatives of the 2Q} \begin{cases} 3q = 3a & 3b & 3c & 3d \\ 3Q = 3A & 3B & 3C & 3D \end{cases}$$

The division to 64 cells follows the same pattern, with appropriate coding changes and additions of superscripts. The displacement is levotropic and results in the following cells:

$$\text{Derivatives of the 1q} \begin{cases} 1a^{111} & 1b^{111} & 1c^{111} & 1d^{111} \\ 1a^{112} & 1b^{112} & 1c^{112} & 1d^{112} \\ 1a^{121} & 1b^{121} & 1c^{121} & 1d^{121} \\ 1a^{122} & 1b^{122} & 1c^{122} & 1d^{122} \\ 1a^{211} & 1b^{211} & 1c^{211} & 1d^{211} \\ 1a^{212} & 1b^{212} & 1c^{212} & 1d^{212} \\ 1a^{221} & 1b^{221} & 1c^{221} & 1d^{221} \\ 1a^{222} & 1b^{222} & 1c^{222} & 1d^{222} \end{cases}$$

$$\text{Derivatives of the 2q} \begin{cases} 2a^{11} & 2b^{11} & 2c^{11} & 2d^{11} \\ 2a^{12} & 2b^{12} & 2c^{12} & 2d^{12} \\ 2a^{21} & 2b^{21} & 2c^{21} & 2d^{21} \\ 2a^{22} & 2b^{22} & 2c^{22} & 2d^{22} \end{cases}$$

$$\text{Derivatives of the 3q} \begin{cases} 3a^1 & 3b^1 & 3c^1 & 3d^1 \\ 3a^2 & 3b^2 & 3c^2 & 3d^2 \end{cases}$$

$$\text{Derivatives of the 3Q} \begin{cases} 4q = 4a & 4b & 4c & 4d \\ 4Q = 4A & 4B & 4C & 4D \end{cases}$$

Notice that no two cells share the same code, so exact identification of individual blastomeres and their lineages is always possible.

Late in the spiral cleavage of certain animals, distinctive cell patterns appear, formed by the orientation of some of the apical first quartet micromeres (Figure 5.6E). The topmost cells ($1q^{111}$ micromeres) lie at the embryo's apex and form the rosette. In some groups (e.g., annelids), other micromeres ($1q^{112}$ micromeres) produce an annelid cross roughly at right angles to the rosette cells. In molluscs, the annelid cross may appear (often called peripheral rosette cells in these groups), but an additional molluscan cross forms from the $1q^{12}$ cells and their derivatives. The arms of the molluscan cross lie between the cells of the annelid cross (Figure 5.6E), and this configuration is not known to occur in any other metazoan phylum. Some phylogenetic significance has been given to the appearance of these crosses, as we discuss in later chapters.

Cell Fates

Tracing the fates of cells through development has been a popular and productive endeavor of embryologists for over a century. Such studies have played a major role in allowing researchers to describe development as well as establish homologies among the attributes in different animals. The cells of embryos eventually become established as functional parts of tissues or organs, but before they do there is much variation in the timing and degree to which cell fates become firmly fixed. Although under normal conditions their functions are specialized, even in adults, the cells of some animals (e.g., sponges) retain the ability to change their structure and function. Other animal taxa have remarkable power to regenerate lost parts, wherein cells dedifferentiate and then generate new tissues and organs. In still other taxa, cell fates are relatively fixed and cells are able only to produce more of their own kind.

By carefully watching the development of any animal, it becomes clear that certain cells predictably form certain structures. Here too, the emerging field of molecular developmental biology has shown that many molecular components of development are also widely conserved throughout the animal kingdom. For example, some transcription factors and cell signaling systems from widely divergent phyla are clearly homologous and evidently operate in much the same way. On the other hand, these highly conserved molecular components can also be used in diverse ways by embryos. The pattern of orthologous gene expression in early metazoan embryos illustrates both aspects of this relationship. Even such basic developmental features as adult body axis formation and cleavage geometry differ among the metazoan phyla (Figure 5.7). Such fundamental developmental variations appear to have been essential in fabricating the highest levels of animal body plans.

In some cases, cell fates are determined very early during cleavage—as early as the 2- or 4-cell stage. If one experimentally removes a blastomere from the early embryo of such an animal (as Roux did), then that embryo will fail to develop normally; the fates of the cells have already become fixed, and the missing cell cannot be replaced. Animals whose cell fates are established very early are said to have **determinate cleavage**. On the other hand, the blastomeres of some animals can be separated at the 2-cell, 4-cell (as Driesch did), or even later stages (as Spemann did), and each separate cell will develop normally; in these cases the fates of the cells are not fixed until relatively late in development. Such animals are said to have **indeterminate cleavage**. Eggs that undergo determinate cleavage are often called **mosaic ova**, because the fates of regions of undivided cells can be mapped. Eggs that undergo indeterminate cleavage are called **regulative ova**, in that they can "regulate" to accommodate lost blastomeres and thus cannot easily be predictably mapped prior to division.

In any case, formation of the basic body plan is generally determined by the time the embryo comprises about 104 cells (usually after one or two days). By this time, all available embryonic material has been apportioned into specific cell groups, or "founder regions." These regions are relatively few, each forming a territory within which still more intricate developmental patterns unfold. As these zones of undifferentiated tissue are established, the unfolding genetic code drives them to develop into their "preassigned" body tissues, organs, or other structures. Graphic representations of these regions are called **fate maps**, although such devices are rarely used by developmental biologists any longer.

In the past, mosaic eggs and determinate cleavage have been equated with spirally cleaving embryos, and regulative ova and indeterminate cleavage with radially cleaving embryos. However, surprisingly few actual tests for determinacy have been performed, and what evidence is available suggests that there are many exceptions to this generalization. That is, some embryos with spiral cleavage appear indeterminate, and some with radial cleavage appear determinate.

In spite of the variations and exceptions, there is a remarkable underlying consistency in the fates of blastomeres among embryos that develop by typical spiral cleavage. Many examples of these similarities are discussed in later chapters, but we illustrate the point by noting that the germ layers of spirally cleaving embryos tend to arise from the same groups of cells. The first three quartets of micromeres and their derivatives give rise to ectoderm (the outer germ layer), the 4a, 4b, 4c, and 4Q cells to endoderm (the inner germ layer), and the 4d cell to mesoderm (the middle germ layer). Many students of embryology view this uniformity of cell fates as strong evidence that taxa sharing this

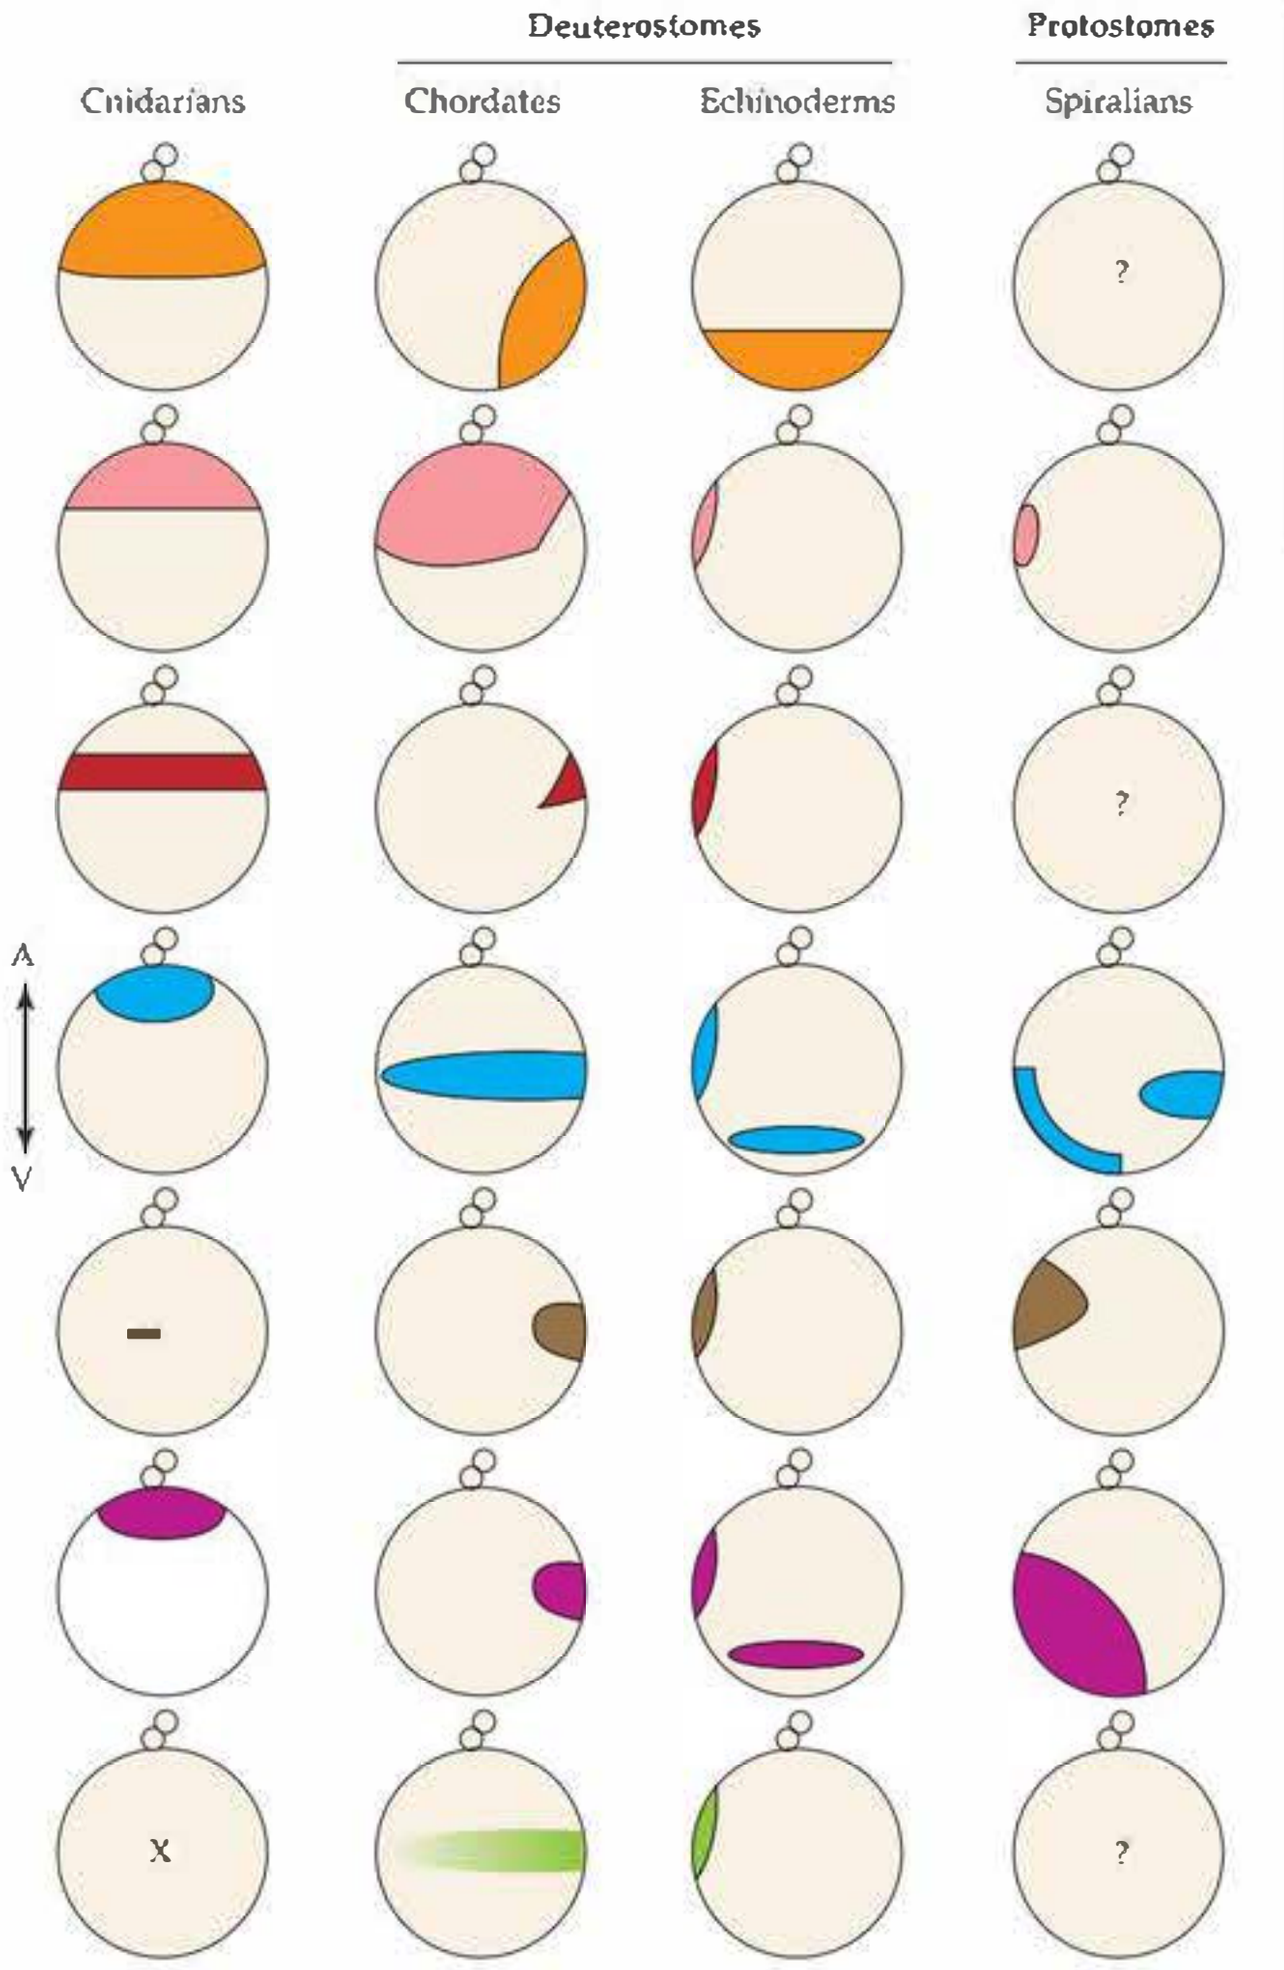

Figure 5.7 Locations and patterns of expression in some genes at the beginning of gastrulation in diverse metazoan embryos (cnidarians, chordates, echinoderms, spiralians). A↔V represents the animal-vegetal axis. All but one of the genes shown (*nodal*) are present in cnidarians as well as in chordates. While some genes (e.g., nuclear β-*catenin*) seem to track the changing location of gastrulation across taxa, other genes (e.g., *chordin* [*chrd*] and *goosecoid* [*gsd*] in echinoderms) are associated with gastrulation in some species and disassociated from such activity in others. The two circles at the animal pole represent polar bodies. X indicates that the gene is not present in the genome of a lineage, and ? indicates that the gene has not been recovered in a lineage. Gene abbreviations: *bmp*, bone morphogenetic protein; *dpp*, decapentaplegic; *sog*, short gastrulation; *hnf-forkhead*, hepatocyte nuclear factor, a forkhead homolog.

pattern are related to one another in some fundamental way and that they share a common evolutionary heritage. We will have much more to say about this idea throughout this book.

EvoDevo analyses, for their part, provide an objective means for assessing germ layer homology by identifying genes that are transcribed at different developmental times, rather than identifying pools of cells by eventual fate (Figure 5.7). Genes that have proven useful for such analyses include: *GATA 4, 5,* and *6*, genes associated with mucus production in endodermal tissue; *twist*, a gene associated with mesodermal development; *snail*, a repressor of E-cadherin, and thus important for downregulating ectodermal genes within mesoderm and allowing mesenchymal development; and *brachyury*, a gene important in defining the midline of many bilaterians. However this approach is complicated by the fact that even among closely related taxa, similar structures may be derived from different germ layers (e.g., Malpighian tubules are derived from ectoderm in insects but arise from endoderm in chelicerates). As explained above, traits used for evolutionary comparative analyses, even at the molecular level, must be selected with caution.

Blastula Types

The product of early cleavage is called the **blastula**, which may be defined developmentally as the embryonic stage preceding the formation of embryonic germ layers. Several types of blastulae are recognized among invertebrates. Holoblastic cleavage generally results in either a hollow or a solid ball of cells. A coeloblastula

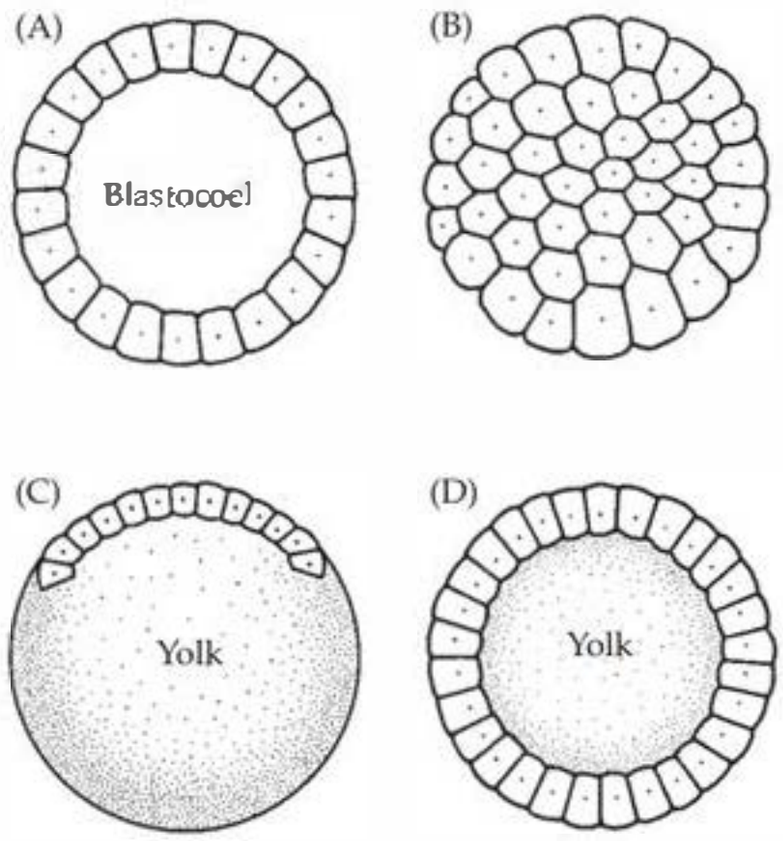

Figure 5.8 Types of blastulae. These diagrams represent sections along the animal-vegetal axis. (A) Coeloblastula. The blastomeres form a hollow sphere with a wall one cell layer thick. (B) Stereoblastula. Cleavage results in a solid ball of blastomeres. (C) Discoblastula. Cleavage has produced a cap of blastomeres that lies at the animal pole, above a solid mass of yolk. (D) Periblastula. Blastomeres form a single cell layer enclosing an inner yolky mass.

(Figure 5.8A) is a hollow ball of cells, the wall of which is usually one cell-layer thick. The space within the sphere of cells is the blastocoel, or primary body cavity. A stereoblastula (Figure 5.8B) is a solid ball of blastomeres; obviously there is no blastocoel at this stage. Meroblastic cleavage sometimes results in a cap or disc of cells at the animal pole over an uncleaved mass of yolk. This arrangement is appropriately termed a discoblastula (Figure 5.8C). Some centrolecithal ova undergo odd cleavage patterns to form a periblastula, similar in some respects to a coeloblastula that is centrally filled with noncellular yolk (Figure 5.8D).

Gastrulation and Germ Layer Formation

Through one or more of several methods the blastula develops toward a multilayered form, a process called gastrulation (Figure 5.9). The structure of the blastula dictates to some degree the nature of the process and the form of the resulting embryo, the gastrula. Gastrulation is the formation of the embryonic germ layers, the tissues on which all subsequent development eventually depends. In fact, we may view gastrulation as the embryonic analogue of the transition from protistan to metazoan grades of complexity. It achieves separation of those cells that must interact directly with the environment (i.e., locomotor, sensory, and protective functions) from those that process materials ingested from the environment (i.e., nutritive functions).

The initial inner and outer sheets of cells are the **endoderm** and **ectoderm**, respectively; in most animals a third germ layer, the mesoderm, is produced between the ectoderm and the endoderm. One striking example of the unity among the Metazoa is the consistency of the fates of these germ layers. For example, ectoderm always forms the nervous system, the outer skin and its derivatives; endoderm forms the main portion of the gut and associated structures; mesoderm forms the coelomic lining, the circulatory system, most of the internal support structures, and the musculature The process of gastrulation, then, is a critical one in establishing the basic materials and their locations for building the whole organism.

Coeloblastulae often gastrulate by invagination, a process commonly used to illustrate gastrulation in general zoology classes. The cells in one area of the surface of the blastula (frequently at or near the vegetal pole) pouch inward as a sac within the blastocoel (Figure 5.9A). These invaginated cells are now called the endoderm, and the sac thus formed is the embryonic gut, or **archenteron**; the opening to the outside is the **blastopore**. The outer cells are now called ectoderm, and a double-layered hollow coelogastrula has been formed. The blastopore may become the primordial mouth or anus depending on the animal lineage. If this structure becomes the mouth, the ectoderm lining the interior of the blastopore is considered **stomodeal**. If the blastopore becomes the anus, the ectoderm lining the interior of this structure is considered **proctodeal**. Note that the diagrams in Figure 5.9 represent 3-dimensional embryos. Thus, the coelogastrula (Figure 5.9A) actually resembles a balloon with an invisible finger poking into it.

The coeloblastulae of many cnidarians undergo gastrulation processes that result in a solid gastrula (stereogastrula). Usually the cells of the blastula divide such that the cleavage planes are perpendicular to the surface of the embryo. Some of the cells detach from the wall and migrate into the blastocoel, eventually filling it with a solid mass of endoderm. This process is called **ingression** (Figure 5.9B) and may occur only at the vegetal pole (**unipolar ingression**) or more or less over the whole blastula (**multipolar ingression**). In a few instances (e.g., certain hydroids), the cells of the blastula divide with cleavage planes that are parallel to the surface, a process called **delamination** (Figure 5.9C). This process produces a layer or a solid mass of endoderm surrounded by a layer of ectoderm.

Stereoblastulae that result from holoblastic cleavage generally undergo gastrulation by **epiboly**. Because there is no blastocoel into which the presumptive endoderm can migrate by any of the above methods, gastrulation of this form involves a rapid growth by a sheet of presumptive ectodermal cells around the presumptive endoderm (Figure 5.9D). Cells of the animal pole proliferate rapidly, growing down and over the vegetal cells to enclose them as endoderm. The blastopore forms where the edges of this ectodermal sheet

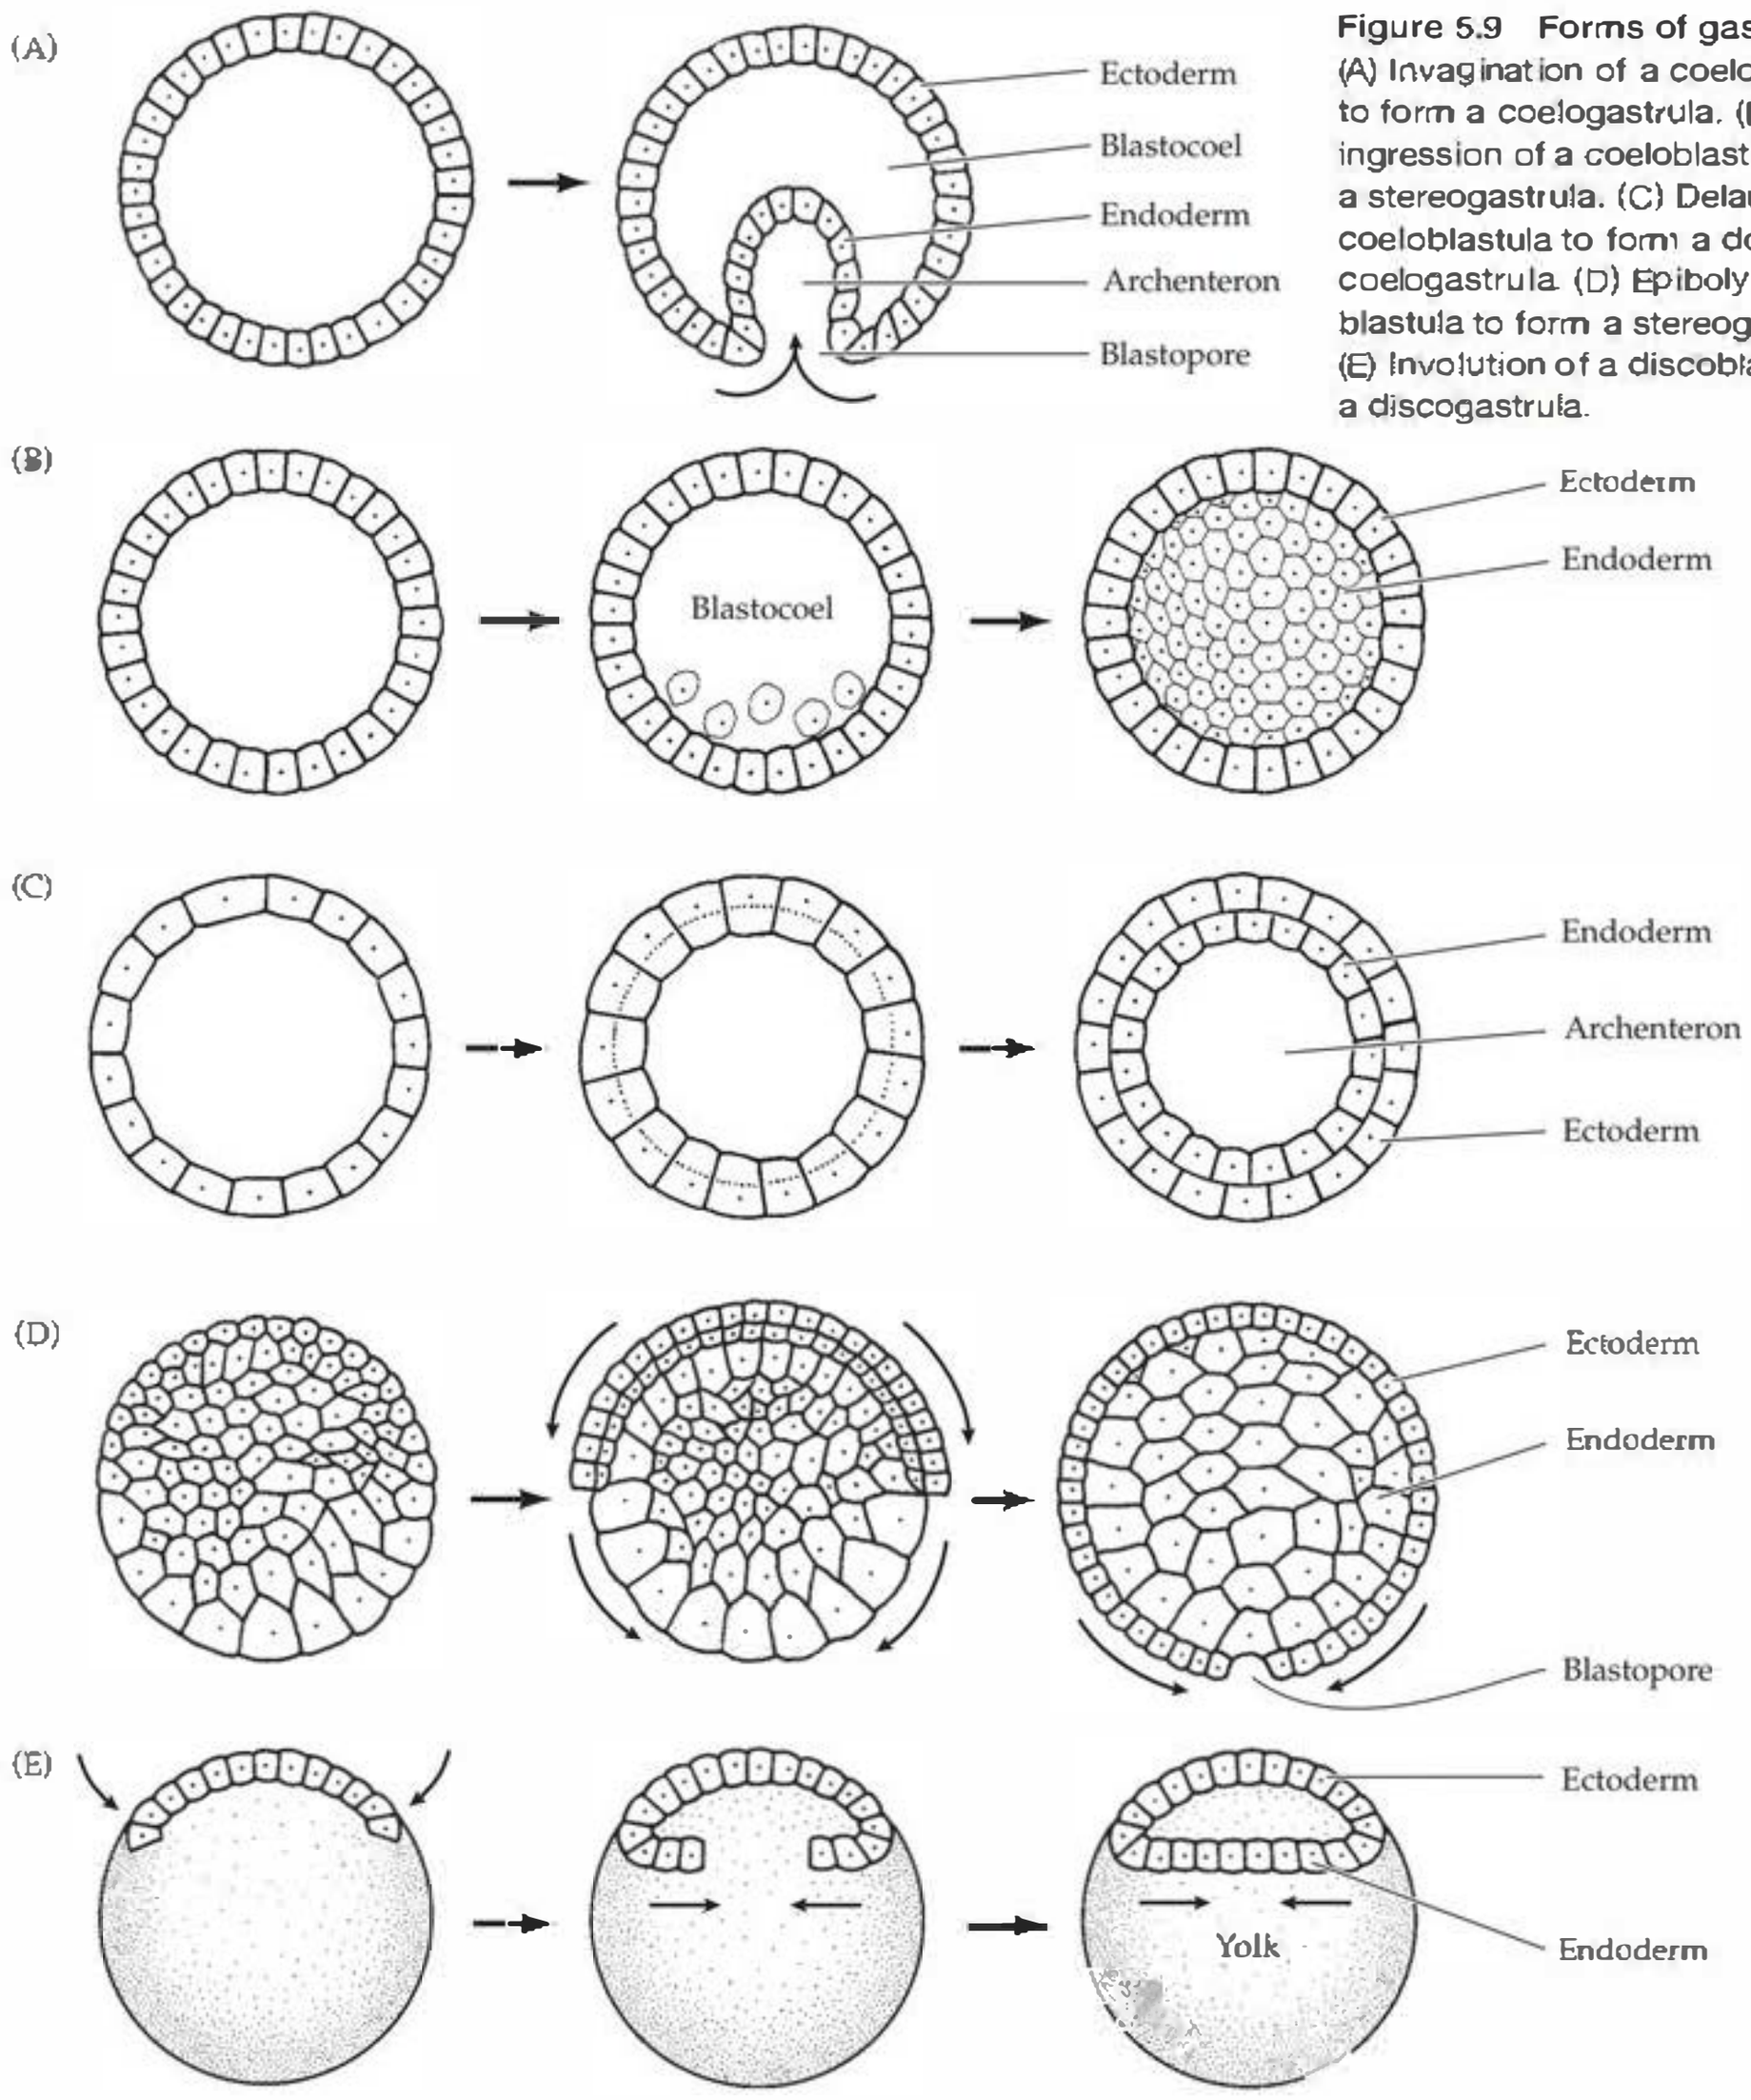

Figure 5.9 Forms of gastrulation. (A) Invagination of a coeloblastula to form a coelogastrula. (B) Unipolar ingression of a coeloblastula to form a stereogastrula. (C) Delamination of a coeloblastula to form a double-layered coelogastrula. (D) Epiboly of a stereoblastula to form a stereogastrula. (E) Involution of a discoblastula to form a discogastrula.

converge from all sides upon a single point at the vegetal pole. The archenteron typically forms secondarily as a space within the developed endoderm.

Figure 5.9E illustrates gastrulation by **involution**, a process that usually follows the formation of a discoblastula. The cells around the edge of the disc divide rapidly and grow beneath the disc, thus forming a double-layered gastrula with ectoderm on the surface and endoderm below. There are several other types of gastrulation, mostly variations or combinations of the above processes. These gastrulation methods are discussed in later chapters.

During gastrulation, subtle shifts in the timing of regulatory gene expression, the timing of cell fate specification, or in the movement of cells relative to one another, can generate distinct developmental pathways. Such developmental divergences may dramatically shift larval or even adult formation within a lineage. For example, sea urchin larvae appear to have switched from **planktotrophy** (feeding larvae) to **lecithotrophy** (nonfeeding larvae) at least 20 times within the history of this echinoderm clade. Among nonfeeding larvae, egg size is often greater, cleavage is significantly altered, and the average larval life span is shorter.

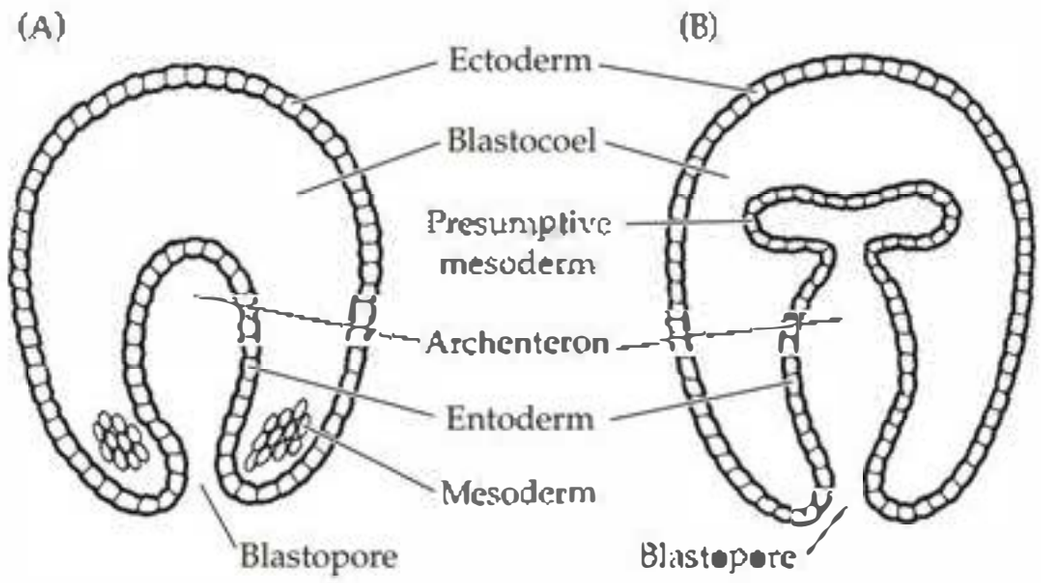

Figure 5.10 Methods of mesoderm formation in late gastrulae (frontal sections). (A) Mesoderm formed from derivatives of a mesentoblast. (B) Mesoderm formed by archenteric pouching.

Mesoderm and Body Cavities

During or soon after gastrulation, a middle layer forms between the ectoderm and the endoderm. This middle layer may be derived from ectoderm, as it is in members of the diploblastic phylum Cnidaria, or from endoderm, as it is in members of the triploblastic phyla. In the first case the middle layer is said to be ectomesoderm, and in the latter case endomesoderm (or "true mesoderm"). Thus, the triploblastic condition, by definition, includes endomesoderm. In this text, and most others, the term mesoderm in a general sense refers to endomesoderm rather than ectomesoderm. Although endomesoderm is characteristic of triploblastic metazoans, in many lineages some ectomesoderm is also produced.

In diploblastic and certain triploblastic phyla (the acoelomates), the middle layer does not form thin sheets of cells; rather it produces a more- or less solid but loosely organized mesenchyme consisting of a gel matrix (the mesoglea) containing various cellular and fibrous inclusions. In a few cases (e.g., the hydrozoans) a virtually noncellular mesoglea lies between the ectoderm and endoderm (see Chapter 7).

In most animals, the area between the inner and outer body layers includes a fluid-filled space. As discussed in Chapter 4, this space may be either a blastocoelom, a cavity not completely lined by mesoderm, or a true coelom, a cavity fully enclosed within thin sheets of mesodermally derived tissue. Endomesoderm generally originates in one of two basic ways, as described below (Figure 5.10); modifications of these processes are discussed in later chapters. In most phyla that undergo spiral cleavage (e.g., flatworms, annelids, molluscs), a single micromere—the 4d cell, called the mesentoblast—proliferates as mesoderm between the developing archenteron (endoderm) and the body wall (ectoderm) (Figure 5.10A). The other cells of the 4q (the 4a, 4b, and 4c cells) and the 4Q cells generally contribute to endoderm. In some other taxa (e.g., echinoderms and chordates) the mesoderm arises from the wall of the archenteron itself (that is, from preformed endoderm), either as a solid sheet or as pouches (Figure 5.11B).

In addition to giving rise to other structures (such as the muscles of the gut and body wall), in coelomate animals mesoderm is intimately associated with the formation of the body cavity. In those instances where mesoderm is produced as solid masses derived from a mesentoblast, the body cavity arises through a process called schizocoely. Normally in such cases, bilaterally paired packets of mesoderm gradually enlarge,

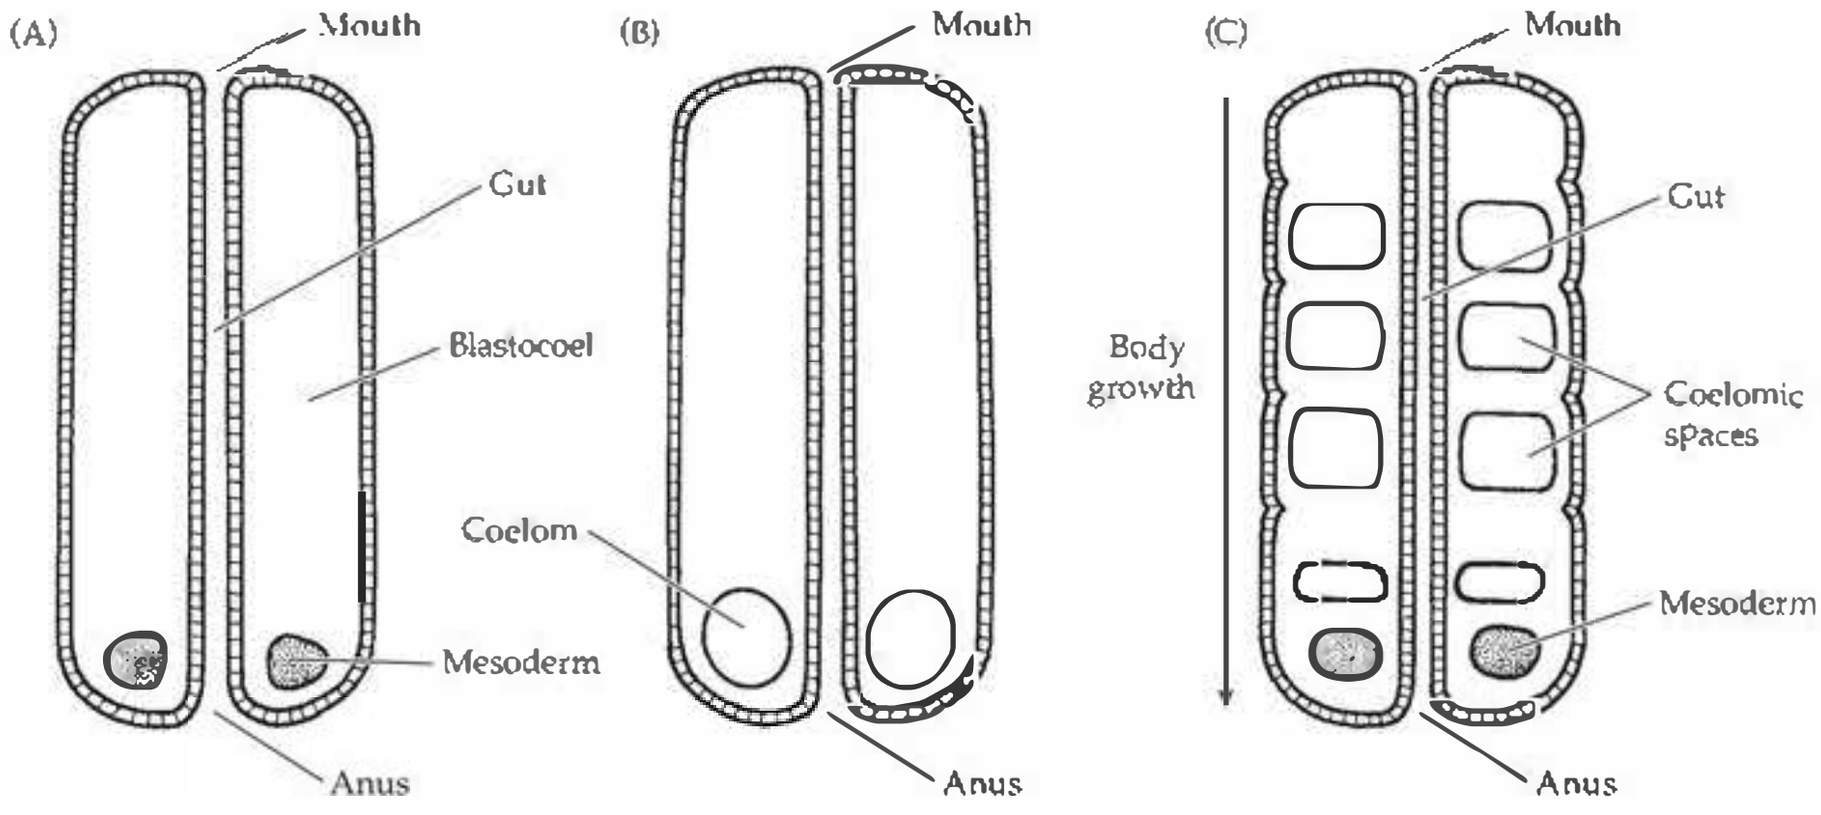

Figure 5.11 Coelom formation by schizocoely (frontal sections). (A) Precoelomic conditions with paired packets of mesoderm. (B) Hollowing of the mesodermal packets to produce a pair of coelomic spaces. (C) Progressive proliferation of serially arranged pairs of coelomic spaces. This process occurs in metameric annelids.

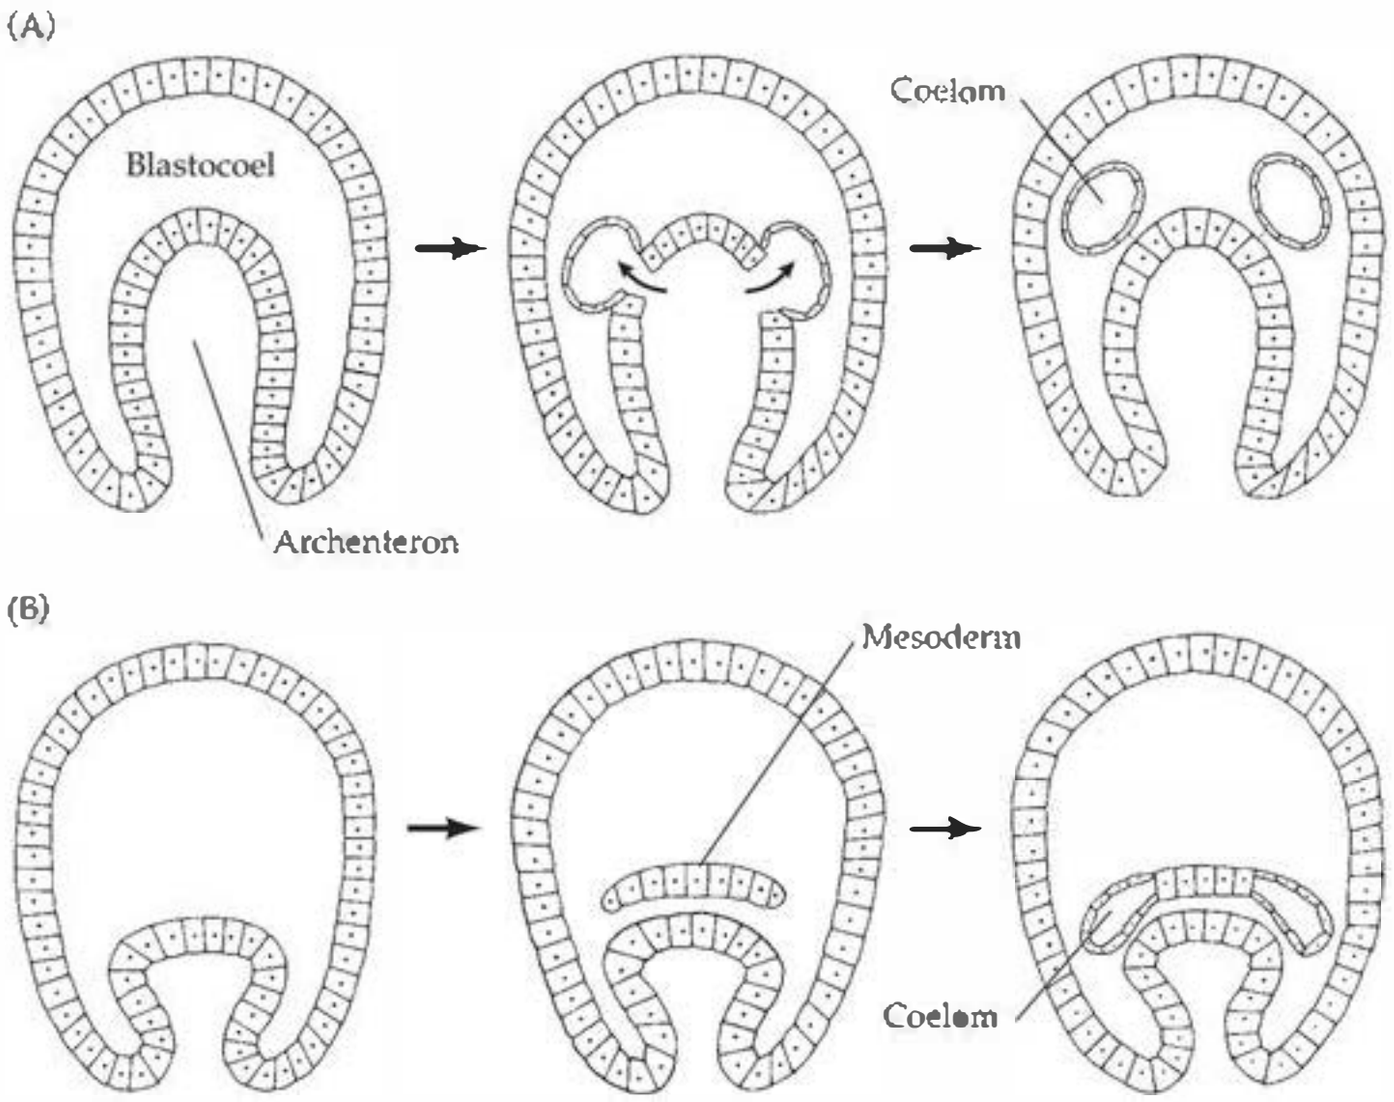

Figure 5.12 Coelom formation by enterocoely (frontal sections). (A) Archenteric pouching. (B) Proliferation and subsequent hollowing of a plate of mesoderm from the archenteron. (C) The typical tripartite arrangement of coeloms in a deuterostome embryo.

split internally, and then expand to simultaneously line the body wall, support viscera and create thin-walled coelomic spaces (Figure 5.11A,B). The number of such paired coeloms varies among different animals and is frequently associated with segmentation, as it is in annelid worms (Figure 5.11C).

The other general method of coelom formation is called **enterocoely**; it accompanies the process of mesoderm formation from the archenteron. In the most direct sort of enterocoely, mesoderm production and coelom formation are one and the same process. Figure 5.12A illustrates this process, which is called **archenteric pouching**. A pouch or pouches form in the gut wall. Each pouch eventually pinches off from the gut as a complete coelomic compartment. The walls of these pouches are defined as mesoderm. In some cases the mesoderm arises from the wall of the archenteron as a solid sheet or plate that later becomes bilayered and hollow (Figure 5.12B). Some authors consider this process to be a form of schizocoely (because of the "splitting" of the mesodermal plate), but it is in fact a modified form of enterocoely. Enterocoely frequently results in a tripartite arrangement of the body cavities, which are designated **protocoel, mesocoel, and metacoel** (Figure 5.12C).

Following germ tissue establishment, cells begin to specialize and sort themselves out to form the organs and tissues of the body—a poorly understood process known as **morphogenesis**. Cell movements are an essential part of morphogenesis. In addition, in order to sculpt the organs and systems of the body, cells need to "know" when to stop growing and even die. For example, in nematode worms the vas deferens first develops with a closed end; the cell that blocks the end of this tube helps the vas deferens link up to the cloaca. But once the connection has been made, this terminal cell dies and disassociates, creating the opening to the cloaca.

Recent research suggests that the same families of molecules that guide the earliest stages of embryogenesis—setting up the elements of body patterning (Figure 5.7)—also play vital roles during morphogenesis. Communication among adjacent cells is also critical to morphogenesis, and there are three ways cells "talk" to one another during this process, known as induction. The first is via diffusible signaling molecules released from one cell and detected by the adjacent cell. These substances include hormones, growth factors, and special substances called **morphogens**. A second method involves actual contact between the surfaces of adjacent cells, allowing cell surface molecules to interact. Cells selectively recognize other cells, adhering to some and migrating over others. A third method involves the movement of substances through gap junctions between cells. Of all the stages of ontogeny, we know least about morphogenesis.

Life Cycles: Sequences and Strategies

The patterns of early development described above are not isolated sequences of events, but are related to the mode of sexual reproduction, the presence or absence of larval stages in the life cycle, and the ecology of the adult. Efforts to classify various invertebrate life cycles and to explain the evolutionary forces that gave rise to them have produced a large number of publications and a great deal of controversy. Most of these studies concern marine invertebrates, on which we center our attention first. We then present some comments on the special adaptations of terrestrial and freshwater forms.

Classification of Life Cycles

Our discussion of life cycles focuses on sexually reproducing animals. Sexual reproduction with some degree of gamete dimorphism is nearly universal among eukaryotes. Male and female gametes may be produced by the same individual (**hermaphroditism**, cosexuality, or in plants, monoecy) or by separate individuals (**gonochory**, or in plants, dioecy). Most terrestrial animals are gonochoristic, but hermaphroditism is widespread among marine invertebrates (as is monoecy among land plants). Mechanisms of sex determination are diverse; in certain arthropods, females may be diploid and males haploid, a system known as **haplodiploidy**. Other forms of sex determination involve structurally distinct sex chromosomes. In **male heterogamety**, males carry X and Y sex chromosomes and females are XX, as in some vertebrates. In **female heterogamety**, females are ZW and males ZZ, as seen in many crustaceans. There is typically little or no recombinational exchange between X and Y chromosomes (or between Z and W) because there is almost no genetic homology between the sex chromosomes. Most of the Y (or W) chromosome is devoid of functional gene loci, other than a few RNA genes and some genes required for male (or female) fertility and sex determination. In any event, it is the fusion of male and female gametes that initiates the process of ontogeny and a new cycle in the life history of an organism.

A number of classification schemes for life cycles have been proposed over the past five decades (see papers by Thorson, Mileikovsky, Chia, Strathmann, Jablonsky, Lutz, and McEdward). We have generalized from the works of various authors and suggest that most animals display some form of one of the three following basic patterns (Figure 5.13).

1. **Indirect development** The life cycle includes free spawning of gametes followed by the development of a free larval stage (usually a swimming form), which is distinctly different from the adult and must undergo a more or less drastic metamorphosis to reach the juvenile or young adult stage. The equivalent in terrestrial invertebrates is seen in insects with holometabolous development. In aquatic groups, two basic larval types can be recognized.
   a. Indirect development with **planktotrophic** larvae. The larva survives primarily by feeding, usually on plankton. (The feeding larvae of some deep sea species are demersal and feed on detrital matter, never swimming very far off the bottom.)
   b. Indirect development with **lecithotrophic** larvae The larva survives primarily on yolk supplied to the egg by the mother.
2. **Direct development** The life cycle does not include a free larva. In these cases the embryos are cared for by the parents in one way or another (generally by brooding or encapsulation) until they emerge as juveniles. The equivalent in terrestrial invertebrates is seen in insects with ametabolous or hemimetabolous development
3. **Mixed development** The life cycle involves brooding or encapsulation of the embryos at early stages of development and subsequent release of free planktotrophic or lecithotrophic larvae. The initial source of nutrition and protection is the adult.

Not every species can be conveniently categorized into just one of the above developmental patterns. For example, some species have free larvae that depend on yolk for a time, but begin to feed once they develop the ability to do so. Some species actually display different developmental strategies under different environmental conditions—convincing evidence that embryogenies, like so many other aspects of a species or population, are subject to selection pressures and can readily evolve.

These life cycle patterns provoke three basic questions. First, how do different developmental sequences relate to other aspects of reproduction such as egg types and mating or spawning activities? Second, how do overall developmental sequences relate to the survival strategies of larvae and adults? Third, what evolutionary mechanisms are responsible for the patterns seen in any given species? Given the large number of interacting factors to be considered, these are complex questions, and our understanding of them is still incomplete. However, by first examining cases of direct and indirect development, we can illustrate some of the principles that underlie their relationships to different ecological situations. Then we will briefly address some ideas about mixed development.

Indirect Development

Consider first a life cycle with planktotrophic larvae (Figure 5.13A). The metabolic expense incurred on the part of the adults involves only the production and

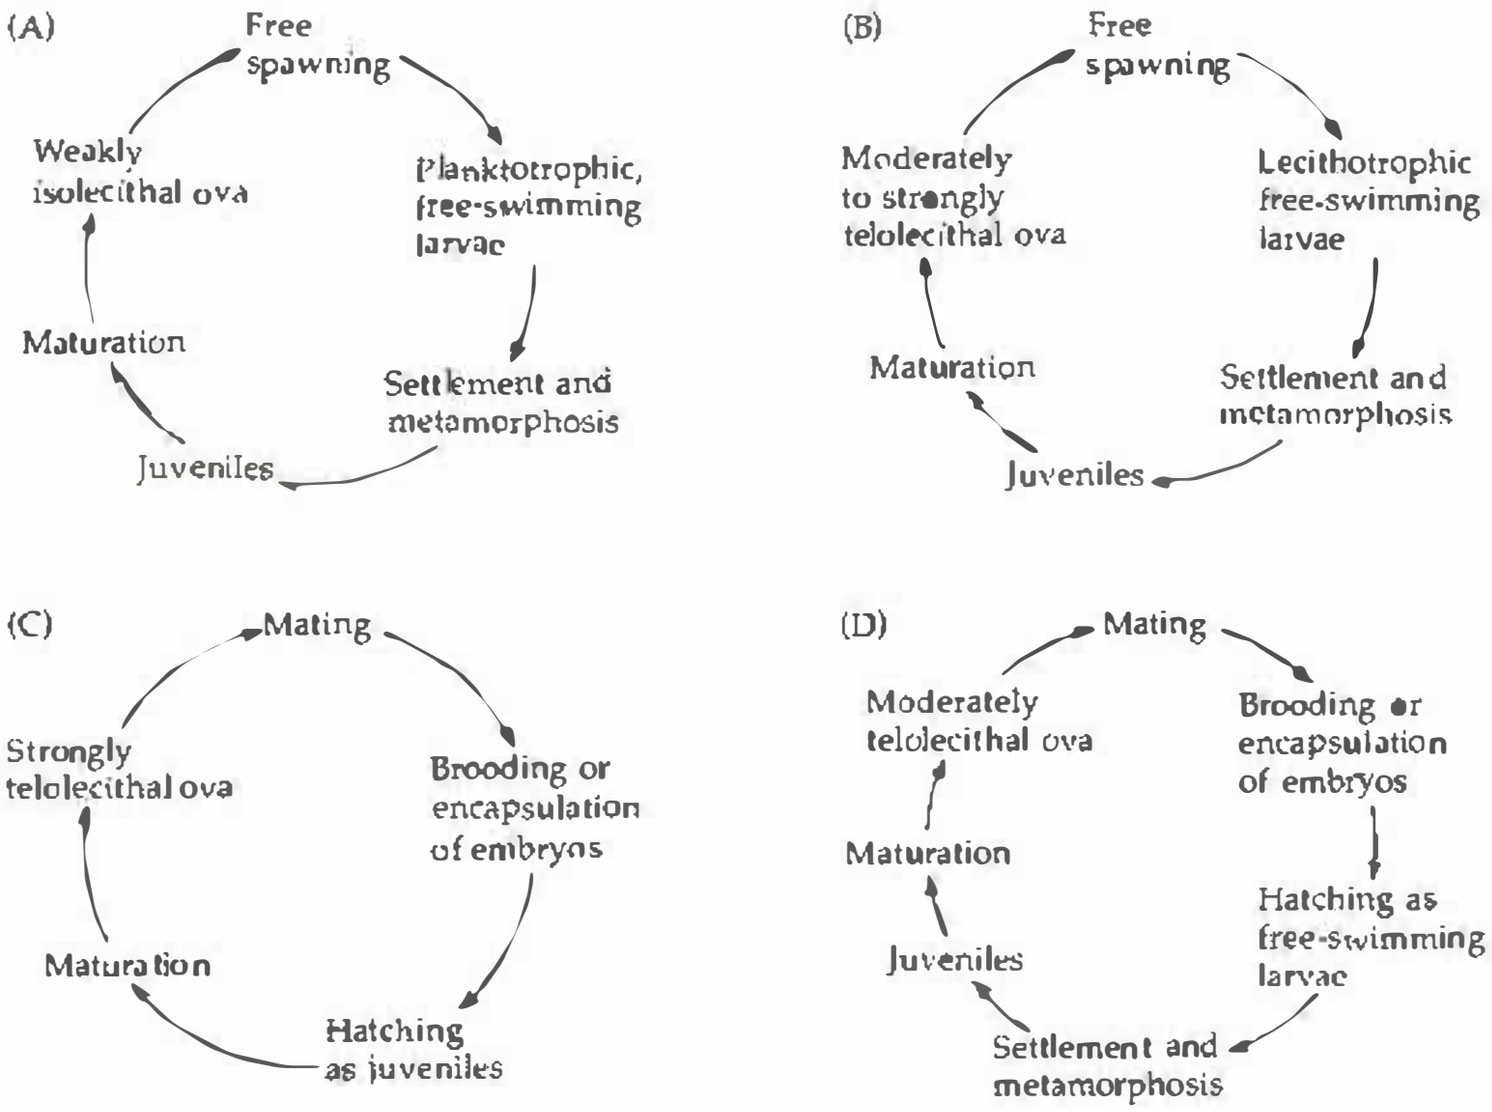

Figure 5.13 Some generalized invertebrate life cycle strategies. (A) Indirect development with planktotrophic larvae (B) Indirect development with lecithotrophic larvae. (C) Direct development. (D) Mixed life cycle.

release of gametes. Animals with fully indirect development generally do not mate; instead, they shed their eggs and sperm into the water, thus divorcing the adults from any further responsibility of parental care. Such animals typically undergo synchronous (epidemic) broadcast spawning of large numbers of gametes, thereby ensuring some level of successful fertilization. This pattern of development is relatively common in opportunistically settling and colonizing (*r*-selected) marine species that make use of tides or ocean currents to disperse their progeny, and are capable of rapid production of high numbers of gametes.

The eggs of animals expressing such traits are usually isolecithal and individually inexpensive to produce. The overall cost—and it is a significant one to each potential parent—is in the production of very large numbers of eggs. Being supplied with little yolk, the embryos must develop quickly into feeding larvae to survive. Mortalities among the embryos and larvae are extremely high and can result from a variety of factors, including lack of food, predation, or adverse environmental conditions. Each successful larva must accumulate enough nutrients from feeding to provide for its immediate survival, as well as for the processes of settling and metamorphosis from larva to juvenile or subadult. That is, they must feed to excess as they prepare for a new lifestyle as a juvenile. Survival rates from zygote to settled juvenile are often less than one percent. Such high mortalities are offset by the initial high production of gametes. But by the same token, high larval mortalities offset the high production of gametes—if all of these zygotes survived, the Earth would quickly be covered by the offspring of animals with indirect development.

What are the advantages and limitations of such a life history, and under what circumstances might it be successful? This sort of planktotrophic development is most common among benthic marine invertebrates in relatively shallow water and the intertidal zones of tropical and warm temperate seas. Here the planktonic food sources are more consistently available (although often in low concentration) than they are in colder or deeper waters, thus reducing the danger of starvation of the larvae. Such meroplanktonic life cycles allow animals to take advantage of two distinct resources (plankton in the upper water column as larvae; benthos and bottom plankton as adults). This arrangement reduces or eliminates competition between larvae and adults. Indirect development also provides a mechanism for dispersal, a particularly important benefit to species that are sessile or sedentary as adults. There is good evidence to suggest that animals with free-swimming larvae are likely to recover more quickly from damage to the adult population than those engaging in direct development. A successful set of larvae is a ready-made new population to replace lost adults.

The disadvantages of planktotrophic development result from the unpredictability of larval success. Excessive larval deaths can result in poor recruitment and the possibility of invasion of suitable habitats by competitors. Conversely, unusually high survival rates of larvae can lead to overcrowding and intraspecific competition upon settling.

Animals that produce fully lecithotrophic larvae (Figure 5.13B) must produce yolky and thus more metabolically expensive eggs. This built-in nutrient supply releases the larvae from dependence on environmental food supplies and generally results in reduced

mortalities. It is not surprising that these animals produce somewhat fewer ova than those with planktotrophic larvae. The eggs are either spawned directly into the water or are fertilized internally and released as zygotes Again, the adults' parental responsibility ends with the release of gametes or zygotes into the environment. Although survival rates of lecithotrophic larvae are generally higher than those of planktotrophic types, they are low compared with those of embryos that undergo direct development.

Marine invertebrates that live in relatively deep benthic environments tend to produce lecithotrophic larvae. Here, some of the advantages of indirect development are realized, but larvae do not require environmental food supplies and therefore avoid the intense predation commonly encountered in surface water. The trade-off is clear: In deeper water fewer, more expensive zygotes are produced, but they can survive where more numerous, less expensive planktotrophic larvae cannot.

Settling and Metamorphosis

Of particular importance to the successful completion of animal life cycles with free larval stages are the processes of settlement and metamorphosis. These events are crucial and dangerous times in an animal's life cycle because they often require rapid and dramatic changes in individual habitats and lifestyle. Freeswimming larvae usually metamorphose into benthic juveniles, a process that involves the shedding of larval structures and the rapid growth or mobilization of juvenile ones. Surviving this transformation in form and function and adopting a new mode of life requires adequate stored resources, appropriate responses to internal and external conditions, and considerable luck.

Throughout their freeswimming lives larvae have been "preparing" for these events, until they reach a condition in which they are physiologically capable of metamorphosis. Such larvae are termed competent. The duration of the free swimming period varies greatly among metazoan larvae and depends on factors such as original egg size, yolk content, and the availability of food for planktotrophic forms. Once a larva becomes competent, it generally begins to respond to certain environmental cues that induce settling behavior. Metamorphosis is often preceded by settling, although some species metamorphose prior to settling and still others engage in both processes simultaneously. In any case, larvae typically become negatively phototactic and/or positively geotactic and move toward the bottom to settle. In species that are planktonic both as larvae and as adults (holoplanktonic species), the larvae obviously do not settle on the benthos.

Once contact with a substratum is made, a larva tests it, to determine its suitability as a habitat This act of substratum selection may involve processing physical, chemical, and biological information. A number of studies show that important factors include: substratum texture, composition, and particle size; presence of conspecific adults (or dominant competitors); presence of key chemical cues; presence of appropriate food sources; and the nature of bottom currents or turbulence. Contact with the substrate includes risks. Previously settled planktivores and predators are likely to be common in many potentially suitable habitats. Once again, larval mortalities at this stage are high.

Many invertebrate larvae touch down on the bottom for a few minutes, and then launch themselves back up into the current again and again until a suitable substratum is found. Assuming an appropriate situation is encountered, metamorphosis is induced and proceeds to completion. Interestingly, some feeding larvae are able to postpone metamorphosis and resume planktonic life if they initially encounter an unsuitable substratum. In such cases, however, the larvae become gradually less selective; eventually, metamorphosis ensues regardless of the availability of a proper substratum. The ability to prolong the larval period until conditions are favorable for settlement has obvious survival advantages, and invertebrates differ greatly in this capability. Those that can postpone settlement may do so by several hours, days, or even months (based on laboratory experiments).

Direct Development

Direct development avoids some of the disadvantages but also misses some of the advantages of indirect development. A typical scenario involves the production of relatively few, very yolky eggs, followed by some sort of mating activity and internal fertilization (Figure 5.13C). The embryos receive prolonged parental care, either directly (by brooding in or on the parent's body) or indirectly (by encapsulation in egg cases provided by the parent). Animals that simply deposit their fertilized eggs, either freely or in capsules, are said to be oviparous. A great number of invertebrates as well as some vertebrates (amphibians, many fishes, reptiles, and birds) display oviparity. Animals that brood their embryos internally and nourish them directly, such as placental mammals or peracarids crustaceans, are described as viviparous. Ovoviviparous animals brood their embryos internally but rely on the yolk within the eggs to nourish their developing young. Most internally brooding invertebrates are ovoviviparous.

The large, yolky eggs of most invertebrates with direct development are metabolically expensive to produce. But while only a few eggs are possible, the investment is protected though parental effort and survival rates are relatively high. The dangers of planktonic larval life and metamorphosis are avoided and the embryos eventually hatch as juveniles.

What sorts of environments and lifestyles might result in selection for such a developmental sequence? At the risk of overgeneralizing, we can say that there is a

tendency for specialist (e.g., K selected) species to display direct development. Another situation in which direct development occurs is when the adults have no dispersal problems. We find, for example, that holoplanktonic species with pelagic adults (e g., arrow worms, phylum Chaetognatha; pelagic gastropods) often undergo direct development, either by brooding or by producing floating egg cases. A second situation is one in which critical environmental factors (e g, food, temperature, water currents) are highly variable. There is a trend among benthic invertebrates to switch from planktotrophic indirect development to direct development at increasingly higher latitudes. The relatively harsh conditions and strongly seasonal occurrence of planktonic food sources in polar and subpolar areas partially explain this tendency.

In addition to avoiding some of the danger of larval life, direct development has another distinct advantage The juveniles hatch in suitable habitats where the adults brooded them or deposited the eggs in capsules. Thus, there is a reasonable assurance of appropriate food sources and other environmental factors for the young.

Mixed Development

As defined earlier, mixed life histories involve some period of brooding prior to release of a free larval stage Costly, yolky zygotes are protected for some time and then are released as larvae, exploiting the advantages of dispersal. This developmental pattern is often ignored when classifying life histories, but in fact it is widespread among gastropods, insects, crustaceans, sponges, cnidarians, and a host of other animal groups. Some workers view mixed development as either the "best" or the "worst" of both worlds (i.e., fully indirect or direct). Others suggest that such sequences are evolutionarily unstable, and that local environmental pressures are driving them toward direct or indirect development There are, however, other possible explanations It may very well be that under some environmental situations a brooding period followed by a larval phase is adaptive and stable.

Furthermore, at least some species show population variability in the relative lengths of time embryos exist in a brooded versus a free larval phase If this variability responds to local environmental pressures, then clearly such a species might adapt quickly to changing conditions, or even exploit this ability by extending its geographic range to live under a variety of settings. In this regard, mixed life histories may represent developmental polymorphisms, in which the frequency and intensity of particular environmental cues influences the proportion of the population that expresses or does not express a particular larval phenotype Such phenotypic plasticity in life history expression is an area in need of further investigation.

Our short description of life history strategies certainly does not explain all observable patterns in nature. The historical and evolutionary forces acting on invertebrates (and their larvae) are highly complex. For example, larvae are subject to all manner of oceanographic variables (e.g., diffusion, lateral and vertical transport, sea floor topography, storms) as well as their self directed vertical movements, seasonality, and biotic factors (predators, prey, competition, nutrient availability). Life history predictions based strictly on environmental conditions do not always hold true. Invertebrates living in the deep sea and at the poles do not always brood (as was once thought). We now know that all life history strategies occur in these regions, and many deep sea and polar species release freeswimming larvae, and even planktotrophic larvae. Even some invertebrates of deep-sea hydrothermal vent communities produce free swimming larvae. In many cases, this may be due to evolutionary constraints: vent gastropods, for example, belong to lineages that are almost strictly lecithotrophic, regardless of latitude or habitat. Thus, vent gastropods are apparently constrained by their phylogenetic histories. Other vent species that release free larvae, however, are not so constrained: mytilid bivalves, for example, possess a wide range of reproductive modes, and tend to release planktotrophic larvae in deep sea and vent environments. Furthermore, reproductive cycles in many abyssal invertebrates appear to be seasonal, perhaps cued by annual variations in surface water productivity. There is still much to be learned.

Adaptations to Land and Fresh Water

The foregoing account of life cycle strategies applies largely to marine invertebrates. Many invertebrates, however, have invaded land or fresh water, and their success in these habitats requires not only adaptation of the adults to special problems, but also adaptation of the developmental forms. As discussed in Chapter 1, terrestrial and freshwater environments are more rigorous and unstable than the sea, and they are generally unsuitable for reproductive strategies that involve free spawning of gametes or the production of delicate larval forms. Most groups of terrestrial and freshwater invertebrates have adopted internal fertilization followed by direct development, while their marine counterparts often exhibit external fertilization and produce free swimming larvae. The insects, flatworms and nematodes are notable exceptions, in which a wide range of mixed development life histories have evolved. In these cases, larvae are highly adapted to their freshwater, terrestrial or parasitic environments with unique traits that are unlikely to have existed in any marine larval ancestor.

Parasite Life Cycles

The evolutionary success of parasites is clear. Every animal species examined for symbionts appears to provide habitat for at least one, and usually many as-

sociated species. These symbionts often draw benefits from their host at their host's expense, and thus are parasites. Most parasites have rather complicated life cycles, and specific examples are given in later chapters. For now, we will examine parasitic lifestyles in a general way to understand their central features, and to introduce some basic terminology.

As outlined in Chapter 1, parasites may be classified as **ectoparasites** (living upon the host), **endoparasites** (living internally, within the host), or **mesoparasites** (living in some cavity of the host that opens directly to the outside, such as the oral, nasal, anal, or gill cavities). While associated with a host, a parasite may engage in sexual or asexual reproduction, but the eggs or embryos are usually released to the outside via some avenue from the host's body. The problems at this point are very similar to those encountered during indirect larval development: some mechanism must be provided to ensure adequate survival through the developmental stages, and some sequence of events must bring the parasite back to an appropriate host (the proper "substratum") for maturation and reproduction. As explained earlier, habitat transitions are risky. Thus, many parasites are parthenogenetic a form of reproduction in which the ovum undergoes embryonic development and produces a new individual without fertilization. Parthenogenesis produces offspring that are genetically identical to their parent. Other parasites may be capable of asexual reproduction by way of fission or budding. The production of asexual progeny appears to be one mechanism by which parasites offset the high mortality that attends transitions from one host to the next.

Parasites exploit at least two different habitats in their life cycles. This practice is essential because when hosts die, their parasites usually die with them. Thus, the developmental period from zygote to adult parasite involves either the invasion of another host, or a free-living period between host invasions. When more than one host species is utilized for the completion of the life cycle, the organism harboring the adult parasite is called the **primary** or **definitive** host. Hosts in which developmental or larval forms reside are called **intermediate hosts**. The completion of complex life cycles often requires elaborate methods of transfer from one host to the other, and again, surviving the changes from one habitat to another can be problematic. Losses are routinely high. Thus, we find that many parasites enjoy some of the benefits of indirect development (e.g., dispersal and exploitation of multiple resources) while being subjected to accompanying high mortalities and the dangers of very specialized lifestyles.

We emphasize again that the above discussions of life cycles are generalities to which there are many exceptions. But given these basic patterns, you should recognize and appreciate the adaptive significance of life history patterns of the different invertebrate groups discussed later. You might also be able to predict the sorts of sequences that would be likely to occur under different conditions. For example, given a situation in which a particular species is known to produce very high numbers of free spawned, isolecithal ova, what might you predict about cleavage pattern, blastula and gastrula type, presence or absence of a larval stage, type of larva, adult lifestyle, and ecological settings in which such a sequence would be advantageous? We hope you will develop the habit of asking these kinds of questions and thinking in this way about all aspects of your study of invertebrates.

The Relationships Between Ontogeny and Phylogeny

Of the many fields of study from which we draw information used in phylogenetic investigations, embryology has been one of the most important. The construction of phylogenies may be accomplished and subsequently tested by several different methods (Chapter 2). But regardless of method, one of the principal problems of phylogeny reconstruction in fact, central to the process—is separating true homologies from similar character traits that are the result of evolutionary convergence. Even when these problems involve comparative adult morphology, one must often seek answers in studies of the development of the organisms and structures in question. The search is for developmental processes or structures that are homologues and thus demonstrate relationships between ancestors and descendants. Changes that take place in developmental stages are not trivial evolutionary events. It has been effectively argued that developmental phenomena may themselves provide the evolutionary mechanisms by which entire new lineages originated (Chapter 1). As Stephen Jay Gould (1977) has noted,

> *Evolution is strongly constrained by the conservative nature of embryological programs. Nothing in biology is more complex than the production of an adult . . . from a single fertilized ovum. Nothing much can be changed very radically without discombobulating the embryo*

Indeed, the persistence of distinctive body plans throughout the history of life is testimony to the resistance to change of complex developmental programs. (See Hall 1996 for an excellent analysis of these issues.)

Although few workers would argue against a significant relationship between ontogeny and phylogeny, the exact nature and extent of the relationship have historically been subjects of considerable controversy, a good deal of which continues today. (Gould 1977 presents a fine analysis of these debates.) Central to much of the controversy is the concept of recapitulation.

The Concept of Recapitulation

In 1866 Ernst Haeckel, a physician who found a higher calling in zoology and never practiced medicine, introduced his law of recapitulation (or the biogenetic law), most commonly stated as "ontogeny recapitulates phylogeny." Haeckel suggested that a species' embryonic development (ontogeny) reflects the adult forms of that species' evolutionary history (phylogeny). According to Haeckel, this was no accident, but a result of a close mechanistic relationship between the two processes: phylogenesis is the actual cause of embryogeny. Restated, animals have an embryogeny *because* of their evolutionary history. Evolutionary change over time has resulted in a continual adding on of morphological stages to the developmental process of organisms. The implications of Haeckel's proposal are immense. Among other things, it means that to trace the phylogeny of an animal, one need only examine its development to find therein a sequential or "chronological" parade of the animal's adult ancestors.

Ideas and disagreement concerning the relationship between ontogeny and phylogeny were by no means new even at Haeckel's time. Over 2,000 years ago Aristotle described a sequence of "souls" or "essences" of increasing quality and complexity through which animals pass in their development. He related these conditions to the adult "souls" of various lower and higher organisms, a notion suggestive of a type of recapitulation.

Descriptive embryology flourished in the nineteenth century, stimulating vigorous controversy regarding the relationship between development and evolution. Many of the leading developmental biologists of the time were in the thick of things, each proposing his own explanation (Meckel 1811; Serres 1824, von Baer 1828; and others). It was Haeckel, however, who really stirred the pot with his discourse on the "law" of recapitulation. He offered a focal point around which biologists argued pro or con for 50 years; sporadic skirmishes still erupt periodically. Walter Garstang critically examined the biogenetic law and gave us a different line of thinking. His ideas, presented in 1922, are reflected in many of his poems (published posthumously in 1951). Garstang made clear what a number of other biologists had suggested: that evolution must be viewed not as a succession of ancestral adult forms, but as a succession of ontogenies. Each animal is a result of its own developmental processes, and any change in an adult must represent a change in its ontogeny. So what we see in the embryogeny of a particular species are not tiny replicas of its adult ancestors, but rather an evolved pattern of development in which clues or traces of ancestral ontogenies, and thus phylogenetic relationships to other organisms, may be found.

Arguments over these matters did not end with Garstang, and they continue today in many quarters. In general, we tend to agree with the approach (if not all of the details) of Gosta Jägersten in *Evolution of the Metazoan Life Cycle* (1972). Recapitulation per se should not categorically be accepted or dismissed as an "always" or "never" phenomenon. The term must be clearly defined in each case investigated, not locked in to Haeckel's original definition and implications. For instance, similar, distinctive, homologous larval types within a group of animals reflect some degree of shared ancestry (e.g., crustacean nauplii or molluscan veligers). And we may speculate on such matters at various taxonomic levels, even when the adults are quite different from one another (e.g., the similar trochophore larvae of polychaetes and molluscs). These phenomena may be viewed as developmental evidence of relatedness through shared ancestry, and thus they are examples of "recapitulation" in a broad sense.

Jägersten's example of vertebrate gill slits is particularly appropriate because, to him, it provides a case in which Haeckel's strict concept of recapitulation is manifest. In writing of this feature Jägersten (1972) stated,

> *The fact remains . . . that a character which once existed in the adults of the ancestors but was lost in the adults of the descendants is retained in an easily recognizable shape in the embryogenesis of the latter. This is my interpretation of recapitulation (the biogenetic 'law').*

Hyman (1940) perhaps put it most reasonably when she wrote,

> *Recapitulation in its narrow Haeckelian sense, as repetition of adult ancestors, is not generally applicable; but ancestral resemblance during ontogeny is a general biological principle. There is no need to quibble over the word recapitulation; either the usage of the word should be altered to include any type of ancestral reminiscence during ontogeny, or some new term should be invented.*

Other authors, however, are not comfortable with such flexibility and have made great efforts to categorize and define the various possible relationships between ontogeny and phylogeny, of which strict recapitulation is considered only one (see especially Chapter 7 of Gould 1977). Although much of this material is beyond the scope of this book, we discuss a few commonly used terms here because they bear on topics in later chapters. We have drawn on a number of sources cited in this chapter to mix freely with our own ideas in explaining these concepts.

Heterochrony and Paedomorphosis

When comparing two ontogenies, one often finds that some features appear earlier or later in one sequence than in the other. Such temporal displacement during development is called **heterochrony**. When comparing suspected ancestral and descendant embryogenies, for example, we may find the very rapid (accelerated) development of a particular feature and thus its relatively

early appearance in a descendant species or lineage. Conversely, the development of a trait may be slower (retarded) in a descendant than in an ancestor and thus appear later in the descendant's ontogeny. This retardation may be so pronounced that a structure may never develop to more than a rudiment of its ancestral condition. (For excellent reviews of heterochrony and its impact on phylogeny see Gould 1977, and McKinney and McNamara 1991.)

Particular types of heterochrony result in a condition known as **paedomorphosis**, wherein sexually mature adults possess features characteristically found in early developmental stages of related forms (i.e., juvenile or larval features). Paedomorphosis results when adult reproductive structures develop before completion of the development of all the adult nonreproductive (somatic) structures. Thus, we find a reproductively functional animal retaining what in the ancestor were certain embryonic, larval, or juvenile characteristics. This condition can result from two different heterochronic processes. These are **neoteny**, in which somatic development is retarded, and **progenesis**, in which reproductive development is accelerated. These two terms are frequently used interchangeably because it is not always possible to know which process has given rise to a particular paedomorphic condition. Recognition of paedomorphosis may play a significant role in examining evolutionary hypotheses concerning the origins of certain lineages. For example, the evolution of precocious sexual maturation of a planktonic larval stage (that would "normally" continue developing to a benthic adult) might result in a new diverging lineage in which the descendants pursue a fully pelagic existence. Such a scenario, for example, may have been responsible for the origin of some small planktonic crustaceans. Paedomorphosis has also played major roles in theories regarding the origin of the vertebrates.

Myriad questions about the role of embryogenesis in evolution and the usefulness of embryology in constructing and testing phylogenies persist. As the following accounts show, different authors continue to hold a variety of opinions about these matters.

The Origin of the Metazoa

One theme we develop throughout this book is the evolutionary relationships within and among the invertebrate taxa. Life has probably existed on this planet for nearly 4 billion years; humans have been observing it scientifically for only a few hundred years, and evolutionarily for only about 150 years. Thus, the thread of evolutionary continuity we actually see around us today looks a bit like frazzled ends, representing the many successful animal lineages that survive today, but omitting the legions of extinct species and lineages whose identities could provide a clearer understanding of the history of life on Earth. It is only through conjecture, study, inference, and the testing of hypotheses that we are able to trace phylogenetic strands back in time, joining them at various points to produce hypothetical pathways of evolution. We do not operate blindly in this process, but use rigorous scientific methodology to draw upon information from many disciplines in attempts to make our evolutionary hypotheses meaningful and (we hope) increasingly closer to the truth — to the actual biotic history of Earth (Chapter 2).

In Chapter 1 we briefly reviewed the history of life, in part inferred from the fossil record, and in Chapter 28 we present a phylogenetic tree of the animal kingdom. However, many workers have not been satisfied to develop phylogenetic analyses based solely upon known (extant and extinct) animal groups, but have felt compelled to speculate on hypothetical ancestors that might have occurred along the evolutionary road to modern life. A variety of evolutionary stories have been proposed to describe these sequences of hypothetical metazoan ancestors. We discuss some of these below, and some key works are cited in the references at the end of this chapter and Chapter 28.

Origin of the Metazoan Condition

The origin of the metazoan condition has received attention for more than a century. One of the most spectacular phenomena in the fossil record is the abrupt diversification of nearly all of the metazoan phyla living today in a brief span of 30 million years, at the Precambrian Cambrian transition (approximately 570–600 million years ago). There is now little doubt that animals — the Metazoa — arose as a monophyletic group from a protist ancestor, 650 million years ago or earlier (Chapter 1). The debates now concern which protist group was ancestral to the first Metazoa, what these first animals were like, what environments they inhabited, and how the changes from unicellularity to multicellularity took place.

Historical Perspectives on Metazoan Origins

What intermediate forms might have linked protists and metazoans? Some authors have chosen to design logical but hypothetical creatures for this purpose. Others rummage among extant types, arguing the advantages of using "real" organisms. Although it is probable that the actual precursor of the Metazoa is long extinct, the existence of modern-day forms that combine protist and metazoan traits keeps this debate alive. These organisms include enigmatic multicellular animals of uncertain position, imagined and real colonial flagellates, and hypothetical multinucleate ciliates. Figure 5.14 illustrates some of these creatures for comparative purposes.

Before molecular tools convincingly linked protists to metazoan ancestry, several theories of metazoan evolution enjoyed support. In 1892, Johannes Frenzel

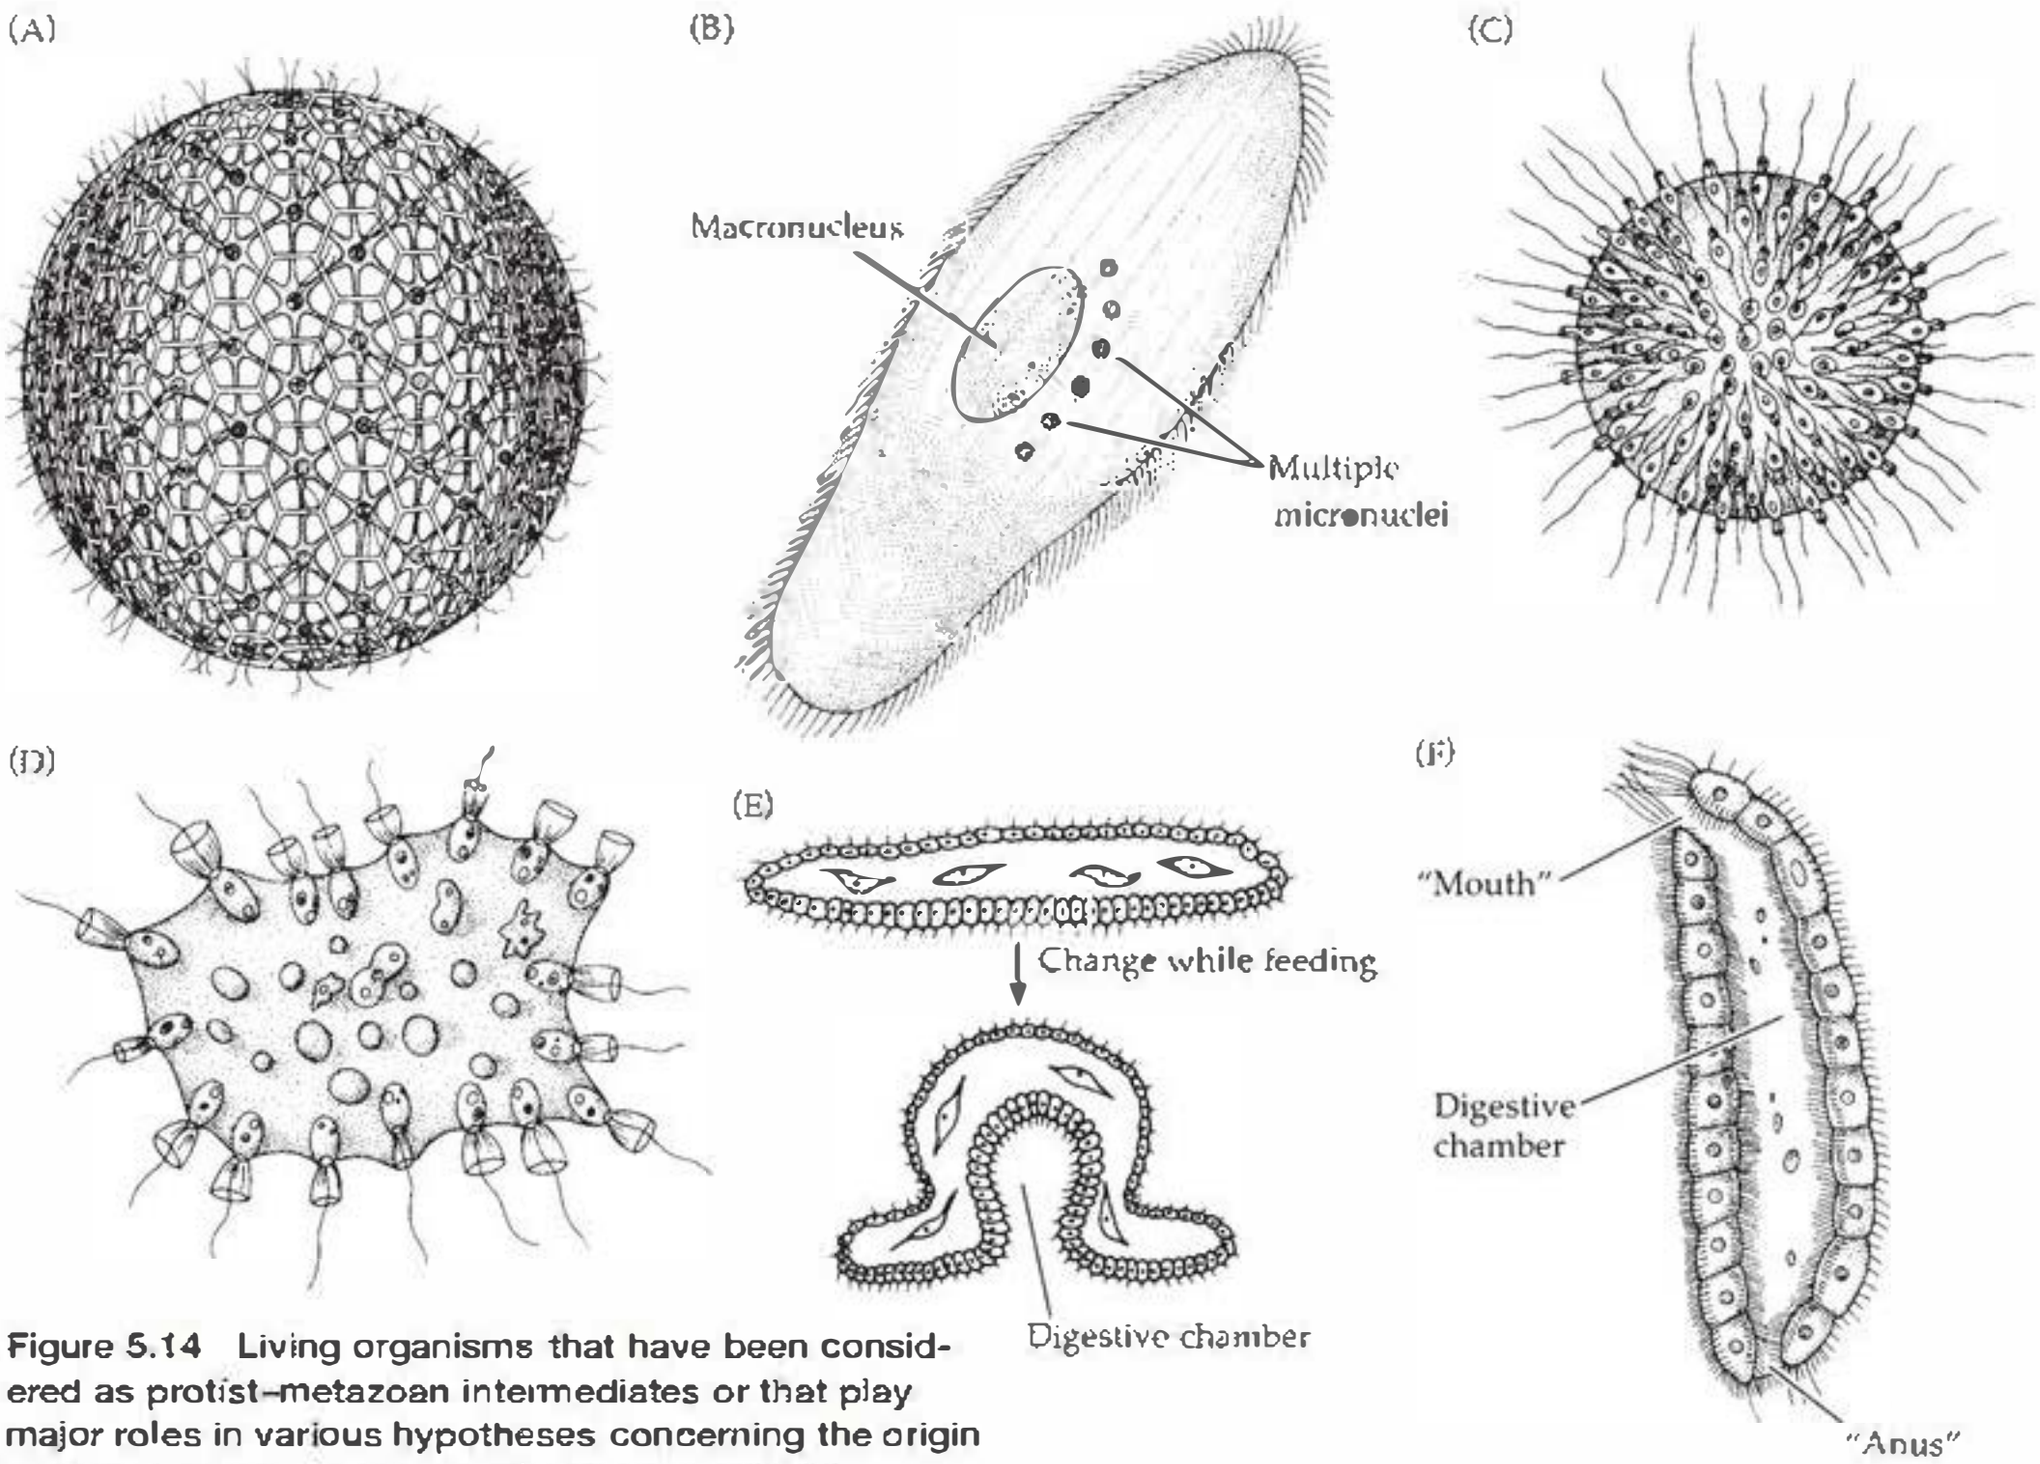

Figure 5.14 Living organisms that have been considered as protist–metazoan intermediates or that play major roles in various hypotheses concerning the origin of the metazoan condition. (A) *Volvox*, a colonial flagellate. (B) A multinucleate ciliate (*Paramecium*). (C,D) *Sphaeroeca volvox* and *Proterospongia*, two choanoflagellates. (E) *Trichoplax*. (F) *Salinella*. (G) A dycyemid rhombozoan. (H) An orthonectid.

described one such organism collected from salt beds in Argentina (Figure 5.14F). Tiny *Salinella* possessed a mouth and an anus, fed on organic detritus, and a single layer of cells formed its entire body wall. Although this creature lacked the layered cellular construction of the Metazoa, it displayed a higher level of organization than colonial protists, and the phylum Monoblastozoa was erected for it. Sadly, *Salinella* has not been seen since the original report, and many zoologists suspect that Frenzel seriously misinterpreted whatever creature he saw. Other so-called "mesozoan" phyla, Rhombozoa and Orthonectida (Figure 5.14G,H), are also structurally simple, but these animals are endoparasites of invertebrates and have complex life cycles. While possibly resembling early metazoans, most workers consider their body organization and life cycles, and their phylogenetic position to be more derived than ancestral.

The colonial theory of metazoan evolution was first expressed by Ernst Haeckel (1874), who proposed that a colonial flagellated protist gave rise to a planuloid metazoan ancestor (the planula is the basic larval type of cnidarians; see Chapter 7). The ancestral protist in this theory was a hollow sphere of flagellated cells that developed anterior–posterior locomotor orientation, and specialization of cells into separate somatic and reproductive functions. As we explain in Chapter 3, similar conditions are common in living colonial protists, including freshwater, colonial, photosynthetic flagellates such as *Volvox* (Figure 5.14A). Haeckel called this hypothetical protometazoan ancestor a blastea (Figure 5.15A) and supported its validity by noting the widespread occurrence of coeloblastulae among modern animals.

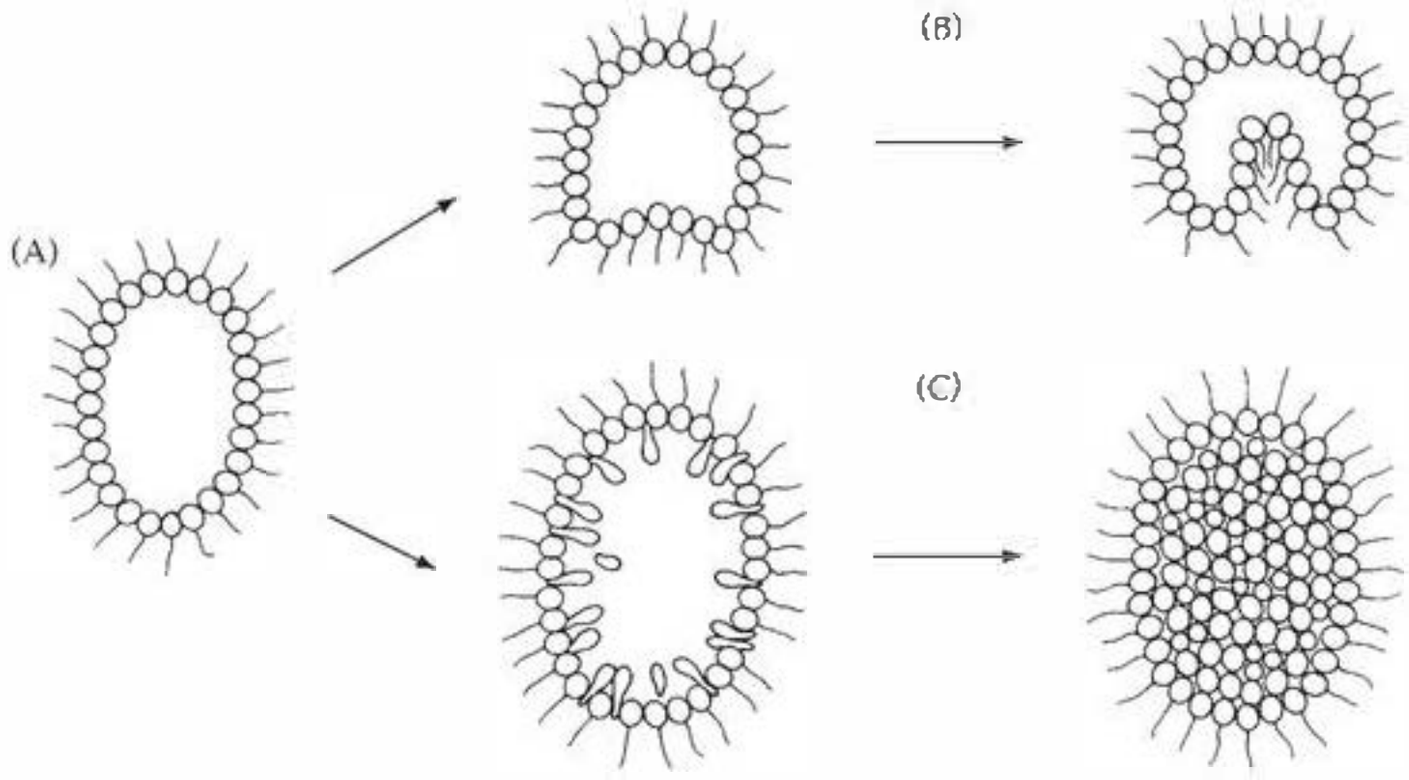

Figure 5.15 Two versions of the colonial theory of the origin of the Metazoa. (A) The hypothetical colonial flagellate ancestor, Haeckel's "blastea" (section). (B) According to Haeckel, the transition to a multicellular condition occurred by invagination, a developmental process that resulted in a hollow "gastrea." (C) According to Metschnikoff, the formation of a solid "gastrea" occurred by ingression.

In Haeckel's scenario, the first Metazoa arose by invagination of the blastea; the resulting animals had a double-layered, gastrula-like body (a **gastrea**) with a blastoporelike opening to the outside (Figure 5.15B) similar to the gastrulae of many modern animals. Haeckel believed that these ancestral creatures (the blastea and gastrea) were recapitulated in the ontogeny of modern animals, and the gastrea was viewed as the metazoan precursor to the cnidarians. It has been said that the monociliated cells of the body wall of Porifera and Cnidaria support this hypothesis. Haeckel's original ideas were somewhat modified over the years by various authors (e.g., Elias Metschnikoff, Libbie Hyman). Some have argued that the transition to a layered construction occurred by ingression rather than by invagination, and that the original Metazoa were solid, not hollow, based in large part on the view that ingression is the primitive form of gastrulation among cnidarians (Figure 4.15C).

In 1883, Otto Bütschli presented another variant of the colonial theory, a bilaterally symmetrical, flattened creature consisting of two cell layers, which fed by crawling over its food, and using its ventral layer as a digestive surface. Bütschli called this creature a **plakula**. In amazing support of the plakula hypothesis, a tiny, flagellated, multicellular creature was discovered in a marine aquarium in the early twentieth century. *Trichoplax adhaerens* was placed in its own phylum, the Placozoa (see Chapter 6), and like Bütschli's plakula has an outer, partly flagellated epithelium surrounding an inner mesenchymal cell mass. Its body margins are irregular, its cells show some specialization for somatic and reproductive function, and when feeding, *Trichoplax* "hunches up" to form a temporary digestive chamber on its underside (Figure 5.14E)—producing a form strikingly similar to Bütschli's hypothetical creature. While this hypothesis is compelling, molecular phylogenetic analyses do not place *Trichoplax* at the base of the metazoan tree.

In the 1950s and 60s J. Hadzi and E. D. Hanson envisioned the metazoan ancestor as a multinucleate, bilaterally symmetrical, benthic ciliate, crawling about with its oral groove directed toward the substratum. This syncytial theory, proposed that a cellular epidermis surrounding an inner syncytial mass could form if this creature's surface nuclei partitioned themselves off from one another with cell membranes, producing acoel worm-like creature. Arguments in support of this hypothesis rested upon similarities between modern ciliates and acoels (Chapter 9), including shape, symmetry, mouth location, surface ciliation and size; large ciliates are larger than small acoels. However, objections to this hypothesis were more convincing. Acoels undergo a complex embryonic development; nothing of this sort occurs in ciliates. Acoel guts are cellular, not syncytial. And molecular phylogenetics has shown acoels to be basal bilaterians, not primitive metazoans. Not surprisingly, the syncytial theory enjoys little support today.

The Origin of Multicellularity

Molecular phylogenetic studies have revealed that multicellularity likely evolved in at least a dozen or more eukaryotic clades, and has led to monophyletic lineages of such disparate groups as plants, animals, several different groups of amoebas, and others. Conditions favoring unicellularity persisted for protists over 1.5 billion years by most accounts until two events occurred. First, atmospheric oxygen of sufficient concentration to support multicellular organization became available due to the activities of photosynthetic algae. Second, predation pressure from heterotrophic protists, capable of phagocytizing or otherwise devouring other unicellular individuals, appears to have favored aggregation of cells after mitosis.

Once a tendency to aggregate arose, there appears to have been competition within individuals for certain functions If, as appears likely, the first multicellular animals were flagellated, these individuals faced a tradeoff between the ability to swim and the ability to engage in mitotic division. The cellular machinery for both functions appear to compete, as is evidenced even today by

the fact that animal cells bearing flagella or cilia never replicate until they have retracted and inactivated their flagellar or ciliary apparatus. In xenacoelomorphs, worn out ciliated epidermal cells are simply reabsorbed (Chapter 9). A balance may have arisen between the ability to move and the ability to replicate cells, favoring a tendency toward cellular specialization. If selection favored a shift in the location of non-flagellated cells toward the interior of the individual, with flagellated cells remaining outside, further specialization of internal cells may have become possible, necessitating the evolution of layers of cells with flexible ontogenetic fates, as well as biochemical mechanisms that distinguished or allowed particular cellular interactions.

Most evidence today points to the protist phylum Choanoflagellata as the likely ancestral group from which the Metazoa arose. Choanoflagellates possess collar cells essentially identical to those found in sponges. Choanoflagellate genera such as *Proterospongia*, *Sphaeroeca*, and others are animal-like colonial protists (Figure 5.14C,D) and are commonly cited as typifying a potential metazoan precursor. However, some recent molecular evidence suggests that ctenophores, not sponges, lie at the base of the metazoan tree. Clearly, debate on the emergence of Metazoa from their protist ancestor will continue for some time to come (Chapter 28).

The Origin of the Bilateral Condition and the Coelom

We discussed the functional significance of bilaterality briefly in Chapter 4. The evolution of an anterior–posterior body axis, unidirectional movement, and cephalization almost certainly coevolved to some degree, and probably coincided with the invasion of benthic environments and the development of creeping locomotion. Furthermore, the origin of the triploblastic condition likely took place soon after the appearance of the first bilateral forms. Among modern-day invertebrates, bilaterality and triploblasty generally co-occur.

Various hypotheses concerning the origin of coelom are summarized in R. B. Clark's fine book *Dynamics in Metazoan Evolution* (1964). Clark's personal approach was a functional one that emphasized the adaptive significance of the coelom as the central criterion for evaluating ideas concerning its origin. When early soft-bodied, bilaterally symmetrical animals larger than a few millimeters assumed a benthic, crawling, or burrowing lifestyle, a fluid (hydrostatic) skeleton was essential for certain types of movement. The evolution of a body cavity filled with fluid against which muscles could operate would have offered a tremendous locomotory advantage in addition to providing a circulatory medium and space for organ development. How might such spaces have originated?

Most of the ideas concerning the evolutionary origin of the coelom were developed from the mid-nineteenth to early twentieth century, during the heyday of comparative embryology. Most of these hypotheses shared the premise of monophyly—that the coelomic condition arose only once. The inherent problem with a monophyletic approach is the difficulty of relating existing coelomate animals to a single common coelomate ancestor. Considering the advantages of possessing a coelom, the very different methods of embryonic development (schizocoely and various forms of enterocoely), and the variety of adult coelomic body plans, it may be more biologically reasonable to suggest that the coelomic condition arose twice. There are several current ideas about how this might have happened, and a number of others have mostly been discarded as being incompatible with existing evidence or with our standard definition of the coelom.

The coelom may have originated by the pinching off and isolation of embryonic gut diverticula as occurs in the development of many extant enterocoelous animals (Figure 5.16). This so-called **enterocoel theory** (in several versions) enjoyed relatively strong support by many authors since it was originally proposed by Sir E. Ray Lankester in 1877. An obvious point in favor of this general idea is that enterocoely does occur in many living animals, thus retaining the hypothetical ancestral process. In addition, various authors cite examples

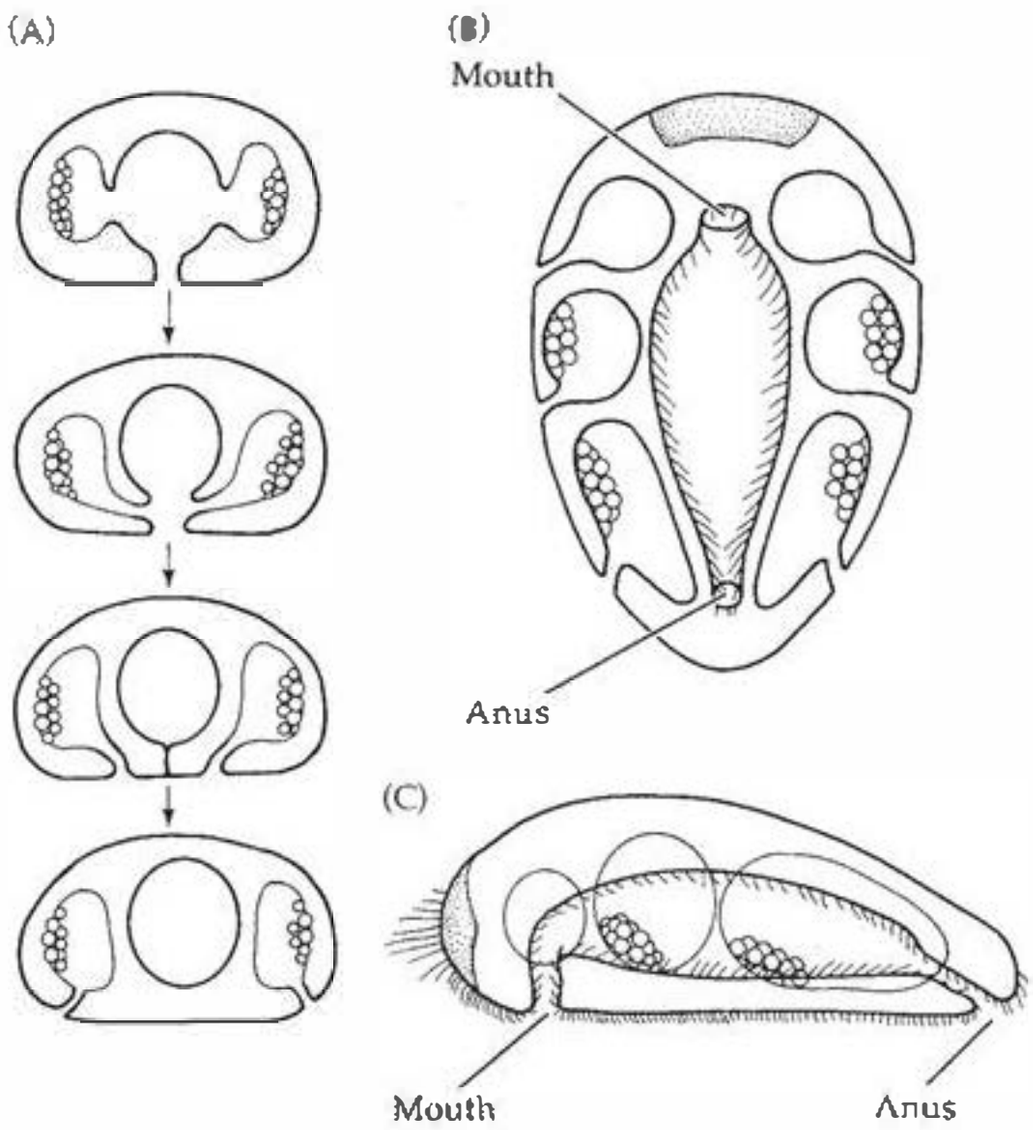

Figure 5.16 Jägersten's bilaterogastrea theory, according to which the coelomic compartments arise by enterocoelic pouching. (A) The formation of paired coeloms from the wall of the archenteron. The slitlike blastopore of the bilaterogastrea closes midventrally, leaving mouth and anus at opposite ends (B). (B,C) The tripartite coelomic condition in Jägersten's hypothetical early coelomate animal (ventral and lateral views).

of noncoelomate animals (anthozoans and flatworms) in which gut diverticula exist in arrangements that resemble possible ancestral patterns.

Another popular idea concerning coelom origin is the **gonocoel theory** (see publications by Bergh, Hatschek, Meyer, Goodrich and others). This hypothesis suggests that the first coelomic spaces arose by way of mesodermally derived gonadal cavities that persisted subsequent to the release of gametes (Figure 5.17). The serial arrangement of gonads, as seen in animals such as flatworms and nemerteans, could have resulted in serially arranged coelomic spaces and linings such as occurs in annelids, where they often still produce and store gametes. A major argument against this hypothesis is that in no modern-day coelomate animals do gonads develop before coelomic spaces. As we have seen, however, heterochrony can account for such turnabouts.

Another idea on coelom origin is called the **nephrocoel theory** (see publications by Lankester, Ziegler, Faussek, Snodgrass, and others). The association between the coelom and excretion has prompted different versions of this hypothesis through about 85 years of moderate support. One idea is that the protonephridia of flatworms expanded to coelomic cavities, arguing that the coelom first arose from ectodermally derived structures. Another view is that coelomic spaces arose as cavities within the mesoderm and served as storage areas for waste products. Certainly the coelomic cavities of many animals are related to excretory functions, but there is no convincing evidence that this relationship was the primary selective force in the origin of the coelomate condition.

Clark (1964) speculated that schizocoely, as we know it today, could have evolved by the formation of spaces within the solid mesoderm of acoelomate animals and then have been retained in response to the positive selection for the resulting hydrostatic skeleton. This is a very straightforward view, in part because, like the enterocoel theory, it accommodates a real developmental process.

As we mentioned earlier, these hypotheses share the fundamental constraint of arguing a monophyletic origin to all coelomate animals. The basic developmental differences between the two great clades of coelomate animals (the Protostomia and the Deuterostomia) suggest that the coelom may have arisen separately in these two lineages. Given the strong similarities between the coelomate Protostomia and acoelomorph worms, it is easy to envision the protostome clade arising from a triploblastic acoelomate ancestor. Hollowing of the mesoderm in such a precursor to produce fluid-filled hydrostatic spaces can be easily explained both developmentally (modern-day schizocoely) and functionally (peristaltic burrowing, increased size, and so on).

To derive the Deuterostomia and Protostomia from an immediate coelomate ancestor creates a

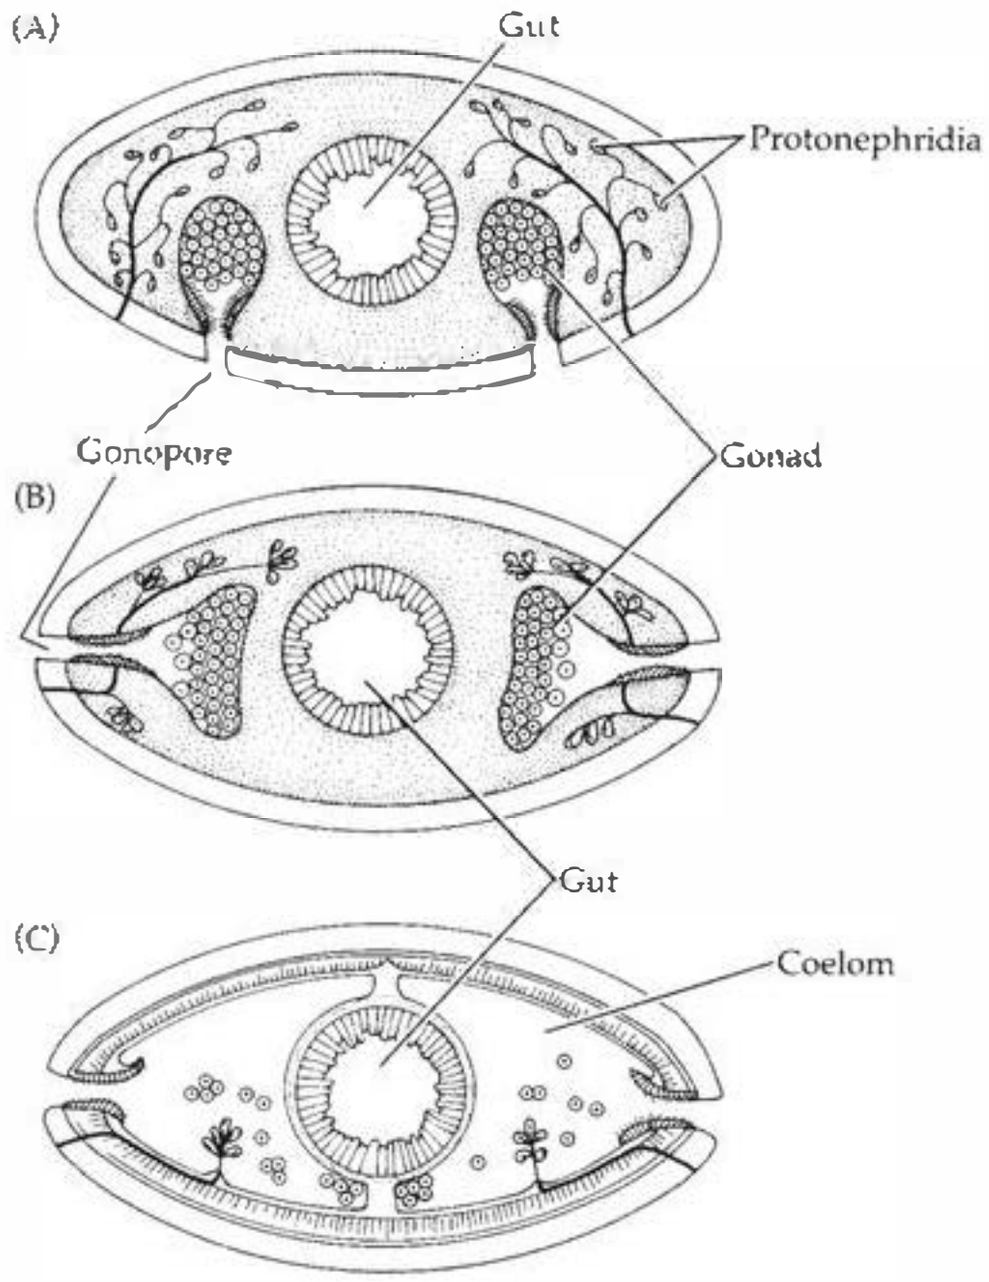

Figure 5.17 A version of the gonocoel theory (schematic cross sections). (A) The condition in flatworms, which have mesodermally derived gonads leading to ventral gonopores. (B) The condition in nemerteans, which have serially arranged gonadal masses leading to laterally placed gonopores. (C) The condition in polychaetes, in which the linings of the gonads have expanded to produce coelomic spaces with coelomoducts to the outside.

complicated scenario. The simplest hypothesis might be to view the deuterostome ancestor as a diploblastic animal, perhaps a planuloid form, in which enterocoely occurred. Deriving the Deuterostomia separately from the evolution of spiral cleavage and the other features of protostomes avoids many of the complications inherent in a monophyletic view of coelom origin. Imagine a hollow, invaginated, gastrula-like metazoan swimming with its blastopore trailing, as do the planula larvae of some cnidarians. Enterocoely may have accompanied a tendency toward benthic life, giving the animal a peristaltic burrowing ability. The archenteron may have then opened anteriorly as a mouth, and the new coelomate creature adopted a deposit-feeding lifestyle. If such a story began at the level of diploblastic Metazoa (e.g., cnidarians), then the radial cleavage seen today in the Bilataria was also present in the ancestor to that group.

The Trochaea Theory

The Danish zoologist Claus Nielsen has envisioned the two major bilaterian clades, Protostomia and Deutero-

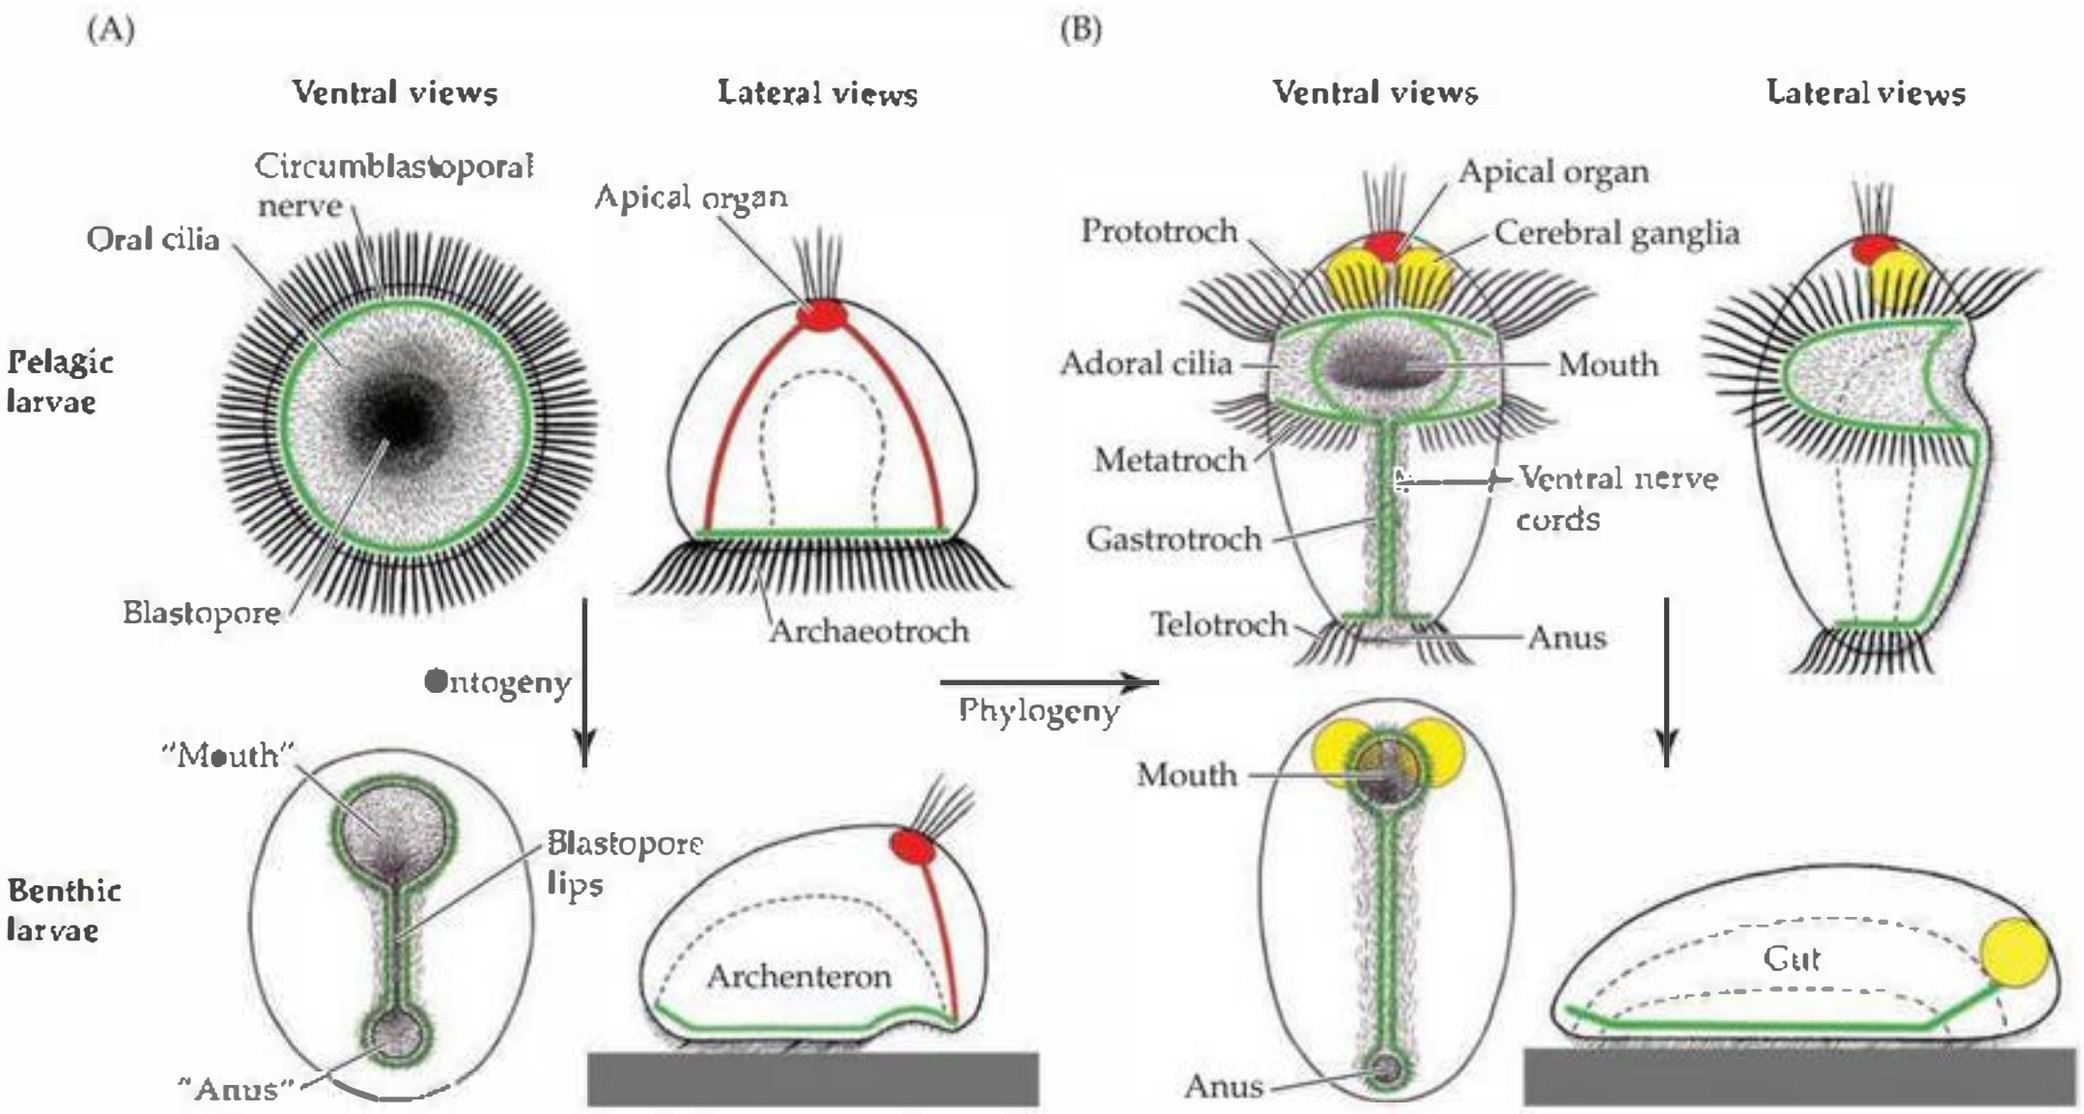

Figure 5.18 The Trochaea Theory. Ventral and lateral views of pelagic larvae and benthic adults predicted by Claus Nielsen's Trochaea Theory. (A) The upper drawings show the morphology of the holopelagic trochaea; the lower drawings illustrate the pelagobenthic life cycle of an early protostomian ancestor. (B) The upper drawings show the pelagic phase of the life cycle of the fully differentiated ancestral protostomian with a trochophore larva, the lower drawings show the benthic form of this animal. Apical organ red; cerebral ganglia yellow; blastoporal nervous system green

stomia, arising from an ancient common ancestor that conforms to Haeckel's radially symmetrical gastrea (see References section). Nielsen's theory proposes that Protostomia arose by way of at least two hypothetical ancestral forms, called the trochaea and the gastroneuron. The deuterostome line was originally believed to have led to the Deuterostomia by way of a hypothetical notoneuron ancestor. (The names gastroneuron and notoneuron referred to the ventral versus dorsal positions of the major nerve cords in most protostomes and deuterostomes, respectively.)

The theory provided a scenario of the evolution of the ancestral Protostomia, which possessed a trochophore larva and a ventral nervous system. The early ancestor in this model was a holopelagic planktotrophic gastraea with a ring of compound cilia (the archaeotroch) around the blastopore, which was used in swimming and particle collection by the downstream method (Figure 5.18A). After settling, the adult form of this animal was presumed to creep on the bottom, collecting detritus using monociliated cells around the blastopore. An anterior-posterior axis evolved along with the establishment of a creeping lifestyle. Transport of food particles into and out of the archenteron may have become enhanced by compression of the lateral blastopore lips, which were fused in the adult leaving an anterior mouth and a posterior anus (i.e., a through gut). This fusion of the blastopore lips may soon have become established in the larval stage. The archaeotroch was lost in the creeping adult but retained in the pelagic larva.

The anterior part of the archaeotroch around the mouth could have become laterally extended, with the anterior region becoming the prototroch and the posterior region the metatroch, bordering a lateral extension of the perioral ciliary area, the adoral ciliary zone (Figure 5.18B). Over evolutionary time, this may have created the characteristic trochophore ciliary feeding and swimming structures seen in modern protostomes, wherein the posterior part of the archaeotroch became the telotroch. The ciliary bands of the trochophores rely on downstream ciliary feeding, in which the larvae capture food particles from the water on the downstream side of the ciliary feeding bands, and these particles then are transported to the mouth by the adoral ciliary band. The lateral blastopore closure may have resulted in a differentiation of a circumblastoporal ring nerve into an anterior loop around the mouth, the paired (or secondarily fused) ventral nerve cords, and a small loop around the anus (in both the trochophore larvae and the adult). The brain of the trochophore and the adult ancestor consisted of the anteriormost part of the perioral nerve loop and a new paired structure, the large cerebral ganglion developing from the episphere of the larva, i.e., from the area in front of the prototroch.

Owing to the realization that Deuterostomia have the neural tube morphologically ventral, and that deuterostomy occurs in several phyla of Protostomia, Nielsen has revised his views on the origin of the former, and in the latest version of his theory the gastroneuron is seen as the latest common ancestor of *all* bilaterians.

As you can see, when one attempts to describe hypothetical ancestors, evolutionary analysis at the level of phyla can be convoluted and problematical. Many different viewpoints of the same phenomena will inevitably arise. We trust, however, that you have gained some insights not only into the particular hypotheses discussed here, but also into evolutionary speculation. A fundamental caveat should be kept in mind: any number of evolutionary pathways can be proposed and made to appear convincing on paper by imagining appropriate hypothetical ancestors or intermediates, but one must always ask whether these marvelous hypothetical creatures would have worked as functional organisms, and whether rigorous phylogenetic analyses support the hypotheses. Clark (1964) spends a good deal of time on this point and emphasizes it in his conclusion with the following passage (p. 258):

> *The most important and least considered of these [principles] is that hypothetical constructs which represent ancestral, generalized forms of modern groups, or stem forms from which several modern phyla diverge, must be possible animals. In other words, they must be conceived as living organisms, obeying the same principles that we have discovered in existing animals*

In such terms, evolutionary hypotheses can be evaluated. From a phylogenetic point of view, it may be best to avoid initial speculation on what a hypothetical ancestor might have looked like, and instead rely on the analysis of known taxa to establish genealogical relationships or branching patterns. Once a tree has been constructed, the pattern of features associated with the taxa on the tree will themselves predict the nature (character combination) of the ancestor for each branch. This method attempts to avoid the potential problem of circular reasoning, in which a hypothetical ancestor is established first and hence constrains and foretells the nature of the taxa descended from it. In either case, for the hypotheses to be truly scientific, they must be testable with new data gathered outside the framework of that used in their initial formulation.

CHAPTER 6

Two Basal Metazoan Phyla

Porifera and Placozoa

Chapters 1 through 5 provide a detailed introduction to the Metazoa (or Animalia). Metazoans are a monophyletic clade of eukaryotes—those creatures whose cells contain membrane-enclosed organelles and have a membrane-enclosed nucleus. However, they differ from other eukaryotes (i.e., fungi, plants, and the myriad protist clades) in their combination of multicellularity, heterotrophic and ingestive nutrition, and unique style of tissue formation through embryonic germ layering. Metazoans are **heterotrophic multicellular eukaryotes that undergo embryogenesis by way of tissue** layering. The formation of embryonic germ layers takes place through a process called gastrulation, and even the most primitive metazoans (e.g., sponges) undergo this process—metazoan gastrulation is a hallmark of this kingdom. Gastrulation is a process that achieves separation of those cells that must interact directly with the environment (e.g., locomotor, sensory, protective) from those that process materials obtained from the environment (e.g., nutritive functions).

As we noted in Chapter 1, Metazoa almost certainly constitutes a monophyletic clade, defined by numerous synapomorphies, including: gastrulation; unique modes of oogenesis and spermatogenesis; a unique sperm structure; mitochondrial gene reduction; epidermal epithelia with septate, tight, or zona adherens junctions; striate myofibrils; actin–myosin contractile elements; type IV collagen; and the presence of a basal lamina or basement membrane beneath epidermal layers (of course, some of these features have been secondarily lost in some groups). Evidence is strong that Metazoa are descended from the choanoflagellate protist group, or a common ancestor, and the two clades comprise sister groups in almost all recent phylogenetic analyses.

However, despite these fundamental shared similarities, there are four phyla of Metazoa that are so ancient and possess such a simple body construction that their relationships to other animals have so far eluded our understanding—these are the four non-bilaterian phyla: Porifera, Placozoa, Cnidaria, and Ctenophora. The first two (sponges and placozoans) are covered in this chapter,

Classification of The Animal Kingdom (Metazoa)

Non-Bilateria*
(a.k.a. the diploblasts)
- PHYLUM PORIFERA
- PHYLUM PLACOZOA
- PHYLUM CNIDARIA
- PHYLUM CTENOPHORA

Bilateria
(a.k.a. the triploblasts)
- PHYLUM XENACOELOMORPHA

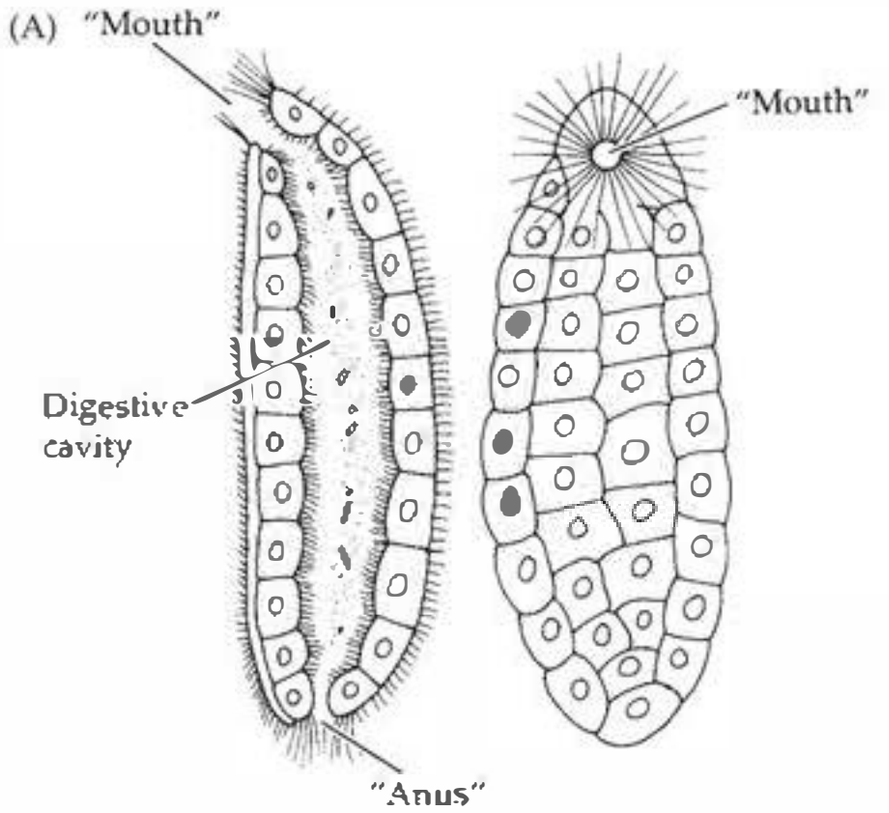
Protostomia
- PHYLUM CHAETOGNATHA

SPIRALIA
- PHYLUM PLATYHELMINTHES
- PHYLUM GASTROTRICHA
- PHYLUM RHOMBOZOA
- PHYLUM ORTHONECTIDA
- PHYLUM NEMERTEA
- PHYLUM MOLLUSCA
- PHYLUM ANNELIDA
- PHYLUM ENTOPROCTA
- PHYLUM CYCLIOPHORA

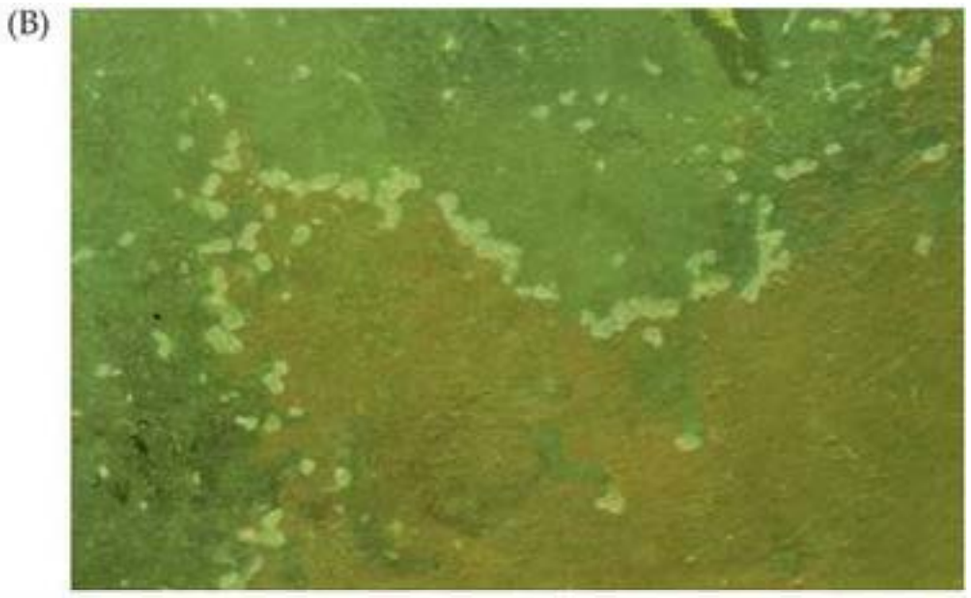
Gnathifera
- PHYLUM GNATHOSTOMULIDA
- PHYLUM MICROGNATHOZOA
- PHYLUM ROTIFERA

Lophophorata
- PHYLUM PHORONIDA
- PHYLUM BRYOZOA
- PHYLUM BRACHIOPODA

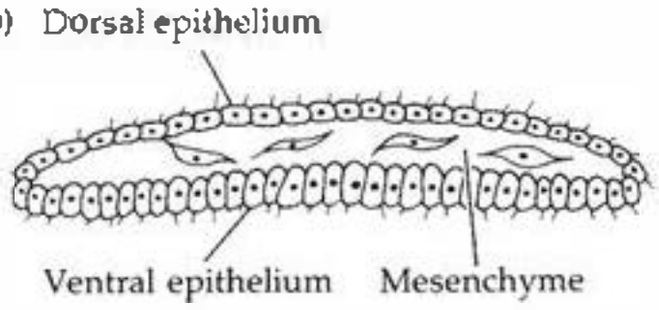
ECDYSOZOA



Nematoida
- PHYLUM NEMATODA
- PHYLUM NEMATOMORPHA



Scalidophora
- PHYLUM KINORHYNCHA
- PHYLUM PRIAPULA
- PHYLUM LORICIFERA



Panarthropoda
- PHYLUM TARDIGRADA
- PHYLUM ONYCHOPHORA
- PHYLUM ARTHROPODA
  - SUBPHYLUM CRUSTACEA*
  - SUBPHYLUM HEXAPODA
  - SUBPHYLUM MYRIAPODA
  - SUBPHYLUM CHELICERATA

Deuterostomia
- PHYLUM ECHINODERMATA
- PHYLUM HEMICHORDATA
- PHYLUM CHORDATA

*Paraphyletic group

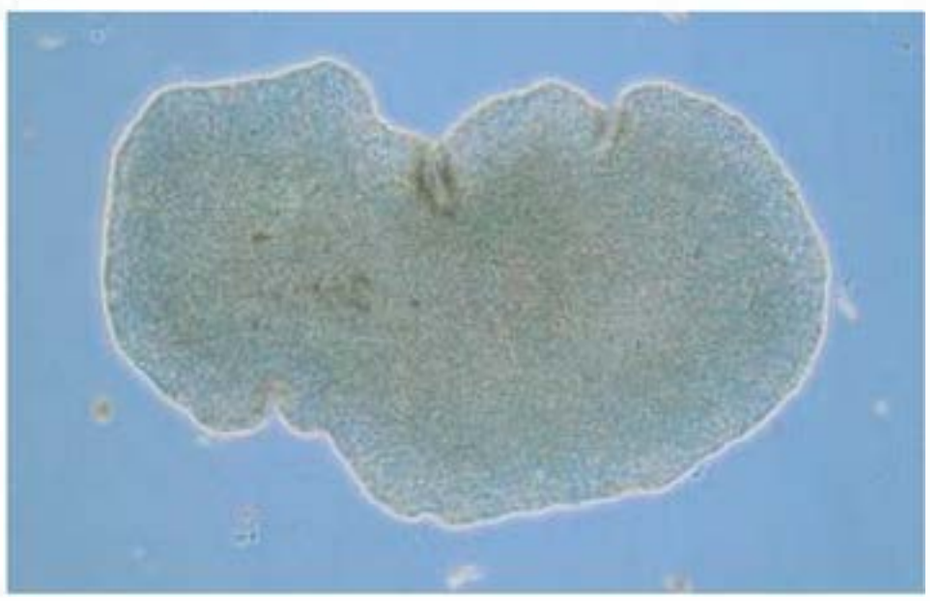


Figure 6.1 (A) The mysterious *Salinella* (Monoblastozoa) (sagittal section and lower view). (B) Several specimens of *Trichoplax adhaerens* (Placozoa) on an algal mat. (C) A single *Trichoplax*. (D) Section through *Trichoplax adhaerens*.

the next two in the following chapters. Phylogenetic analyses inform us that these four phyla are basal to all other Metazoa, and that Porifera is likely the oldest of all living animal phyla. In addition to lacking bilateral symmetry, these four phyla are generally considered to lack true mesoderm development, that is, they are diploblastic (rather than triploblastic) metazoans. Sponges and placozoans appear at the base of the animal tree in most analyses, and many workers consider these two phyla to lack true tissues of any kind, and also to lack a permanent digestive cavity, true nerves, and muscles. The Cnidaria, Ctenophora, and Bilateria are sometimes considered a monophyletic lineage called "Eumetazoa," but this does not seem like a very useful categorization.

One other enigmatic "phylum" was based on a microscopic creature named *Salinella salve*, from salt beds in Argentina. It was described by the German biologist Johannes Frenzel in the nineteenth century. Over the course of time, *Salinella* was treated as a protist and a larval stage of an unknown metazoan, but it was eventually assigned to its own monotypic phylum—Monoblastozoa. The single described species of *Salinella* has not been seen since its reported discovery in 1892, and there is serious question about the accuracy of the original description of this very odd beast. Many attempts have been made to rediscover *Salinella* without success. Yet, Frenzel was a serious scholar and a meticulous artist, leaving us with quite a mystery. One recent, unsuccessful expedition in search of this mystery animal, by another German scholar, Michael Schrödl, discovered that Frenzel had not actually collected the soil samples from which he cultured *Salinella* himself, but that they have been given to him by a geologist friend, adding further to the enigma.

According to Frenzel's description, the body wall of *Salinella* consists of only one or two layers of cells. The inner borders of the cells line a cavity, which is open at both ends (Figure 6.1A). The openings were said to function as an anterior "mouth" and posterior "anus," both of which are ringed by bristles. The rest of the body, inside and out, is densely ciliated. The animal was said to move by ciliary gliding, much like ciliated protists, small flatworms, and xenacoelomorphans (one of which Frenzel might have had under his microscope). *Salinella* was thought to feed by ingesting organic detritus through the "mouth" and digesting it in the internal cavity, undigested material being moved by cilia to the "anus" for expulsion. Asexual reproduction was said to take place by transverse fission of the body, and sexual reproduction was suspected to occur as well. The true nature of this animal, including its very existence, remains elusive. And the combination of characters he presented does not match up very well with anything we can imagine.

Phylum Placozoa

Trichoplax adhaerens was discovered by F. E. Schulze in 1883 in a seawater aquarium at the Graz Zoological Institute in Austria. Specimens have subsequently been found throughout the world's tropical and subtropical seas. A second species, *Treptoplax reptans*, was described in 1896, but has not been seen since. These creatures remained a mystery until the great German protozoologist Karl Grell, Director of the Zoology Institute at Tübingen, began working on them. Molecular genetics of *T. adhaerens* from around the world has recently suggested that this species could be a cryptic amalgamation of many species, yet to be distinguished morphologically. Box 6A lists the major characteristics of Placozoa.

BOX 6A Characteristics of the Phylum Placozoa

1. Minute, flattened metazoans comprised of ciliated upper and lower cell layers (epithelia layers?), with fibrous cells in between; adults asymmetrical. Only four somatic cell types have been identified.
2. Cells with desmosome cell-cell connections
3. With unique shiny spheres, possibly defensive structures, in upper cell layer
4. Without a structural nervous system, muscles, or digestive system

The body of *Trichoplax* is only 1 to 3 mm in diameter, although it consists of a few thousand cells, of only a few types, arranged as a simple double-layered plate (Figure 6.1B–D). It lacks anterior–posterior polarity, symmetry, a mouth or gut, nervous system, muscles, or extra-cellular matrix. However, the cells of the upper (top) and lower (bottom) layers differ in shape, and there is a consistent orientation of the body relative to the substratum. Because the concepts of dorsal and ventral are generally taken to be characteristics of triploblastic animals, we will use the terms upper and lower cells. The upper layer cells are flattened and monociliate, epithelium-like, and they have curious extracellular structures, called shiny spheres, unique to placozoans. Long thought to be lipid inclusions, they appear to be easily dislodged and fall out of the cell layer. In 2007, Vicki Buchsbaum Pearse and Oliver Voight reported that gastropods, flatworms, and sabellid polychaetes recoil upon contact with placozoans, suggesting they might possess a chemical deterrent to predators. In 2009, Alexis Jackson and Leo Buss tested this hypothesis, finding that when individual *Trichoplax* were fed to the hydrozoan *Podocoryna carnea*, the polyps became paralyzed, suggesting that the shiny spheres might indeed be anti-predator devices.

Most of the lower layer cells are also monociliate, but they are all more columnar and lack distinct shiny spheres; "gland cells" may also occur on the lower surface. Fiber cells can be seen between the upper and lower cell layers. These internal cells have thin extensions that connect to each other in a network. Cellular material such as microtubules and microfilaments traverse the extensions from fiber cell to fiber cell. It has been suggested that this network plays a role in coordinating movement of the animal. Importantly, desmosomes, cell–cell junctions of extracellular cell-adhesion proteins, have been found in placozoans, a feature not seen in Porifera, but present in all higher Metazoa.

The lower cell layer can be temporarily invaginated, presumably for feeding. This observation supports the notion that there are functional as well as structural differences between the two cell layers. Between these two cell layers (or, epithelial sheets) is a mesenchymal layer of stellate ameboid cells embedded in a supportive gel matrix. Grell (1982) considered *Trichoplax* to be a true diploblastic metazoan and suggested that the upper and lower cell layers were true epithelia and might be homologous to ectoderm and endoderm, respectively. However, a basement membrane has not yet been identified beneath either layer, which suggests that *Trichoplax* may be closer to the Porifera in organization than it is to Cnidaria, Ctenophora, or the triploblastic eumetazoa. No fossil placozoans have been found.

Trichoplax moves by ciliary gliding along a solid surface, aided by irregular, ameba-like shape changes along the body edges. Very small, presumably young individuals can swim, while larger individuals seem to always crawl. *Trichoplax* apparently feeds by phagocytosis of organic detritus using the lower surface, which can contract to form a "feeding chamber." Although there is no evidence of extracellular digestion, it is possible that *Trichoplax* secretes digestive enzymes onto its food within the lower digestive pocket. It is not known what these animals eat in nature, but lab cultures can be sustained on diets of flagellated protists (e.g., *Cryptomonas*, *Chlorella*).

Trichoplax reproduces asexually by fission of the entire body into two new individuals, and also by a budding process that yields numerous multicellular flagellated "swarmers," each of which forms a new individual. It is also capable of regeneration from damage to the body. Sexual reproduction is also known, followed by a developmental period of holoblastic cell division and growth. Eggs have been observed within the mesenchyme, but their origin is unknown.

With only four somatic cell types and a lack of defined symmetry or constant body axis, *Trichoplax* has the simplest body of any known metazoan. Over the years, it has been suggested that *Trichoplax* might be a secondarily reduced cnidarian (or a sister group to the Cnidaria). However, the more highly-derived

cnidarians (Scyphozoa, Hydrozoa, Cubozoa) all have a linear mtDNA molecule—a unique synapomorphy of that clade within Cnidaria in contrast to the circular mtDNA of Anthozoa and all other Metazoa. *Trichoplax* also has circular mtDNA. Further, the secondary structure morphology of the 16S mitochondrial genome of *Trichoplax* differs markedly from that seen in Cnidarians. Most recently, phylogenomic analyses have suggested that Placozoa are not cnidarians, but do lie near the base of the metazoan tree, among the other non-bilaterian phyla. The exact position among these four basal phyla was, at the time this book was being written, still unresolved, with the two strongest arguments favoring it branching off between a basal Porifera and the Cnidaria + Ctenophora, or positioning it as a sister group to the Bilateria. Surprisingly, a 2008 genomic study showed that *Trichoplax* has many of the genes responsible for guiding the development of body shape and organ development in higher metazoans, as has also been shown for many cnidarians. And, curiously, a shift from circular to linear mitochondrial genomes also occurred in a clade of calcareous sponges.

Phylum Porifera: The Sponges

The phylum Porifera (Latin *porus*, "pore"; *ferre*, "to bear") comprises those odd but fascinating animals called sponges. At first glance, sponges may seem difficult to reconcile within the animal kingdom adults lack a gut, conventional muscles, nerves and conventional neuronal signaling systems, typical metazoan organs, gap junctions between cells, an obvious anterior–posterior polarity (except in larvae), and some of the key metazoan developmental genes. In addition, they have crossstriated ciliary rootlets in larval cells and choanocytes a feature characteristic of many protists. However, they do possess the metazoan-defining attributes of multicellularity derived by embryonic layering, specialized junctions between cells, actin myosin contractile elements, and type IV collagen. In addition, recent genomic analyses of *Amphimedon queenslandica* (class Demospongiae) and *Oscarella carmela* (class Homoscleromorpha) reveal the presence of certain key homeobox genes, and representatives of most higher metazoan molecules involved in cell–cell communication, signaling pathways, complex epithelia, and immune recognition. They also undergo typical animal like sexual reproduction, and the development of embryos through a structured series of cellular divisions (cell cleavages) that result in a spatially organized larva with multiple cell layers and sensory capabilities. Most larvae have an obvious anterior posterior symmetry, and many adult sponges possess an apical–basal symmetry, or polarity, defined by the presence of a large osculum at one end (although the positions of oscula are often dictated purely by hydrodynamic forces in the environment). Others show such polarity by virtue of their pedunculate or pinnate growth form, often even with stems/stalks and root-like structures. On the other hand, many sponges have no symmetry whatsoever as adults. Molecular genetic analyses indicate Porifera is monophyletic and clearly within Metazoa. In fact, sponge genes have been recently discovered that are implicated in regulating anterior posterior polarity and specifying particular tissues during the development of other basal metazoans, supporting the contention that sponges undergo true gastrulation during embryogenesis. Figure 6.2 illustrates a variety of sponge body forms and some sponge anatomy. Box 6B lists the major characteristics of sponges.

Sponges are sessile, primarily suspension-feeding, multicellular animals that utilize flagellated cells called

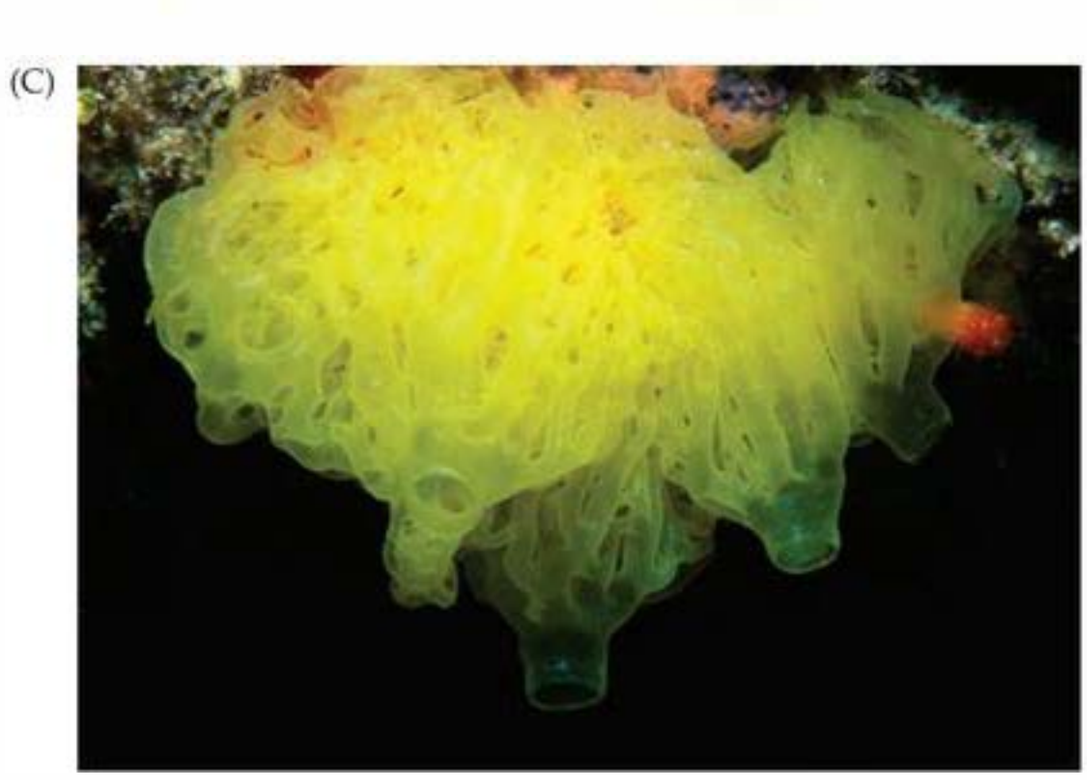
BOX 6B Characteristics of the Phylum Porifera

1. Metazoa partly at the cellular grade of construction, with simple tissues, but with a high degree of cellular pluripotency; adults asymmetrical or with a distinct apical-basal axis (often superficially appearing as radially symmetrical); larvae usually with anterior posterior symmetry
2. Cells with adhaerens junctions in some species, but without gap junctions
3. With unique flagellated cells—choanocytes—that drive water through canals and chambers constituting the aquiferous system
4. Adults are primarily sessile suspension feeders; larval stages are motile and usually ecithotrophic.
5. Type IV collagen basement membranes occur in most Homoscleromorpha and also (to a lesser extent) in the other classes.
6. Middle layer—the mesohyl—is variable but always includes motile cells and usually some skeletal material
7. Skeletal elements, when present, are composed of calcium carbonate or silicon dioxide (typically in the form of spicules), and/or collagen fibers.
8. Without neurons; only true sense organ is the osculum, which utilizes primary cilia to detect water flow rates
9. Ciliated cells of adult sponges bear only a single cilium (largely lacking the rootlet system seen in higher metazoans); some larvae with cilia that have rootlet systems; some larvae with ciliated cells on surface (postulated by some workers to be products of defective cell division)
10. Porifera is one of the few animal phyla to possess both cilia (e.g., larval epithelial cells, adult osculer epithelium) and flagella (e.g., adult choanocytes) in somatic tissues.

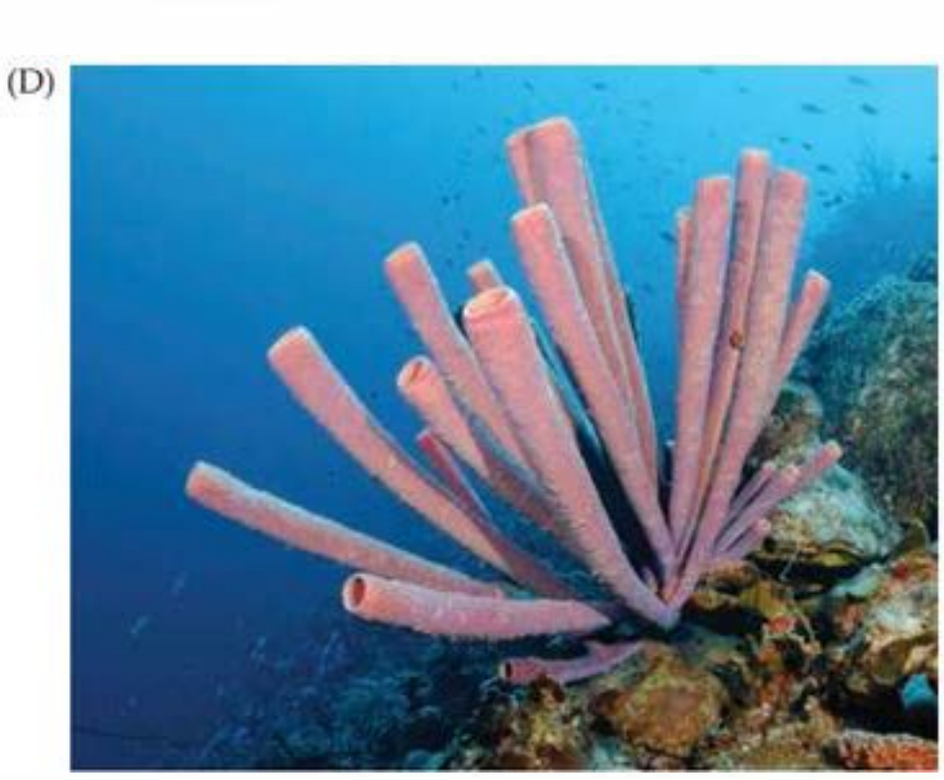
choanocytes to circulate water through a unique system of water canals Most rely on an internal skeleton of calcium carbonate or silicon dioxide spicules to support their body, which can be quite large It was long thought that Porifera lacked distinct embryological germ layering that leads to definable tissues, a condition sometimes referred to as "the parazoan grade of body construction." However, we now know that sponges undergo distinct gastrulation events from which the adult tissues derive, and the old concept of "parazoa" is probably best laid to rest. However, some of the adult tissues in sponges are somewhat transmutable and not fixed, due to a degree of cellular pluripotency most cells are capable of changing form and function, and some are kept in a totipotent state to be recruited "on demand" (although pinacocytes and sclerocytes cannot do so). So, despite the fact that sponges are large bodied multicellular animals typically supported by an internal skeleton of spicules or stiffened collagen (spongin), in some ways they function like organisms at the unicellular grade of complexity. In fact, as you will discover in this chapter, their nutrition, gas exchange, and response to environmental stimuli are all very protist like. So, superficially, sponges might be viewed as tight consortiums of semi autonomous cells, and thus quite simple animals. But, appearances can be deceiving. Read on.

Despite their seeming simplicity, sponges have experimented with various aspects of higher metazoan body organization, and they have developed primitive tissues, a sparse basement membrane, and in some species even predatory behaviors, and other features typical of the higher Metazoa. Some might argue that poriferans are "caught between two worlds"—the world of protists and the world of higher metazoans—while others would argue they are Metazoans in every sense of the word.

One of the most remarkable attributes of sponges is their tendency to maintain symbiotic relationships with a variety of heterotrophic and autotrophic Bacteria, Archaea, and Protista. Some of these intimate relationships have developed to the point that more biomass is actually contributed by the symbiont than by the sponge, and in these species microscopic examination of the sponge reveals mostly cells of microbes! We are just beginning to explore this community hidden within sponges, but already hundreds of symbiotic species, in over a dozen bacterial and archaean phyla (and several protistan groups) have been documented. As the role of microorganisms in sponges begins to be better understood, the emerging evidence suggests strong mutualism in many cases. Sponges of different types, in different ocean basins, seem to host strikingly similar microbial communities, suggesting the symbiotic relationships are very old. And some of these microbes appear to be transported in the eggs, nurse cells, and even sperm of sponges.



Sponges produce the largest and most diverse storehouse of secondary metabolites of any animal phylum—compounds that function to deter predators, prevent fouling of the sponge's surface, screen ultraviolet radiation, and nurture their symbiotic partnerships. Some sponges even "walk" over rocks, using lobelike extensions of the body that grow and elongate and then disappear, sometimes leaving separate living pieces—progeny—in their wake. At least one lineage of sponges, possibly more, has taken a dramatic evolutionary turn and become predatory carnivores; instead of filter feeding, these magnificent creatures are carnivores that capture and engulf small prey that are caught on highly specialized Velcro like surfaces. Well over 100 species of carnivorous sponges have been described, mainly in the deepsea family Cladorhizidae and two other small carnivorous families.



As of this writing, nearly 9,000 living species of sponges have been described, all but about 220 (the freshwater species) being restricted to benthic marine environments. Freshwater species occur at all latitudes, from deserts to equatorial rainforests, and from sea level to alpine lakes and even subterranean habitats. About 60 new sponge species are described each year It has been estimated that less than half of the living species have so far been described. Sponges occur at all depths, but are most abundant in unpolluted littoral and tropical reef habitats, cold temperate continental shelf regions, and Antarctic seas. However, deepwater "sponge grounds" are also important components of deep-sea ecosystems. Most littoral sponges grow as thick or thin layers, or as erect structures, on hard surfaces. Sponges that live on soft substrata typically are upright and tall, or possess funnel-like structures on top of a buried basal body, thus avoiding burial by the shifting sediments of their environment.

Some sponges reach considerable size (up to 2 m in height on Caribbean reefs, and even larger in Antarctica) and may constitute a significant portion of the benthic structure and biomass. In Antarctic seas, sponges can make up almost 75% of the total benthic biomass at a depth of 100 200 m. Areas of the deep Antarctic shelf have been called "sponge kingdoms," and here over 300 species have been recorded with high biomass and density. Subtidal and deeper water species that do not confront strong tidal currents or surge are often large and exhibit a stable, even symmetrical (radial), external form. The deeper water hexactinellid sponges often assume unusual shapes, many being delicate glasslike structures, others round and massive, and still others growing in a ropelike fashion. Siliceous sponge reefs have been documented from several periods in Earth history, and they culminated in the Late Jurassic when they formed a discontinuous deep water reef belt extending more than 7,000 km. This reef system was the largest biotic structure ever built on Earth (at 2,000 km, the Great Barrier Reef

of Australia is relatively small compared to the Jurassic sponge reef belt).

Sponges display nearly every color imaginable, including bright lavenders, blues, yellows, crimsons, and pure white. In many species it is the symbiotic bacteria or algae that give color to their host's body, especially in the tropics. And, sponges are the only phylum of animals that utilize silica, rather than calcium, in their mineral skeleton (in Demospongiae, Homoscleromorpha, and Hexactinellida). In one of the four classes of sponges, Calcarea, the skeleton is composed not of siliceous spicules but of calcium carbonate spicules (although a few species in other sponge classes are known to secrete a firm calcium carbonate base, upon which the siliceous skeleton rests).

Taxonomic History and Classification

The sessile nature of sponges, and their often amorphous or asymmetrical growth form convinced early naturalists that they were plants. It was not until 1765, when the nature of their internal water currents was described, that sponges were recognized as animals. The great naturalists of the late eighteenth and early nineteenth centuries (e g , Jean-Baptiste Lamarck, Karl Linnaeus, Georges Cuvier) classified sponges under Zoophytes or Polypes, regarding them as allied to anthozoan cnidarians. Throughout much of the nineteenth century they were placed with cnidarians under the name Coelenterata or Radiata. The morphology and physiology of sponges were first adequately understood by R. E. Grant. Grant created for them the name Porifera, although other names were frequently used (e.g., Spongida, Spongiae, Spongiaria).

Historically, the classes of Porifera have been defined by the nature of their internal skeletons. Until recently, three classes of sponges had long been recognized: Calcarea, Hexactinellida, Demospongiae. For a couple of decades (1970–1990) some workers proposed another class, Sclerospongiae, which included those species that produce a solid, calcareous, rocklike matrix (in addition to the spicular skeleton) on which the living animal grows. Over a dozen species of living sclerosponges, also known as coralline sponges, have been described. Late in the twentieth century, ultrastructural work and DNA analyses showed that the class Sclerospongiae was actually a polyphyletic grouping and it was thus abandoned, its members relegated to the Calcarea and Demospongiae. Today, the "coralline sponges" are known to be the last survivors of otherwise extinct stromatoporids, sphinctozoans, and chaetetids ancient reef building sponges that were highly diversified in Paleozoic and Mesozoic seas. These ancient coralline sponges were probably among the first metazoans to produce a carbonate skeleton. In 2010, the distinctive nature of the Homoscleromorpha (formerly included within the Demospongiae) was seen to merit elevating this group to class status, thus establishing a fourth class of living Porifera.

Demospongiae is the largest sponge class, comprising 81% of the living species. Because of its size and morphological variability, the class Demospongiae presents the greatest number of problems for taxonomists. The only synapomorphy that distinguishes the class Demospongiae is the presence of a sponginbased skeleton, and yet not all species of demosponges possess this feature. For many years, spongologists followed the classification of C. Lévi, who created two subclasses of demosponges based upon reproductive modes, Tetractinomorpha and Ceractinomorpha. However, by the turn of the century these were widely recognized as polyphyletic. In the early twenty-first century, molecular phylogenetics showed both that the class is monophyletic (exclusive of Homoscleromorpha), and that it can be divided into three or four distinct subclasses as noted below.

Although the mainstay of sponge taxonomy has traditionally been the chemical composition, shape, ornamentation, dimensions, and localization of the spicules, additional kinds of information, including secondary metabolite chemistry, and more notably molecular systematics are now being used to develop phylogenetic hypotheses and higher classifications. Indeed, some sponge species lack spicules altogether (e.g., *Oscarella*, *Hexadella*, *Halisarca*), whereas many spicules types appear to be homoplasious among sponges (e.g , asters, acanthostyles, sigmata). Sponge specialists also are now using embryological, biochemical, histological, and cytological methods to diagnose and analyze the Porifera. In the past, the considerable difficulty in precisely setting the limits of some sponge species made poriferan taxonomy challenging. Sponges are famous for their paucity of reliable taxonomic characters, and even the great sponge taxonomist Arthur Dendy was known to frequently end a species diagnosis with a question mark.[1]

Since the advent of molecular phylogenetics, the fascinating world of poriferology has grown more tractable, and modern systematics is beginning to build a robust framework for this phylum. A few molecular phylogenetic studies of sponges suggested they might be paraphyletic, but that work considered a relatively small number of nuclear genes and larger studies have not supported that idea. In addition to resolving long-standing phylogenetic questions, molecular work has let to the discovery that many "cosmopolitan species" are, in fact, clusters of closely-related but distinct species.

[1]The term a "sleeze" of sponges was coined by Ristau (1978) to describe an aggregation of sponges, the usage is comparable to other such collect ve nouns that define animal groups (e g , flock, herd, gaggle).

In addition, since the 1970s important bioactive compounds have been discovered in sponges, many having potential pharmacological significance (e.g., antibacterial, antiviral, anti-inflammatory, antitumor, and cytotoxic compounds, as well as channel blockers and antifouling chemicals). The discovery of these natural products in sponges also has led to a renewed interest in the group.

PHYLUM PORIFERA

CLASS CALCAREA Calcareous sponges (Figure 6.2A–C). Spicules of mineral skeleton composed entirely of calcium carbonate laid down as calcite, secreted extracellularly within a collagenous sheath (but with no axial filament); skeletal elements often not differentiated into megascleres and microscleres; spicules usually 1-, 3-, or 4-rayed; body with asconoid, syconoid, or leuconoid construction; many species exhibit superficial radial symmetry around a long axis, but in others there is no visible axial symmetry; early cleavage is total and equal; embryonic cleavage patterns probably fundamentally radial; all studied species are viviparous. All marine; occurring at all latitudes. About 685 described species. Although embryogenesis and larval morphology of the two subclasses differ profoundly, molecular phylogenetics provides evidence that the class and both subclasses are monophyletic.

SUBCLASS CALCINEA Free-living larvae are hollow, flagellated "coeoblastulas" (calcoblastula); choanocyte nuclei located basally, and flagellum arises independent of nucleus (a presumptive synapomorphy of this subclass); with free, regular, triradiate spicules. (e.g., *Clathrina*, *Dendya*, *Leucascus*, *Leucetta*, *Soleneiscus*, the coraline genus *Murrayona*)

SUBCLASS CALCARONEA Free-living larvae are unique, parietally flagellated amphiblastulas, these typically forming by way of eversion of earlier stomoblastula a "prelarvae" (which are held internally)—a presumptive synapomorphy of this subclass; choanocyte nuclei apical, and flagellum arises directly from nucleus; spicules free or fused (e.g., *Amphoriscus*, *Grantia*, *Leucilla*, *Leucosolenia*, *Sycon* [= *Scypha*], the coralline genus *Petrobiona*)

CLASS HEXACTINELLIDA Glass sponges (Figure 6.2N,O,P). Skeleton composed of a large array of siliceous spicules of various shapes and sizes, secreted intracellularly around a square proteinaceous axial filament; spicules with fundamental 3-axon or 6-rayed symmetry (triaxonic); both megascleres and microscleres always present. Entire sponge formed by a single continuous syncytial tissue, the trabecular reticulum, which stretches from the outside or dermal membrane, to the inside or atrial membrane, enclosing the cellular components of the animal. Body wall cavernous, filled primarily with trabecular syncytium, connected via open and plugged cytoplasmic bridges to choanosome, with its flagellated chambers; external pinacoderm absent and replaced by a noncellular dermal membrane; choanosome with anucleate choanocytes embedded in a trabecular syncytium. All studied species are viviparous; some produce a uniquely hexactinellid larva, the trichimella. Long-lived, exclusively marine, usually vase- or tube-shaped (never encrusting), primarily deep water sponges (maximum diversity is at 300 to 600 m depth); 690 described species. Many species harbor Archaea-dominated microbial communities within their bodies. The hexactinellid body plan is perhaps the most unusual in the entire animal kingdom because nearly all the tissues in adults consist of a giant multinucleated syncytium that forms the inner and outer layers of the sponge, joined by cytoplasmic bridges to limited uninucleate cellular regions. Two subclasses

SUBCLASS AMPHIDISCOPHORA Body anchored in soft sediments by a basal tuft or tufts of spicules; megascleres are discrete spicules, never fused into a rigid network; with birotulate microscleres, never hexasters (e.g., *Hyalonema*, *Monorhaphis*, *Pheronema*)

SUBCLASS HEXASTEROPHORA Usually attached to hard substrata, but sometimes attached to sediments by a basal spicule tuft or mat; microscleres are hexasters; megascleres free, or can be fused into a rigid skeletal framework, in which case sponge may assume large and elaborate morphology (e.g., *Aphrocallistes*, *Caulophacus*, *Euplectella*, *Hexactinella*, *Leptophragmella*, *Lophocalyx*, *Rosella*, *Sympagella*)

CLASS DEMOSPONGIAE Demosponges (Figure 6.2D–M). With siliceous spicules and/or an organic skeleton (or, occasionally, with neither) or in some groups, a solid calcitic skeleton; spicules secreted intra- or extracellularly around a triangular or hexagonal axial filament; spicules never 6 rayed (i.e., not triaxons); organic skeleton a collagenous network ("spongin"); most produce parenchymella larvae (Figure 6.1I); viviparous or oviparous (oviparous species occur in the subclasses Myxospongiae, Haploscleromorpha and Heteroscleromorpha); marine, brackish, or freshwater sponges occurring at all depths. Many species exhibit a mesohyl community of Eubacteria, many Proteobacteria and gram positive bacteria, as well as species of Archaea. About 7,400 described species. The two subclasses Tetractinomorpha and Ceractinomorpha, long recognized as polyphyletic, have recently been abandoned, and four new subclasses have been proposed: Keratosa, Myxospongiae, Haploscleromorpha, and Heteroscleromorpha. Molecular analyses to date support the monophyly of these new subclasses, although not all four have been uniquely defined morphologically.

SUBCLASS KERATOSA Skeleton of spongin fibers only, or with a hypercalcified skeleton (*Vacelella*). Spongin fibers either homogenous or pithed, and strongly laminated with pith grading into bark. Reproduction typically viviparous, larvae are parenchymella. All commercial sponges belong to this subclass (e.g., *Spongia*, *Hippospongia*, *Coscinoderma*, *Rhopaleoides*). Includes the two orders Dendroceratida (Darwinellidae: e.g., *Aplysilla*, *Darwinella*, *Dendrilla*; Dictyodendrillidae: e.g., *Dictyodendrilla*, *Spongionella*) and Dictyoceratida (Spongiidae: e.g., *Spongia*, *Hippospongia*, *Rhopaleoides*; Thorectidae: *Cacospongia*; *Thorecta*, *Phyllospongia*, *Carteriospongia*;

Ircini dae: e.g., *Ircinia*, *Sarcotragus*; Dyside dae: e.g., *Dysidea*, *Pleraplysilla*; Ver t cill tidae: *Vaceletia*)

SUBCLASS MYXOSPONGIAE (= VERONGIMORPHA) W thout a ske eton or with skeleton of spongin fibers on y (w th a aminated bark and finely fibr llar or granular p th); one genus with ske eton of s liceous asters (*Chondrilla*). All demosponges ack ng a ske eton belong to this subclass (e.g., *Chondrosia*, *Halisarca*, *Hexadella*, *Thymosi opsis*). Reproduct on ov parous Two or three orders are now recognized (e.g., *Aplysina*, *Aplysinella Chondrosia*, *Chondrilla*, *Halisarca*, *Hexadella*, *Ianthella*, *Suberea*, *Thymosia*, *Thymosiopsis*, *Verongula*).

SUBCLASS HAPLOSCLEROMORPHA With an isodictyal an sotropic or isotropic choanosoma ske eton; spicules diactinal megascleres (oxeas or strongyles); microscleres, f present, sigmas and/or toxas, microxeas or microstrongyles. Reproduct on typical y v v parous, w th the exception of some petrosid genera that are ov parous. Lar vae typically parenchymel a. Inc udes Ca c fibrospongia, prev ously assigned to Sc erospongiae. Inc udes only one order Haploscler da. Most of the famil es and genera are probab y po yphy etic, and this subc ass tse f is somet mes considered part of Heteroscleromorpha. Among the most common genera are: *Haliclona*, *Callyspongia*, *Petrosia*, *Xestospongia*, *Niphates*, *Amphimedon*, *Siphonochalina*, and a so *Calcifibrospongia*, *Dendroxea* and *Janulum*.

SUBCLASS HETEROSCLEROMORPHA Ske eton composed of siliceous spicules that can be monaxones and/or tetraxones and, when present, highly d vers fied m croscleres. Reproduct on mostly viviparous, but ov parous species occur in some genera (e g., *Agelas*, *Axinella*, *Raspailia*, *Suberites*). This subc ass contains most of the Demospongiae (about 5,000 spec es), usually organized into e ght orders. Most of the sponges once ass gned to Sc erospongiae are in th s subclass, including stromatoporoids (e.g., *Astrosclera*), tabu ates (*Merlia*, *Acanthochaetetes*), and ceratoporellids (e.g., *Ceratoporella*, *Goreauiella*, *Hispidopetra*, and *Stromatospongia*). The order Tetractinellida (*Astrophorina*, *Spirophorina* and most of the thist ds) ncludes all sponges with tetractine sp cu es (e.g., *Geodia*, *Penares*, *Stelletta*, *Tetilla*, *Cinachyra*, *Discodermia*). The freshwater sponge order Spongillida is here, which includes 220 spec es n six fam es (e.g., *Spongilla*, *Ephydatia*, *Lubomirskia*, *Metania*, *Potamolepis*). Other orders include: Poec losc erida (e g., *Clathria*, *Hymedesmia*, *Mycale*, *Myxilla*, *Desmacella*, *Asbestopluma*), Agelasida (e.g., *Agelas*, *Astrosclera*, *Hymerhabdia*, *Acanthostylotella*), Ax nel ida (e.g., *Axinella*, *Higginsia*, *Stelligera*, *Raspailia*, *Eurypon*, *Myrmekioderma*), B emnida (e.g., *Biemna*, *Neofibularia*, *Sigmaxinella*), Halichondr da (e.g., *Halichondria*, *Hymeniacidon*), and Hadromerida (e.g., *Cliona*, *Spirastrella*, *Tectitethya*, *Tethya*).

CLASS HOMOSCLEROMORPHA The most recent y proposed class of sponges, homoscleromorphs have been shown to be distinct (and monophy et c) on the basis of mo ecular phy ogenetics, anatomy, and emb yology (Figure 6.20B). Spongin skeleton always absent; r g d skeleton almost a ways absent, but when present composed of smal (mostly <100 µm) tetraxon (four often unequa rays) s liceous spicules cal ed calthrops,[2] s milar but dist nct from cer ain tetraxon sp cules seen in demosponges, or pecul ar r regular k nked oxeas (2 uneven rays); all spicules are of a similar size, with no d fferentiation into megasc eres and microsc eres (hence the class name); w th cil ated exopinacocytes and endopinacocytes; a type IV collagen basement membrane under es both choanoderm and pinacoderm (this type of collagen has a so been found in several species of demosponges and ca careans); zonu a adherens cell junctions n adult and larval epithelia; spermatozo ds with an acrosome; choanocyte chambers oval to spher cal, w th large choanocytes To date, septate junctions have not been found in th s class. Homosc eromorphs are viviparous (ncubate ther embryos) form a hol ow blastula by multipo ar egression, and deve op a unique cinctob astula lar va. A though some work had suggested th s group might be more close y all ed with h gher metazoans than w th other sponges, recent stud es based on complete m tochondria genome sequences strong y support ts inclus on with n a monophy etic Por fera, perhaps most c ose y re ated to the Calcarea. About 85 known species of exclusively marine sponges, d v ded into two monophylet c fami ies, Plak nidae (sp culate species) and Oscarell dae (aspiculate species). Most species inhab t hard bottoms of the cont nenta she f, but some are known from more than 1,000 m depth. The fossil record, poor as t is, dates from the early Carbon ferous. About 90 species (e.g., *Corticium Oscarella*, *Placinolopha*, *Plakina Plakinastrella*, *Plakortis*, *Pseudocorticium*).

The Poriferan Body Plan

A mind boggling diversity exists in the shape, color, and size of sponges. Increases in size and surface area are accomplished by folding of the body wall into a variety of patterns, and also from different growth pat terns that appear in response to environmental conditions. This plasticity, plus the fact that sponges maintain certain cells in a pluripotent state, compensate in part for the absence of true organs. Two unique organizational attributes define sponges and have played major roles in poriferan success: first is the water cur rent channel system, or aquiferous system, and its unique all-purpose cells (pumping, feeding, gas-exchange, and waste-expulsion) known as choanocytes.

[2] A "caltrop" or "calthrop" was an evil looking medieval land mine, consisting mainly of four short, sharpened spikes radiating from a common center at equal angles. These were scattered in front of defensive positions and covered under a thin layer of dirt, where they tended to inconvenience charging knights Homoscleromorph tetractine spicules often have the same general shape

Second is the highly pluripotent nature of sponge cells in general. The aquiferous system brings water through the sponge and close to the cells responsible for food gathering and gas exchange. At the same time, excretory and digestive wastes are expelled by way of the water currents. The volume of water moving through a sponge's aquiferous system is remarkable. A single 1 × 10 cm individual of the complex sponge *Leuconia* pumps about 23 liters of water through its body daily. Researchers have recorded sponge pumping rates that range from 0.002 to 0.84 ml of water per second per cubic centimeter of sponge body. Large sponges filter their own volume of water every 10 to 20 seconds.

The Hexactinellida ("glass sponges") might be the most unusual creatures in the entire animal kingdom. Their triaxonal spicules, with a square proteinaceous internal filament, distinguish them from other siliceous sponges. Their syncytial body, which arises by fusion of early embryonic cells, is unique among Metazoa. Both the larvae and adults have elegant combinations of multinucleate and cellular cytoplasmic regions unlike anything seen in any other animal. The continuity of this tissue allows food to be transported symplastically (analogous to plants), and it also allows electrical signals to travel throughout the sponge body (analogous to the nervous system of higher Metazoa).

Sponges are not colonial animals. Any and all sponge material bounded by a continuous outer covering (the pinacoderm) constitutes a single individual. The growth of each individual is dictated by a combination of genetics (e.g., most larvae have anterior posterior symmetry, many adults have a radial axial growth form) and environmental factors (e.g., water flow dynamics, contours of the substratum). For most sponges, changes in body form can arise anywhere in or on the organism in response to external factors.

Body Structure and the Aquiferous System

The outer surface cells of a sponge make up the pinacoderm and are called pinacocytes, typically unciliated flattened cells that are also known as "pavement cells." The pinacoderm can be considered a true epithelium. Most of the inner surfaces comprise the choanoderm and are composed of flagellated cells called choanocytes. Both of these layers are a single cell thick. Between these two thin cellular sheets is the mesohyl, which may be very thin in some encrusting sponges, or massive and thick in larger species (Figure 6.3). The pinacoderm is perforated by small holes called dermal pores or ostia (sing. ostium), depending on whether the opening is surrounded by several cells or one cell, respectively (Figure 6.3). Water is pulled through these openings and is driven across the choanoderm by the beating of the choanocyte flagella. The choanocytes pump large volumes of water through the sponge body, thus enabling the aquiferous system. The cost of sponges pushing so much water through the body has been estimated to be about one third of its overall metabolism.

Sponge choanocytes are thought to be fundamentally identical to cells of choanoflagellate protists (see Chapter 3). They originate during metamorphosis from the ciliated epithelial cells of larvae, and they can also derive from archaeocytes found in gemmules—in both cases, these precursor cells differentiate into choanoblasts that, in turn, grow collars to become choanocytes. Their long flagellum has a basal, bilaterally-arranged pair of wing-shaped projections called vanes. The flagellar vanes probably lend support to the flagellum. The flagellum is surrounded by a collar of microvilli containing actin filaments, the microvilli being connected to one another via a thin membrane composed of a meshwork of extracellular glycoprotein (the glycocalyx mesh) (Figure 6.8 F–H).[3]

A cuticle, or layer of coherent collagen, may cover the pinacoderm in some species. The pinacoderm itself is a simple external sheet (exopinacoderm) of cells (exopinacocytes), and it also lines some of the internal cavities of the aquiferous system where choanocytes do not occur. Pinacocytes that line internal canals form endopinacoderm and are called endopinacocytes. The choanoderm can be simple and continuous, or folded and subdivided in various ways. The mesohyl varies in thickness and plays vital roles in digestion, gamete production, secretion of the skeleton, and transport of nutrients and waste products by special ameboid cells. The mesohyl includes a noncellular colloidal mesoglea in which are embedded collagen fibers, spicules, and various cells; as such, it is really a type of mesenchyme. A great number of cell types may be found in the mesohyl. Most of these cells are able to change from one type to another as required, but some differentiate irreversibly, such as those that commit themselves to reproduction or to skeleton formation.

Some sponges actually move from one place to another ameboid cells along the base of the sponge "crawl," as others carry forward spicules to support the leading edge of the sponge. Studies suggest that some amoebocytes can actually break free from a sponge and move about on their own for a time, eventually returning to the parent sponge body. This "locomotion" in sponges obviously is not sufficient to provide them with a quick escape mechanism from predators; we're talking about millimeters a day here!

As a sponge grows, the pinacoderm and choanoderm remain only one cell thick. But by increasing

[3] Monociliated cells bearing a collar of microvilli surrounding the cilium have been found in almost all metazoan phyla. However, in other metazoans the cilium is usually immobile, lacks vanes, has a striated rootlet, and is frequently involved in sensory processes. It is therefore thought that such cells are not homologues to sponge choanocytes and choanoflagellate protists.

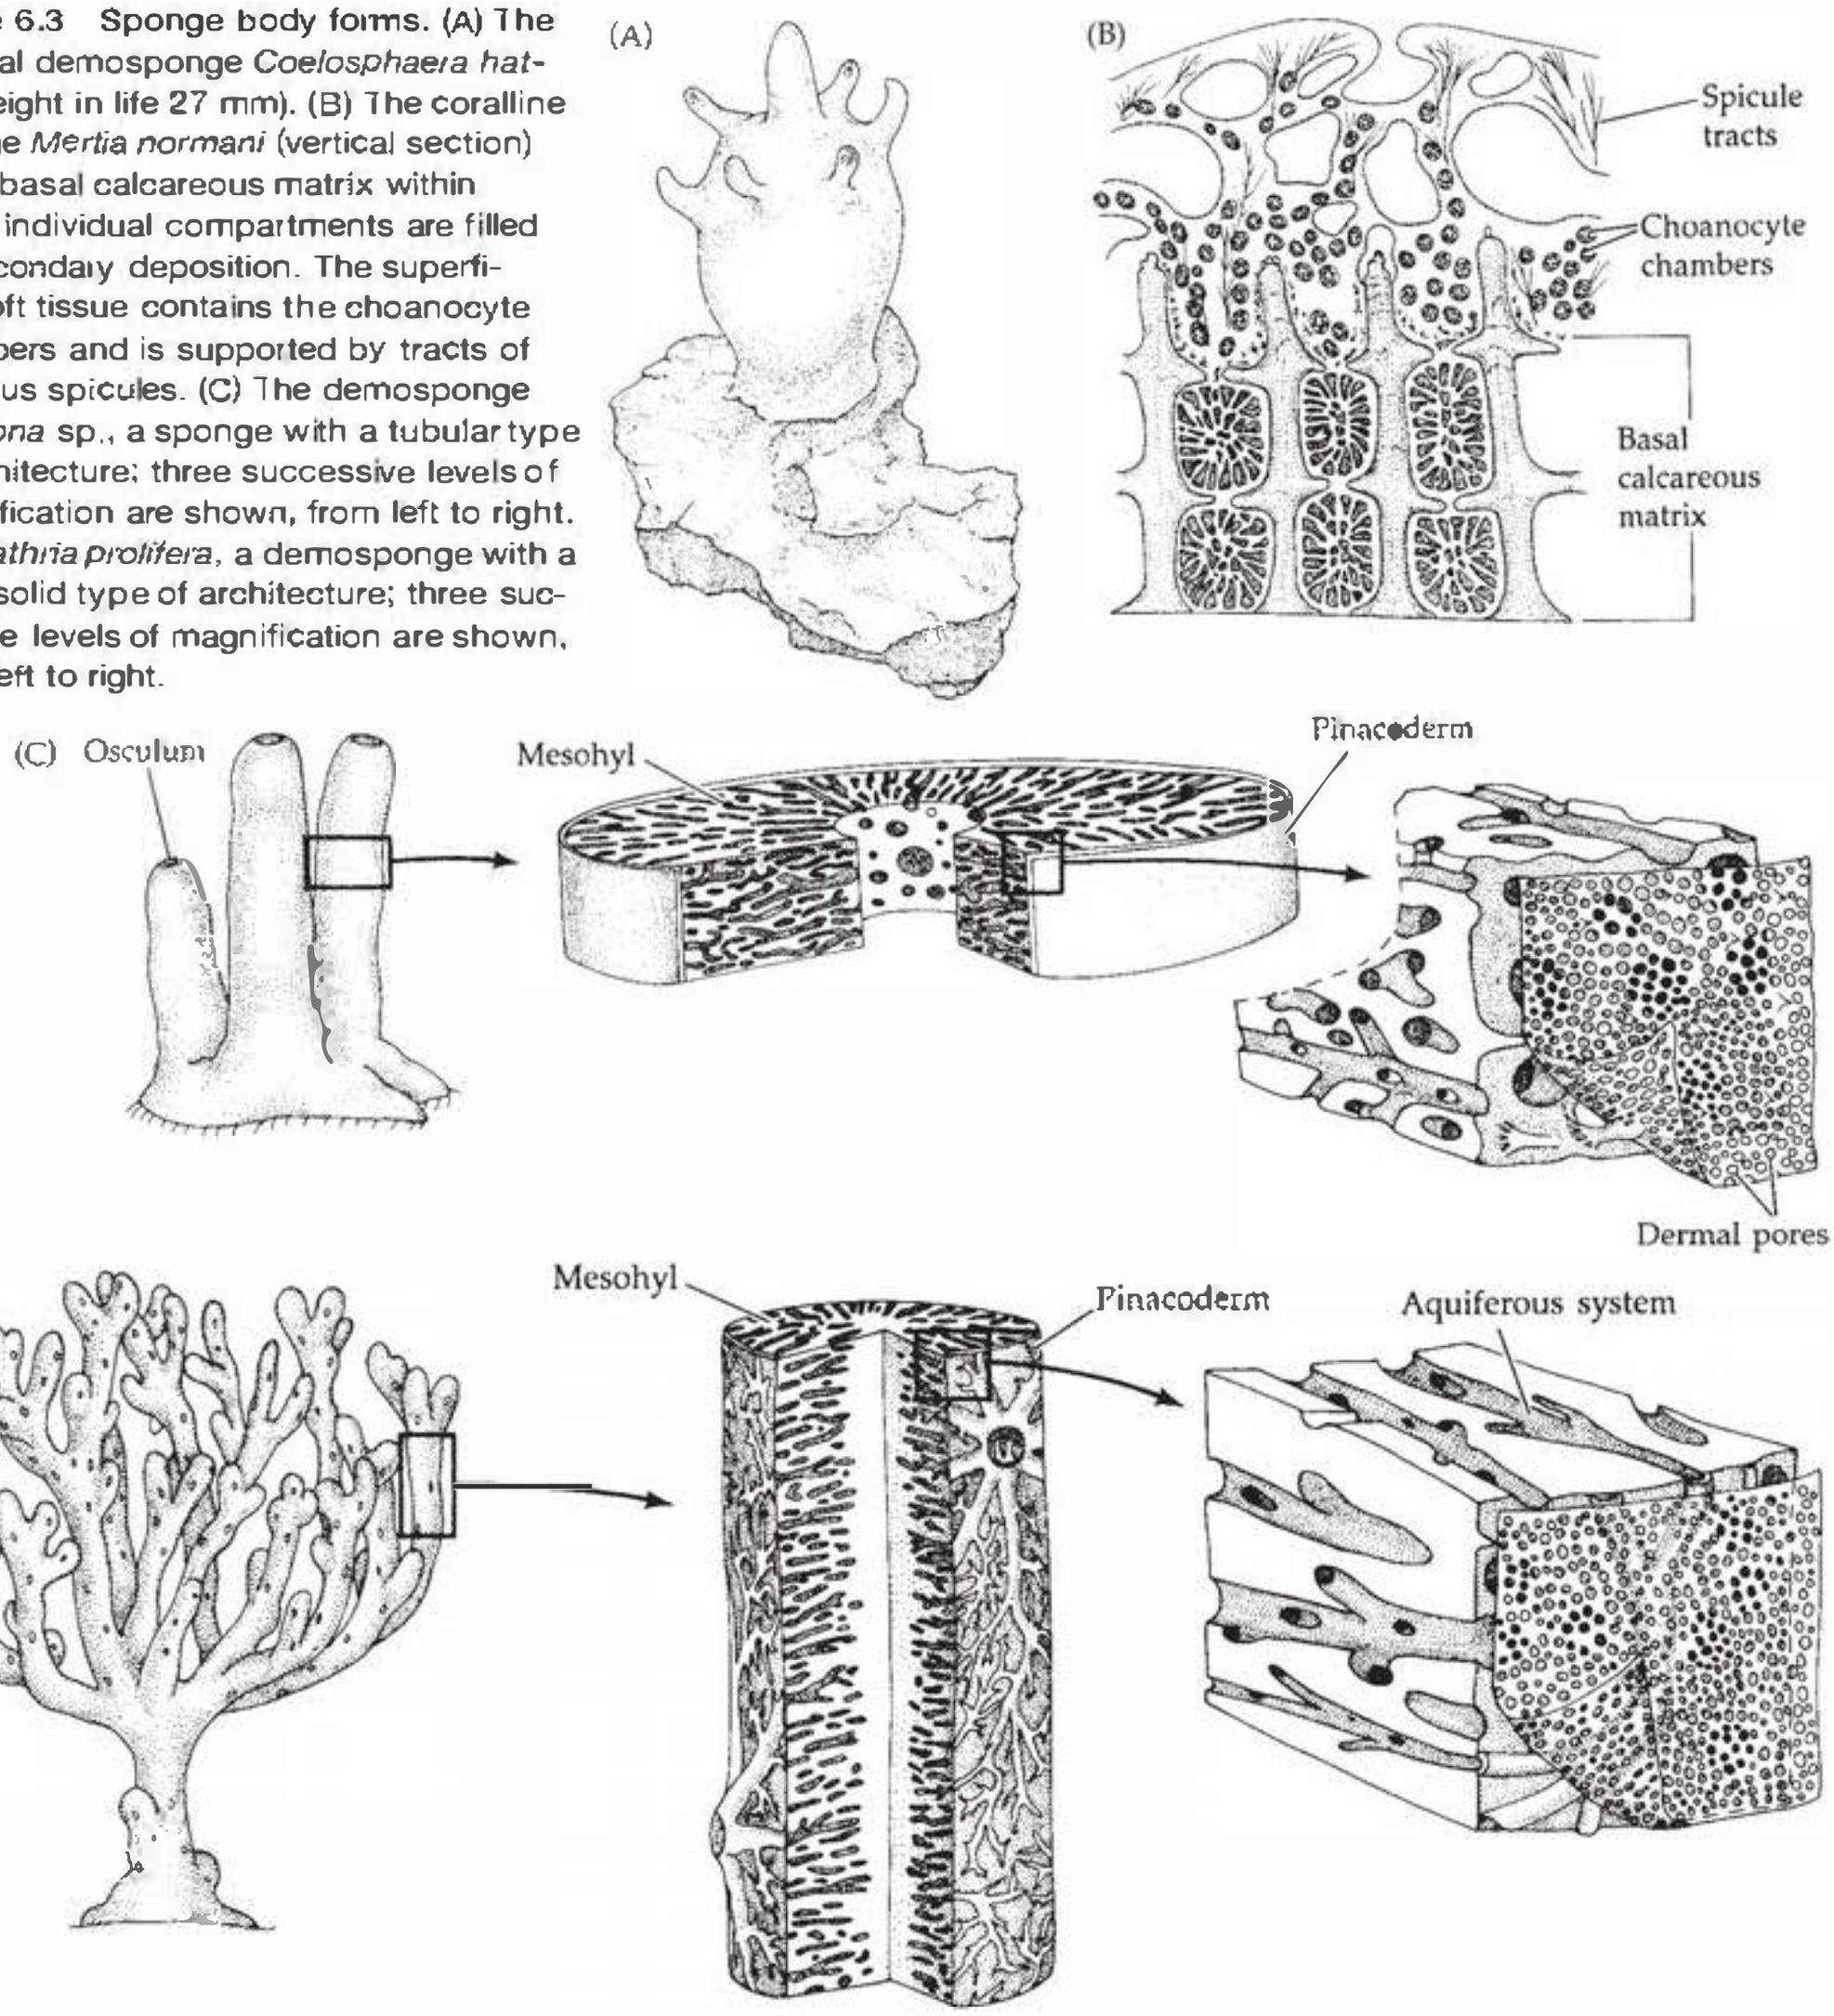

Figure 6.3 Sponge body forms. (A) The unusual demosponge *Coelosphaera hatchi* (height in life 27 mm). (B) The coralline sponge *Mertia normani* (vertical section) has a basal calcareous matrix within which individual compartments are filled by secondary deposition. The superficial soft tissue contains the choanocyte chambers and is supported by tracts of siliceous spicules. (C) The demosponge *Haliclona* sp., a sponge with a tubular type of architecture; three successive levels of magnification are shown, from left to right. (D) *Clathria prolifera*, a demosponge with a more solid type of architecture; three successive levels of magnification are shown, from left to right.

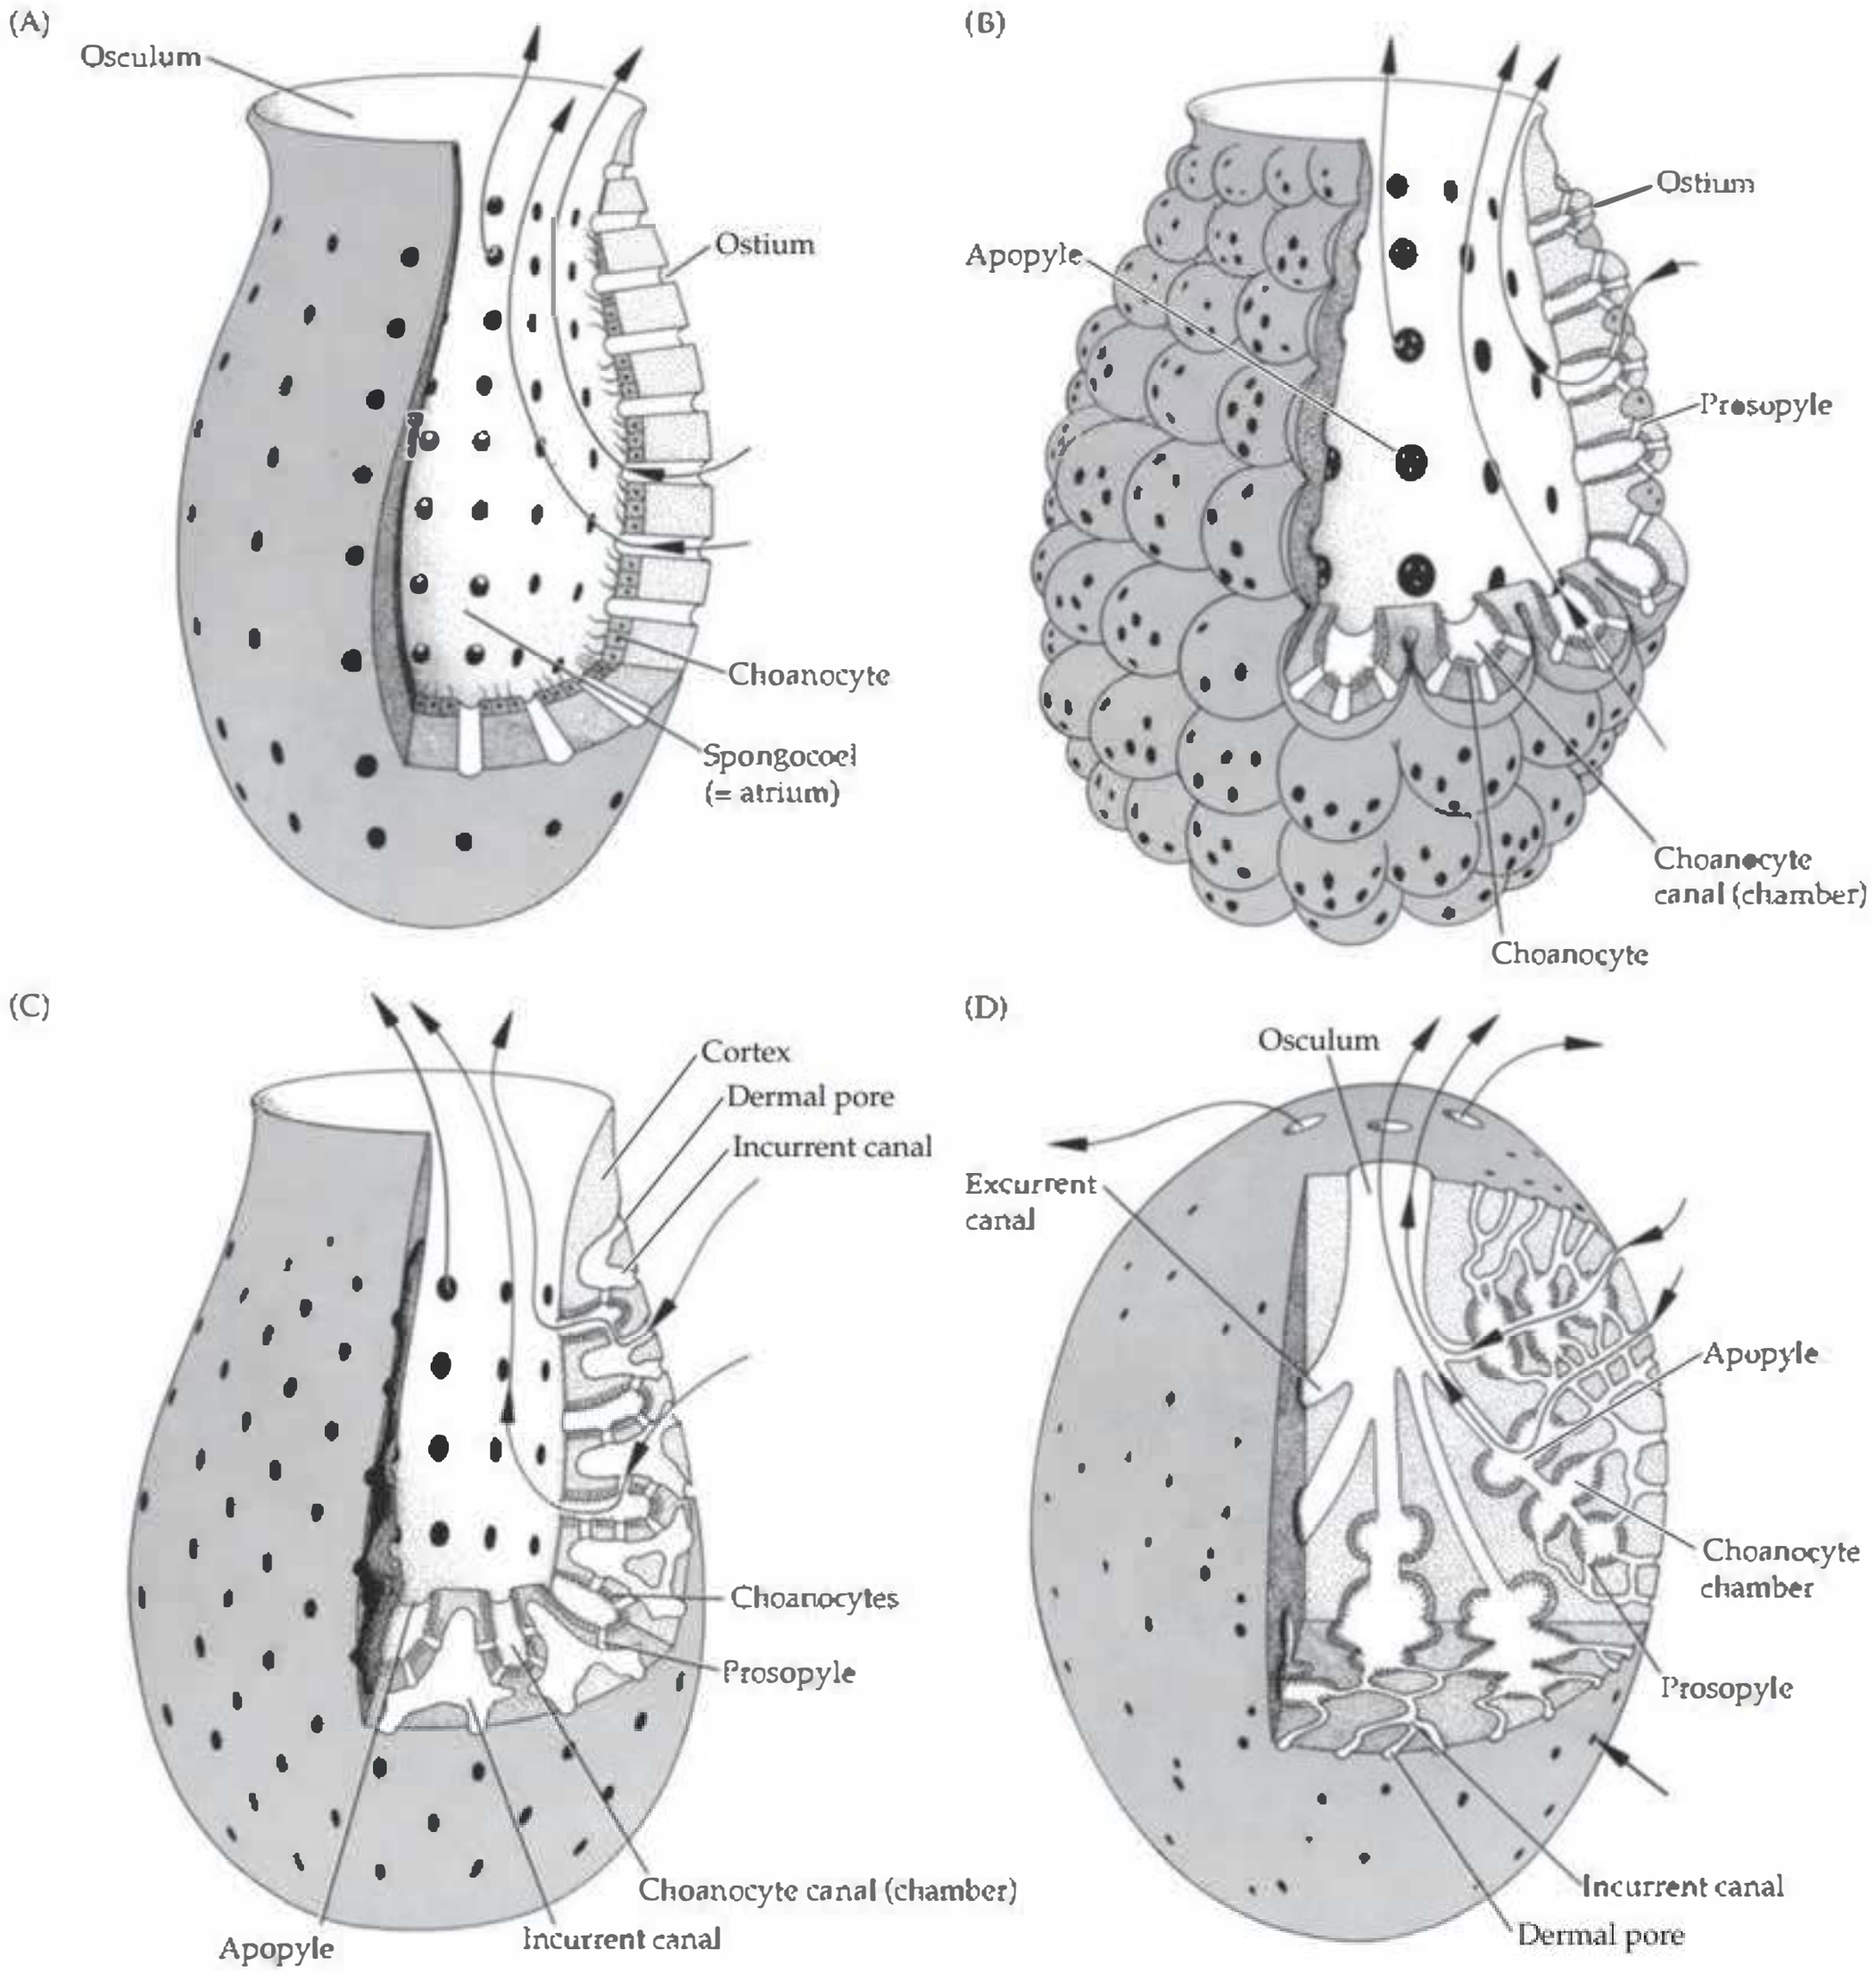
folding as the mesohyl volume increases, these layers maintain a surface area-to-volume ratio sufficient to sustain adequate nutrient and waste exchange throughout the whole individual. Unique to the class Calcarea, some species go through an ontogenetic sequence in which an increasingly complex body architecture develops; adults may express the most complex structure, or they can retain one of the simpler architectures. Thus, some adult Calcarea may retain a largely unfolded, simple, and continuous choanoderm (the **asconoid condition**; Figure 6.4A), or the choanoderm may become folded (the **syconoid condition**; Figure 6.4B,C), or it may become both folded and subdivided into separate flagellated chambers (the **leuconoid condition**; Figure 6.4D). Asconoid and syconoid anatomies occur only in the class Calcarea.

The asconoid condition is found in the early growth stage (olynthus) of newly settled calcareous sponges and in some adult, radially symmetrical calcareous sponges (e.g., *Clathrina, Leucosolenia*) (Figure 6.5). Asconoid and syconoid sponges rarely exceed a few cm in height and remain as simple, vase-shaped (apical–basal radial symmetry) tubular units, or meandering networks of these vase-shaped units, or occasionally



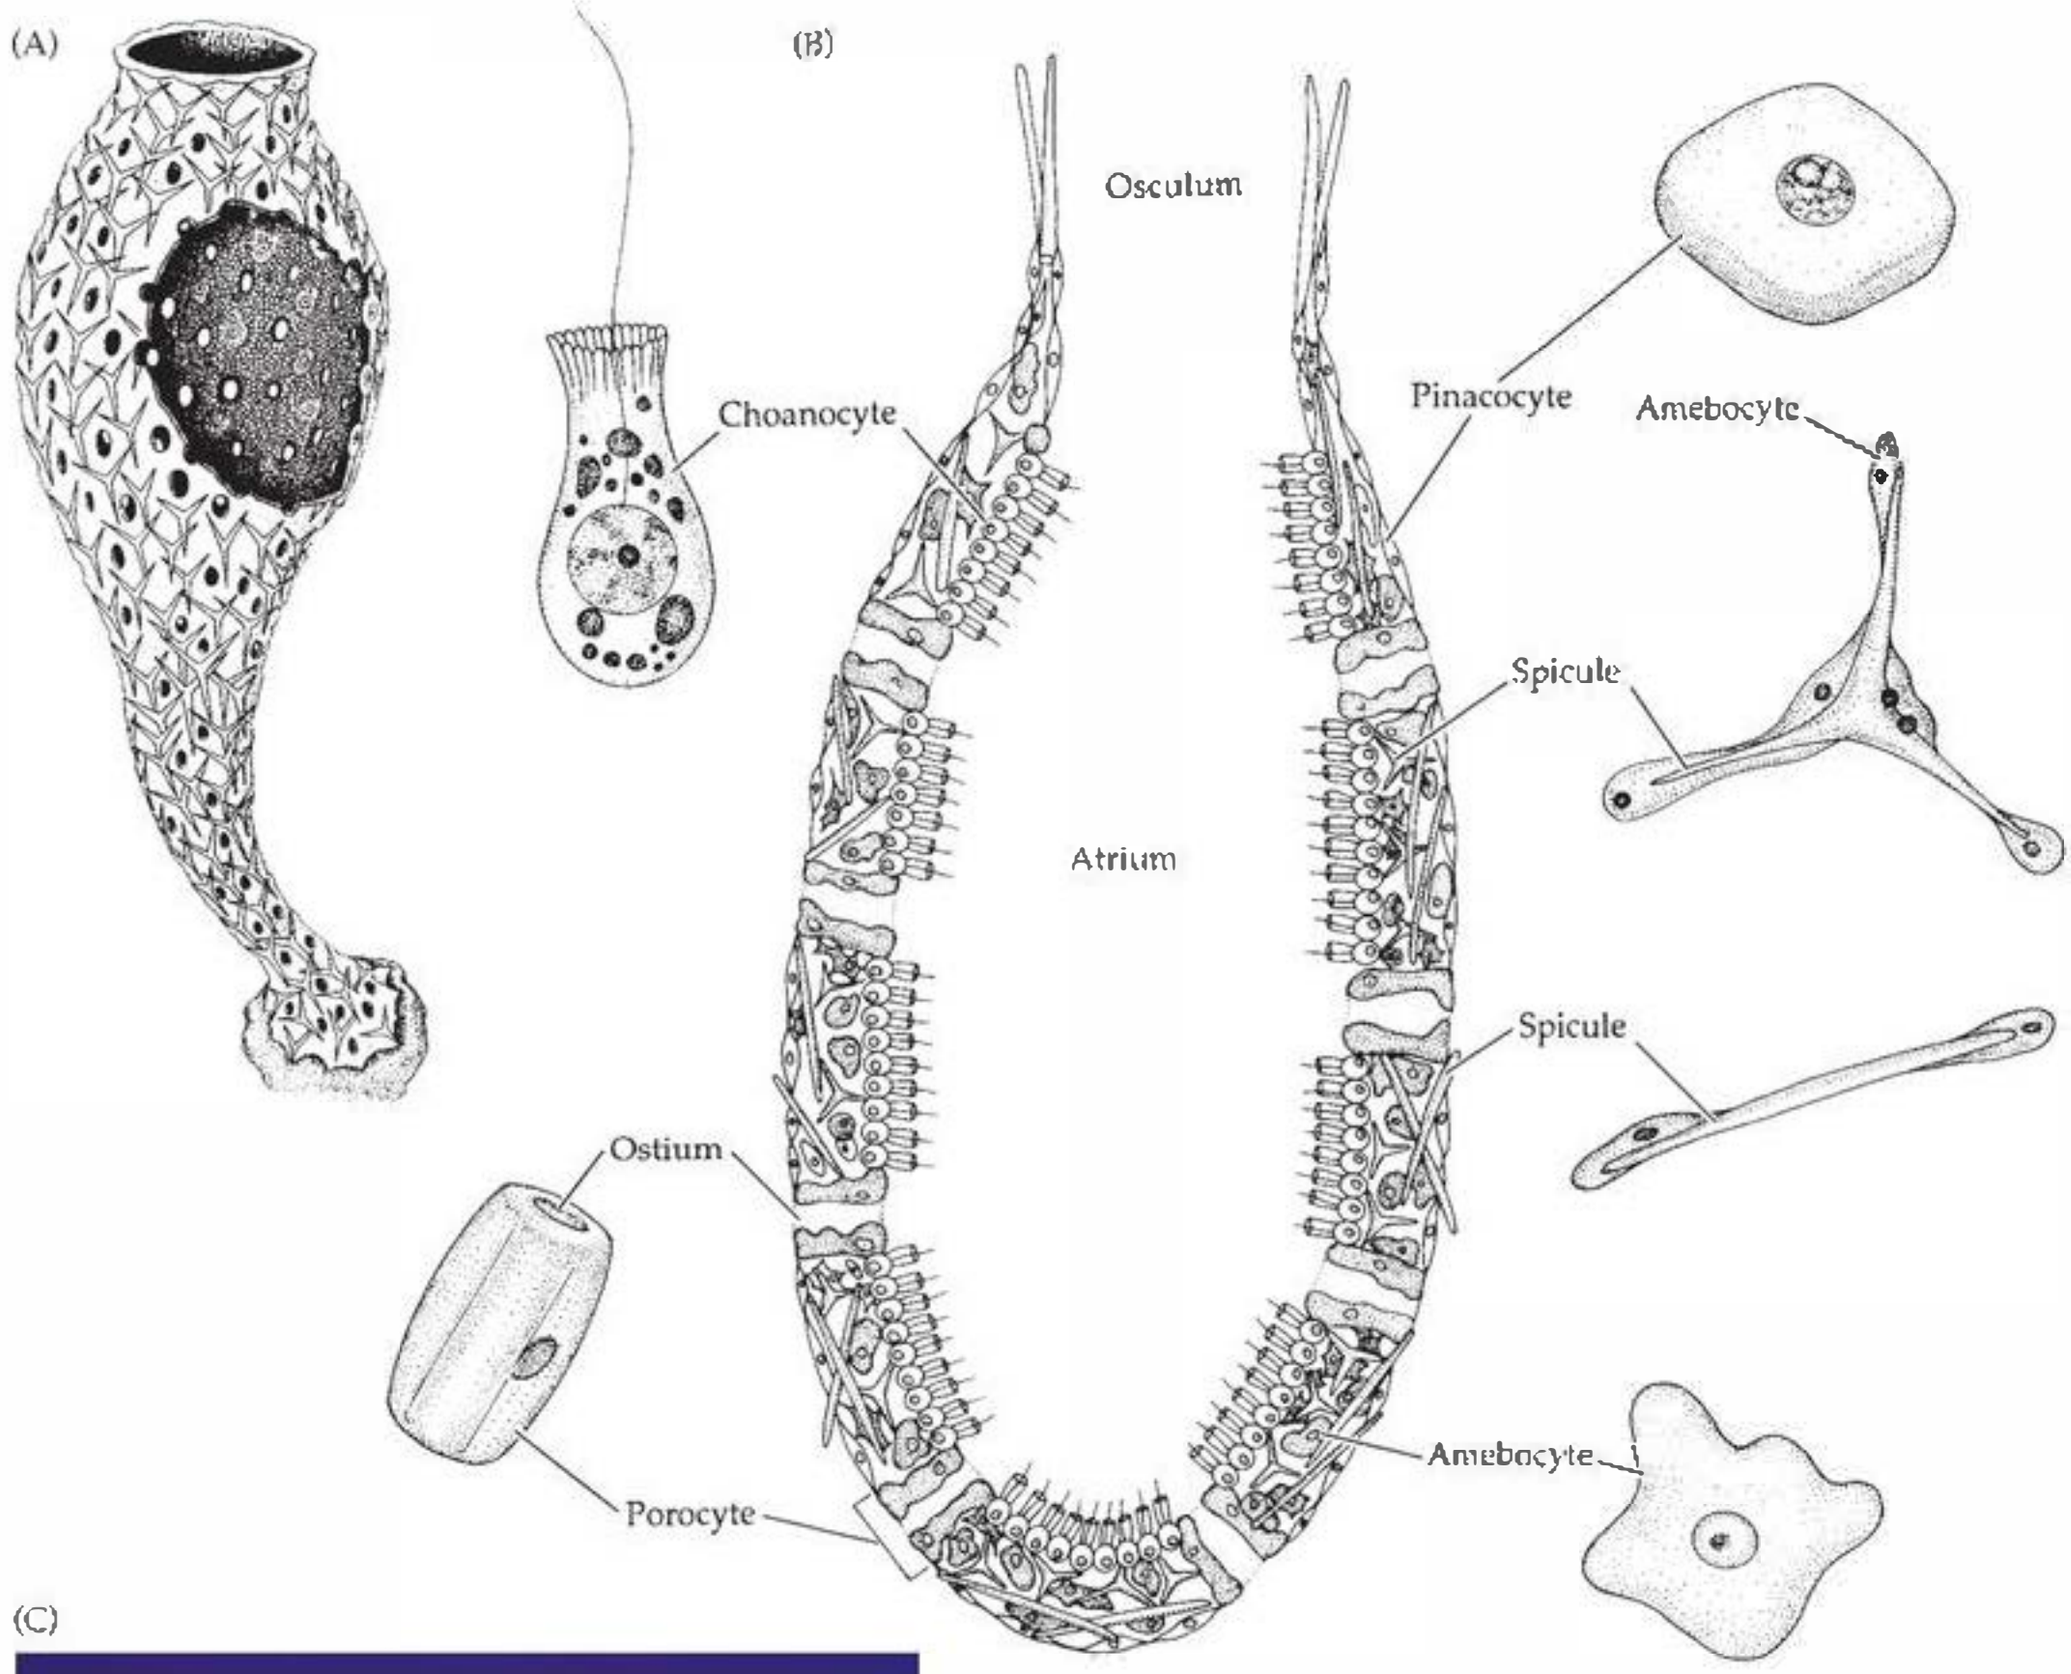


Figure 6.4 Body complexity in sponges (arrows indicate flow of water). (A) The asconoid condition. (B) A simple syconoid condition. (C) A complex syconoid condition with ectosomal growth. (D) A leuconoid condition. Asconoid and syconoid anatomies occur only in the class Calcarea.

even stalked sponges (e.g., some *Clathrina*). The thin walls enclose a central cavity called the atrium (= spongocoel), which opens to the outside via a single osculum (pl. oscula). The pinacoderm of asconoid, and very simple syconoid sponges rely on ostia as their incurrent pores. Ostia develop during embryogeny as specialized cells (porocytes) that elongate and roll to form cylindrical tubes. Each porocyte extends all the way through the pinacoderm, the thin mesohyl, and the choanoderm, and thus into the atrium where it emerges between adjacent choanocytes like a porthole. (Porocytes also occur in a few demosponge groups, particularly the freshwater species.) The choanoderm is a simple, unfolded layer of choanocytes lining the entire atrium. Water moving through an asconoid sponge thus flows through the following structures: ostium → atrium/spongocoel (over the choanoderm) → osculum.

(C)

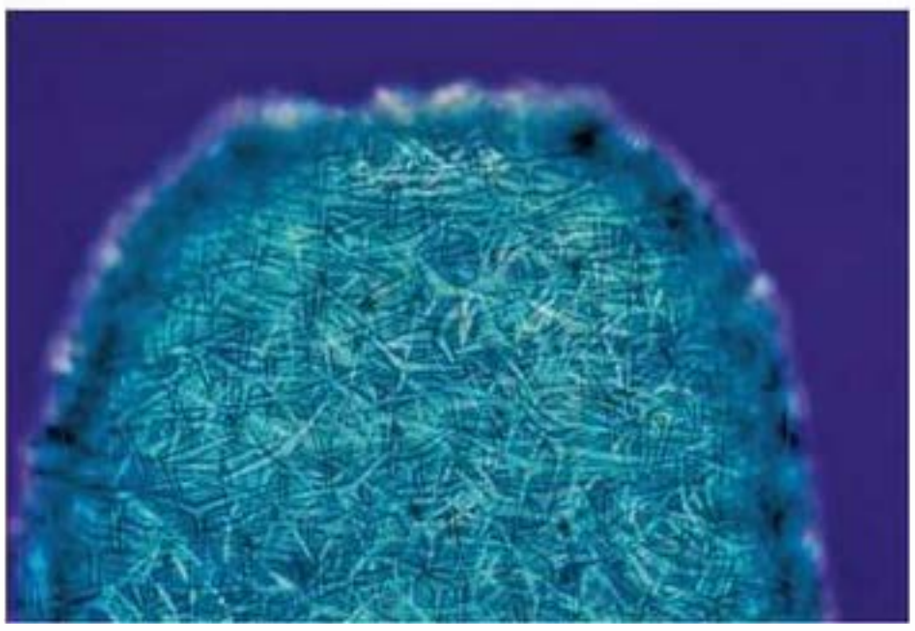

Figure 6.5 The asconoid condition (class Calcarea). (A) An olynthus, the asconoid form that follows larval settlement in calcareous sponges. (B) Major cell types in an asconoid sponge. (C) The simple calcareous sponge *Leucosolenia* shows the asconoid body form and skeleton of $CaCO_3$ spicules.

As stated above, in calcareous sponges, simple folding of the pinacoderm and choanoderm produces the syconoid condition, within which several levels of complexity are possible (Figure 6.4B,C). As complexity increases, the mesohyl may thicken and appear to have two layers. The outer layer (formerly referred to as the cortical region or cortex) is called the **ectosome**. The ectosome contains an accumulation of spicules that are different from those found in the interior portion of the mesohyl. In calcareous sponges with an ectosome, the incurrent openings are lined by several cells (not formed by a single porocyte) and are referred to as **dermal pores**. In the syconoid condition, choanocytes are restricted to specific chambers or diverticula of the atrium called **choanocyte chambers** (also known as flagellated chambers, or radial canals). Each choanocyte chamber opens to the atrium by a wide aperture called an **apopyle**. Syconoid sponges with a thick ectosome possess a system of channels or incurrent canals that lead from the dermal pores through the mesohyl to the choanocyte chambers. The openings from these channels to the choanocyte chambers are called **prosopyles**. In such a complex syconoid sponge, water moving from the surface into the body flows along the following route: dermal (incurrent) pore → incurrent canal → prosopyle → choanocyte chamber → apopyle → atrium → osculum. Syconoid construction is found in many calcareous sponges, including the well-known genera *Grantia* and

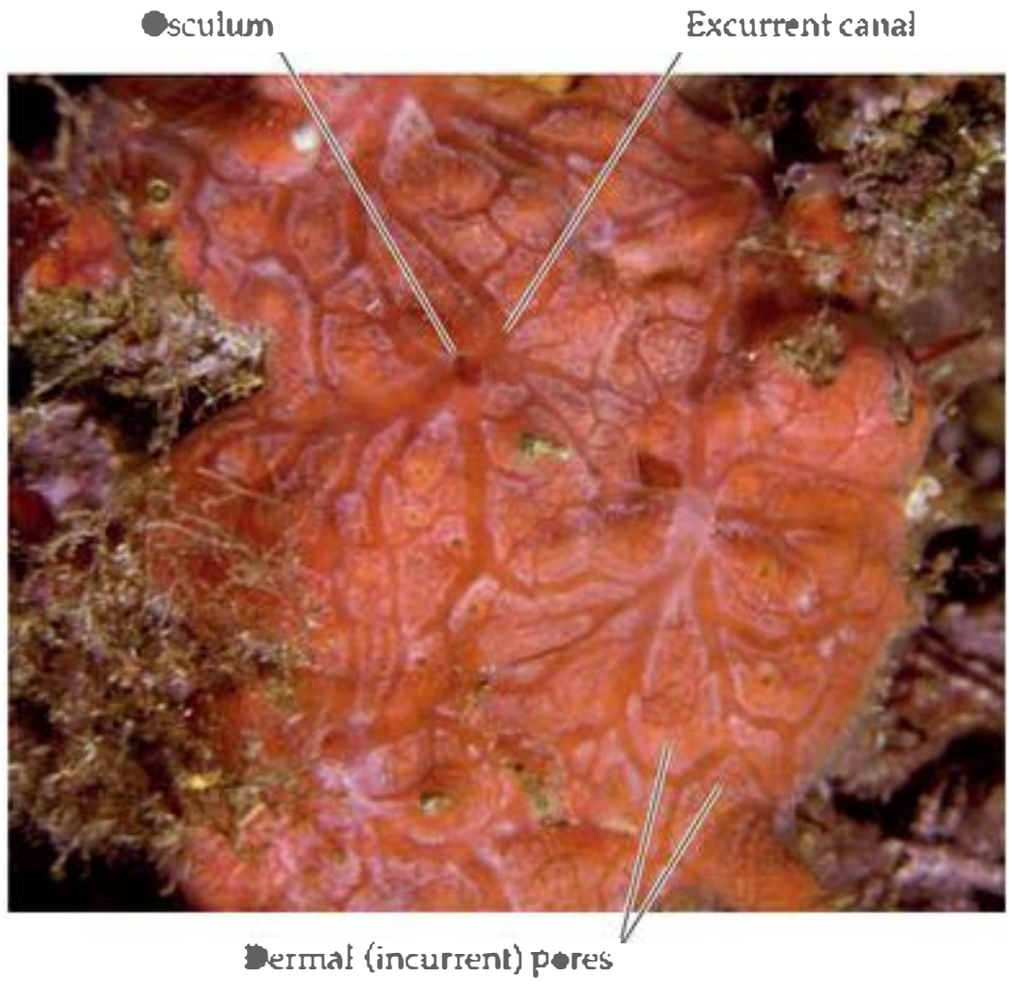

Figure 6.6 The surface of a living demosponge (*Clathria*). The complex system of ostia opens into underlying incurrent canals, and large oscula receive several excurrent canals, all visible through the thin pinacoderm.

Sycon (formerly known as *Scypha*), and such construction often yields vase-shaped adults, as in many asconoid Calcarea. Some syconoid sponges express a radial symmetry externally, but their complex internal organization is largely asymmetrical.

The leuconoid condition is found in all four sponge classes. Here, the choanoderm is much more highly folded and there is a thickening of the mesohyl by growth of the ectosome. Associated with this is a subdivision of the flagellated surfaces into discrete oval choanocyte chambers (Figure 6.4D). In the leuconoid condition, one finds an increase in number and a decrease in size of the choanocyte chambers, which typically cluster in groups in the thickened mesohyl. The atrium is often reduced to a series of excurrent canals (or "exhalent" canals) that carry water from the choanocyte chambers to the oscula (Figure 6.6). The flow of water through a leuconoid sponge is: dermal pore → incurrent canal → prosopyle → choanocyte chamber → apopyle → excurrent canal → (atrium) → osculum. Leuconoid organization is typical of all noncalcareous sponges, and many calcareous sponges (e.g., *Leucilla*).

It is important to realize that flow rate is not uniform through the various parts of the aquiferous system. Functionally, it is critical that water be moved very slowly over the choanoderm, allowing time for exchanges of nutrients, gases, and wastes between the water and the choanocytes. The changes in water flow velocity through this plumbing system are a function of the effective accumulated cross-sectional diameters of the channels through which the water moves (see Chapter 4, or your old physics notes). Water flow velocity decreases as the cross sectional diameter increases liquids move slower in larger pipes or when a single pipe divides into numerous smaller pipes. Thus, in a sponge, velocities are lowest over the choanoderm, which has the largest cross-sectional area. However, water leaving the osculum must be carried far enough away to prevent it from fouling or being immediately recycled by the sponge, so smaller accumulated cross-sectional diameters (and greater water velocity) are found in excurrent canal-osculum system.

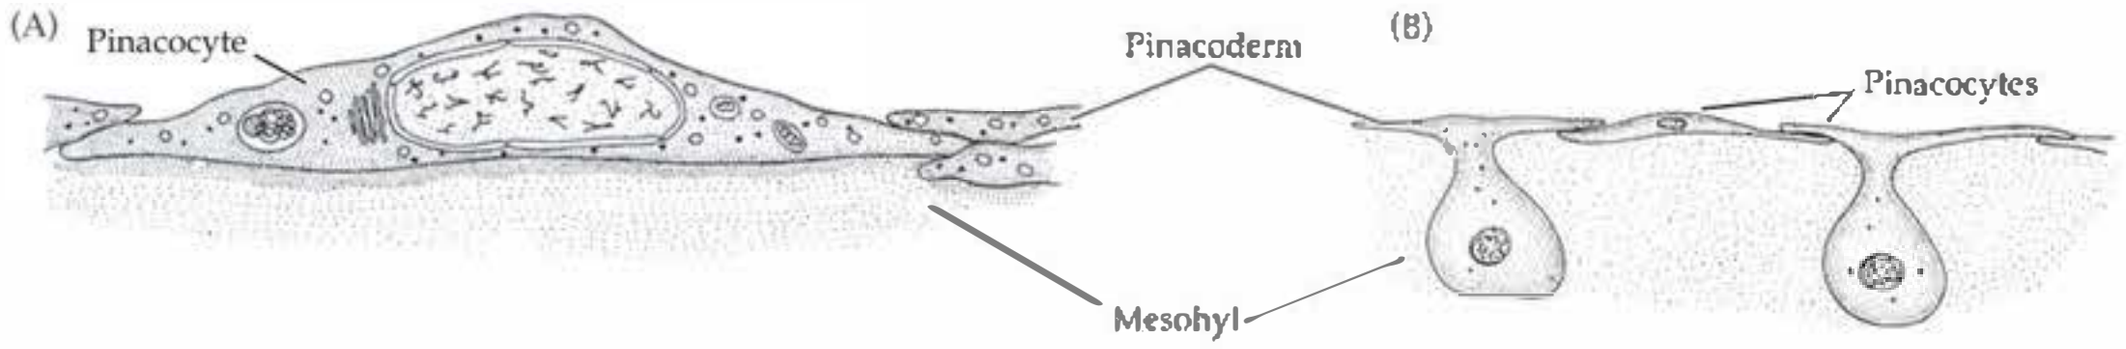
The recognition of the various levels of organization and complexity among calcareous sponges used to be thought to provide important evolutionary clues. However, there is no evidence that the asconoid plan is necessarily the most phylogenetically primitive, or that all sponge lineages have moved through these three levels of complexity during their evolution. Nor do most sponges pass through these three stages during their development. Calcareous sponges of the leuconoid condition usually do pass through asconoid and syconoid stages as they grow, but it is only in this class that all three organizational body plans clearly occur.

The hexactinellid sponges differ strikingly from other sponge classes (Figure 6.7). The bodies of hexactinellid sponges often display a considerable degree of superficial radial symmetry. There is not a typical pinacoderm in hexactinellids. Instead, a dermal membrane is present, but it is extremely thin and is continuous with all the other parts of the sponge; no discrete or continuous cellular structure supports it. Incurrent pores are simple holes in this dermal membrane. The main tissue of the hexactinellid is called the trabecular syncytium—it forms a syncytial, trabecular network stretching across interconnecting internal cavities (the subdermal lacunae) near the surface of the sponge and penetrating into and forming the supporting framework for the choanosome (Figure 6.7A). The trabecular network resembles a three-dimensional cobweb. The thimbleshaped flagellated chambers of the choanosome are arranged in a single layer and are supported within the trabecular network. Both the trabecular network and the walls of the flagellated chambers are syncytial. In these sponges, the choanoblasts produce new collars but do not produce new nuclei, thus creating a single-nucleate syncytium with many collar bodies. As new collars "bud off," the expanding, single-cell body of the choanoblast cell recesses itself beneath the trabecular syncytium, leaving just the collars exposed to do the work. Water enters incurrent pores in the dermal membrane, passes into the subdermal lacunae, and from there enters the syncytial choanosome chambers via the prosopyles. The soft tissue of the syncytium serves to deliver food and other metabolites to all parts of a hexactinellid sponge by cytoplasmic streaming.

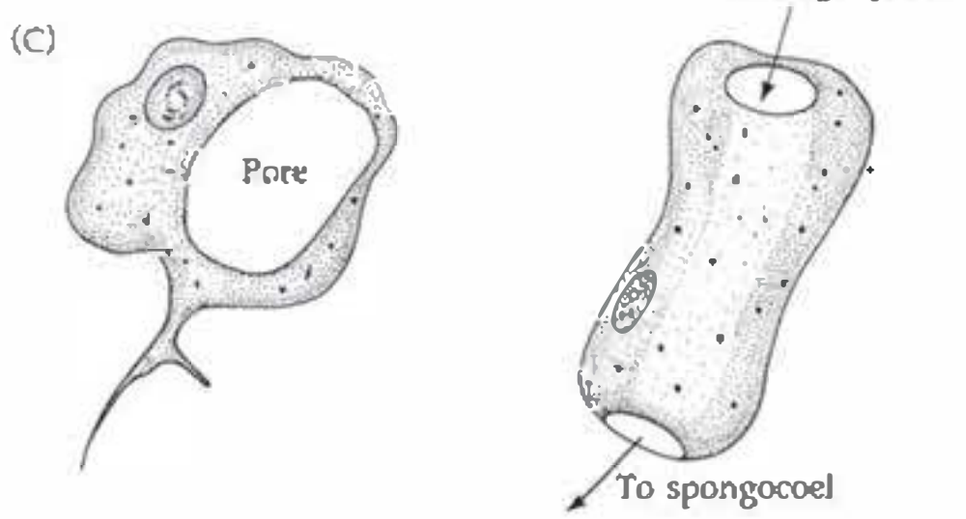
The unique structure of hexactinellids is so striking that some workers have even suggested the

(A) Two flagellated chambers connected to the dermal membrane by trabecular strands; arrow shows water flow (*Farrea occa*). (B) Section through wall of a flagellated chamber, based on *Rhabdocalyptus dawsoni*. Water (arrows) is drawn through prosopyles in the primary reticulum and through choanocyte collars by the beating of the flagella. The secondary reticulum surrounds the collars, forcing water through the collar microvilli. (C) Canal system and tissue structure in *Aphrocallistes vastus* (scanning electron micrograph); primary (R1) and secondary (R2) reticula, extensions of the trabecular reticulum, incurrent pores, prosopyles (pr), collar bodies (cb) branching from choanocytes, with collar microvilli (mv) and flagellum (fl).

hexactinellids might be regarded as a separate subphylum or phylum (the "Syncytia"), distinct from the other sponge classes (the "Cellularia"). However, as explained in Chapter 2, phylogenetic relationships are best sought in similarities among groups (i.e., shared derived features), not in differences. By this reasoning, and through molecular phylogenetics, we know without doubt that hexactinellids are poriferans (and probably closely related to demosponges). Nevertheless, hexactinellids are striking and bizarre in that no other metazoan group possesses such extensive syncytial tissues.[4]

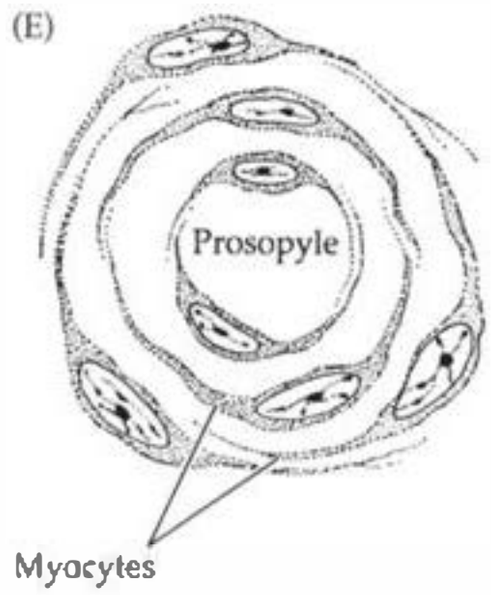


More on Sponge Cell Types



Prior to the 1970s, texts generally recognized only a few basic kinds of poriferan cells. However, subsequent detailed histochemical and ultrastructural studies have revealed a broad variety of cell types. These discoveries make succinct "textbook classification" of their cells difficult. We present below a highly abridged version of sponge cell classification.

[4]Syncytial tissues are seen in some other metazoans. For example, the epithelia of some cnidarians and the skeletogenic tissues of echinoids are syncytial, by way of incomplete cytokinesis. The giant neurons in squid, and vertebrate striated muscle cells (your biceps, for example) are multinucleate by fusion of separate cells.



Cells that line surfaces As noted above, the pinacoderm forms a continuous layer on the external surface of sponges and also lines all incurrent and excurrent canals. The pinacocytes that make up this layer are usually flattened and usually overlapping (Figure 6.8A,B). The external surface, or exopinacoderm, of demosponges has an extracellular matrix (ECM) beneath it, and in the Calcarea a loose collagenous mesohyl underlies the pinacoderm. In homoscleromorph sponges, and some species in other classes, a true basement membrane underlies the pinacoderm. In all cases, this layer of secreted material helps maintain the positional

integrity of pinacocytes. Basal membranes are sheet like complexes of extracellular matrix proteins that are secreted by the epithelial layer; they are highly structured and contain type IV collagen. Such membranes typically underlie epithelial (and endothelial) tissues in the Metazoa, but not in fungi or plants. They provide an added mechanical function as supporting structures, and also play a biological role as molecular sieves. The pinacoderm of Homoscleromorpha is especially well organized, forming a well developed epithelium (with an underlying basal membrane). However, the apparent absence of a basal membrane in most Porifera distinguishes sponge pinacoderm from the well-developed tissue epithelia of the higher Metazoa.[5]

Internal, canal lining pinacocytes (**endopinacocytes**) are usually more fusiform in shape and have less overlap than outer **exopinacocytes**. Although the endopinacoderm is epithelial in function, it is probably phagocytic as well. External cells of the basal or attaching region of a sponge surface are called basopinacocytes. These flattened cells are responsible for secreting a fibrillar collagen–polysaccharide complex by which sponges attach to the substratum. In freshwater sponges, the basopinacocytes are active in feeding and extend ameba-like "filopodia" to engulf bacteria. Freshwater sponge basopinacocytes also play an active role in osmoregulation and contain large numbers of water expulsion vesicles, or contractile vacuoles.

As noted earlier, porocytes are cylindrical or flat, tubelike cells of the pinacoderm that form ostia in some sponge species (Figure 6.8C,D). They are contractile and can open and close the pore and regulate the ostial diameter; however, no microfilaments have been observed in them and their precise method of contraction and expansion is unknown. Some species are capable of producing a diaphragm like cytoplasmic membrane across the ostial opening that also regulates pore size.

Choanocytes are the flagellated collar cells that make up the choanoderm and create the currents that drive water through the aquiferous system (Figure 6.8F–H). Choanocytes are not coordinated in their beating, not even within a given chamber. However, they are aligned such that the flagella, which beat from base to tip, are directed toward the apopyle. The long flagellum is always surrounded by the choanocyte collar, which is made up of 20 to 55 cytoplasmic microvilli (= villi). The villi have microfilament cores and are connected to one another by anastomosing mucous strands (a mucous reticulum) that form a glycocalyx band around the collar. Choanocytes rest on the mesohyl, held in place by interdigitation of adjacent basal surfaces. In keeping with their central role in phagocytosis and pinocytosis, choanocytes are highly vacuolated.

Cells that secrete the skeleton There are several types of ameboid cells in the mesohyl that secrete elements of sponge skeletons. In almost all sponges, the entire supportive matrix is built on a framework of fibrillar collagen. The cells that secrete this material are called collencytes, lophocytes, and spongocytes. **Collencytes** are morphologically nearly indistinguishable from pinacocytes, whereas **lophocytes** are large, highly motile cells that can be recognized by a collagen tail they typically trail behind them (Figure 6.9C). The primary function of both cell types is to secrete the dispersed fibrillar collagen found intercellularly in virtually all sponges. **Spongocytes** produce the fibrous supportive collagen referred to as spongin (Figure 6.12A). Spongocytes operate in groups and are always found wrapped around a spicule or spongin fiber (Figure 6.9D).

Sclerocytes are responsible for the production of calcareous and siliceous sponge spicules (Figure 6.9A,B). They are active cells that possess abundant mitochondria, cytoplasmic microfilaments, and small vacuoles. Numerous types of sclerocytes have been described; these cells always disintegrate after spicule secretion is complete.

Contractile cells Contractile cells in sponges, called **myocytes**, are found in the mesohyl (Figure 6.8E). They are usually fusiform and grouped concentrically around oscula and major canals. Myocytes are distinguished by the great numbers of microtubules and microfilaments contained in their cytoplasm, and they rely on the classic actin/myosin structure seen in all animals. Because of the nature of their filament arrangement, it has been suggested that myocytes are homologous with the smooth muscle cells of higher invertebrates. However, myocytes are independent effectors with a slow response time, and, unlike neurons and true muscle fibers, they are insensitive to electrical stimuli.

Other cell types **Archaeocytes** are highly versatile, largely totipotent ameboid cells that are capable of quickly differentiating to give rise to virtually any other cell type. These large, highly motile cells also play a major role in digestion and food transport (Figure 6.10). They possess a variety of digestive enzymes (e.g., acid phosphatase, protease, amylase, lipase) and can accept phagocytized material from the choanocytes. They also phagocytize material directly through the pinacoderm of water canals. Archaeocytes carry out much of the digestive, transport, and excretory activities in sponges. And, as cells of maximum totipotency, archaeocytes are essential to the developmental program of sponges

[5]Type IV collagen, diagnostic of Metazoa, is a long triple helix molecule; it is one of several collagen types found in sponges and other metazoans, and it occurs in all four sponge classes

and to various asexual processes (e.g., gemmule formation). Spherulous cells are large mesohyl cells containing various chemical inclusions.

Cell reaggregation Around the beginning of the twentieth century, H. V. Wilson first demonstrated the remarkable ability of sponge cells to reaggregate after being mechanically dissociated. Although this discovery was interesting in itself, lending insight into the plasticity of cellular organization in sponges, it also foreshadowed more far-reaching cytological research that has since shed light on basic questions about how cells self-recognize, adhere, segregate, and specialize. Many sponges that are dissociated and maintained under proper conditions will form aggregates, and some will eventually reconstitute their aquiferous system. For example, when pieces of the Atlantic "red beard sponge" (*Clathria prolifera*) are pressed through fine cloth, the separated cells immediately begin to reorganize themselves by active cell migration. Within 2 to 3 weeks, a functional sponge reforms and the original cells return to their respective functions. Furthermore, if cell suspensions of two different sponge species are mixed, the cells sort themselves out and reconstitute individuals of each separate species—a remarkable display of cellular self-recognition. The controversial sponge biologist M. W. de Laubenfels described the situation in 1949 in slightly different terms: "Sponges endure mutilation better than any other known animal." The discovery that dissociated sponge cells will reaggregate to form a functional organism was the basis for the establishment of sponge cell cultures that have been used as a model for the study of fundamental processes in developmental

biology and immunology. We now know that sponge cells (like other animal cells) have surface markers that allow for self- versus non-self recognition.

Support

The skeletal elements of sponges are of two types, organic and inorganic. The former is always collagenous and the latter either siliceous (hydrated silicon dioxide) or calcareous—calcium carbonate in the form of calcite or aragonite. Sponges are the only animals that use hydrated silica as a skeletal material. Calcite is a common crystalline form of natural calcium carbonate, $CaCO_3$, that is the basic constituent of many protist and animal skeletons, as well as the fossiliferous sedimentary rocks known as limestone, marble, and chalk.[6]

Collagen is the major structural protein in invertebrates; it is found in virtually all metazoan connective tissues. In higher Metazoa, about 20 different kinds of collagen have been identified, but in Porifera only two are known so far: fibrillar collagen and type IV collagen (the latter, a key component of basal membranes, has to date been found primarily in the Homoscleromorpha, but also in a number of species of demosponges and calcareans).

In sponges, fibrillar collagen is either dispersed as thin fibrils in the intercellular matrix or organized as a fibrous framework called spongin in the mesohyl. Although the dispersed collagen fibers seen in many sponges are sometimes referred to as "spongin," true spongin (fibrillar collagen forming a skeletal framework in the mesohyl) is found only in members of the

[6]Calcite and aragonite are closely related calcium carbonate ($CaCO_3$) minerals representing the two most common, naturally occurring, crystalline forms. Both are formed by biological and physical processes—primarily precipitation in marine and freshwater environments—and both are used by animals in the construction of their skeletons. Calcite is the more stable of the polymorphs of calcium carbonate. Calcite crystals are trigonal-rhombohedral, though actual calcite rhombohedra are rare as natural crystals. In animal skeletons, calcite occurs as lamellar or compact deposits, or occasionally in a fibrous form. Calcite is transparent to opaque. Single calcite crystals display an optical property called birefringence (double refraction) that causes objects viewed through a clear piece of calcite to appear doubled. Although calcite is fairly insoluble in cold water, acidity can cause its dissolution (a big problem for animals and protists living in an acidifying global ocean). Calcite exhibits an unusual characteristic called retrograde (or inverse) solubility in which it becomes less soluble in water as the temperature increases. Aragonite's crystal lattice differs from that of calcite, resulting in a different crystal shape, an orthorhombic system with needlelike crystals. Aragonite may be columnar or fibrous. Aragonite is thermodynamically unstable at standard temperature and pressure, and tends to alter to calcite on scales of 107 to 108 years. Because calcite is more stable than aragonite, and dissolves more slowly than aragonite in water, it is more likely to fossilize. Thus, the fossil record for Paleozoic corals is better than the fossil record for Cenozoic corals, the former being made of calcite, the latter of aragonite.

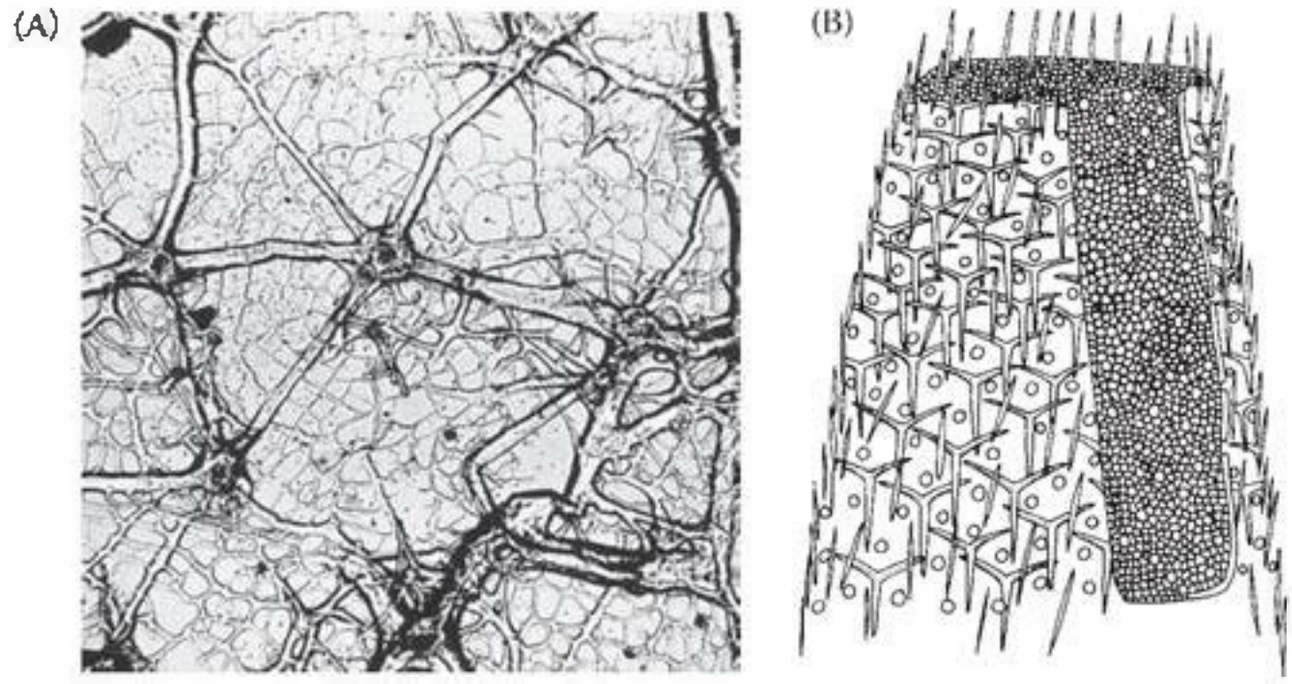
Calcite skeletons occur in most invertebrates that have hard skeletons, including sponges, brachiopods, echinoderms, most bryozoans, and most bivalves. Coccoliths and planktonic foraminiferans also have calcitic skeletons, and certain red algae (coralline red algae) also produce it. Because calcite is so stable, larger calcite shells in the fossil record (e.g., bivalves) thus tend to the "real thing," not mineral replacements. Purely aragonite-based shells do exist, such as in the molluscan class Polyplacophora (the chitons), but they are rare.

Figure 6.11 Mediterranean bath sponges (*Spongia officinalis*) for sale in an open air market in Provence, France.

classes Demospongiae (Figure 6.12A). The amount of this fibrillar collagen varies greatly from species to species; in hexactinellids it is quite sparse, whereas in demosponges it is abundant and may form dense bands in the ectosome. Unlike the ectosome of calcareous sponges, which is fundamentally a layer of concentrated spicules, the ectosome of demosponges is a feature of the outer mesohyl and is basically a well-developed collagen layer lacking choanocyte chambers. The network often contains very thick fibers, and may incorporate siliceous spicules into its structure. Spongin often cements siliceous spicules together at their points of intersection. The encysting coat of the asexual gemmules of freshwater (and some marine) sponges is also composed largely of spongin.

Mineral skeletons of either silica or calcium are found in almost all sponges, except a few species of demosponges and homoscleromorphs. Sponges lacking mineral skeletons possess only fibrous collagen networks, and these are still used as bath sponges despite the prevalence nowadays of synthetic "sponges." Several demosponge and homoscleromorph genera lack both spongin and a spicule skeleton (e.g., *Chondrosia, Halisarca, Hexadella, Oscarella*).

Sponges have been harvested for millennia. Evidence of an active Mediterranean sponge trade is found at least as early as 3,000 BCE (Egyptians), and later in the ancient Phoenician, Greek and Roman civilizations (Figure 6.11). Homer and other ancient Greek writers mention a thriving Mediterranean sponge trade. Prior to the 1950s, active natural sponge fisheries existed in south Florida, the Bahamas, and the Mediterranean. The industry peaked in 1938, when the world's annual sponge catch (including cultivated sponges) exceeded 2.6 million pounds, 700,000 pounds of which came from the United States and the Bahamas. Almost all commercial sponges belong to the genera *Hippospongia* and *Spongia*, but these sponges have now been largely "fished out" in the traditional sponge hunting grounds of the Mediterranean and Florida. In addition, they are prone to current-transmitted epidemic diseases (three such events wiped out bath sponge populations in both the Old World and the New World in 1938, 1947, and in the late 1980s).



Mineralized sponge spicules (Figure 6.12) are produced by special mesohyl cells called sclerocytes, which are capable of accumulating calcium or silicate and depositing it in an organized way. In some cases, one sclerocyte produces one spicule; in others, several sclerocytes work together cooperatively to produce a single spicule, often two cells per spicule ray (Figure 6.9A–D).

The construction of a siliceous spicule begins with the secretion of an organic axial filament within a vacuole in a sclerocyte. As the axial filament elongates at both ends, hydrated silica is secreted into the vacuole and deposited around the filament core. Recent work suggests that, at least in some homoscleromorphan species (e.g., *Corticium candelabrum*) pinacocytes might also be capable of siliceous spicule production. About 92% of all living sponge species are siliceous. One might wonder how a skeleton made of glass (as in the Hexactinellida) could be strong enough to provide support while not being fragile as a windowpane. The trick is that glass sponges have evolved a highly sophisticated, multilayered biomechanical structure to their skeleton. They construct their glass skeleton by first consolidating nanometer scaled silica spheres, arranged in microscopic concentric rings separated from one another by alternating layers of an organic matrix-glue to form laminated spicules. The spicules are then bundled together by an organic, silica-based cement, resulting in the formation of micron scale, multilayered "beams." The beams are then assembled into the recognizable square-lattice cagelike structure we see in glass sponges, such as *Euplectella*. The lattice itself is further reinforced by diagonal ridges, giving the whole skeleton remarkable strength plus a resilient flexibility. In species of *Euplectella*, seven hierarchical structural levels have been identified in the skeleton—a textbook example in biomechanical engineering, and perhaps one day an inspiration for glass fiber manufacturers. Even in Demospongiae and Homoscleromorpha, the siliceous spicules exhibit exceptional flexibility and toughness due to their composite, layered construction.

Unlike siliceous spicules, calcium carbonate spicules do not have an organic axial core. Calcareous spicules are produced extracellularly, in intercellular spaces bounded by a number of sclerocytes. Each spicule is essentially a single crystal of calcite or aragonite.

Considerable taxonomic weight has been given to spicule morphology, and an elaborate nomenclature exists to classify these skeletal structures. Spicules are

termed either microscleres or megascleres. The former are small to minute, reinforcing (or packing) spicules; the latter are large structural spicules. The demosponges and hexactinellids have both types; calcareous sponges often have only megascleres (although the spicules can differ considerably in size). Descriptive terms that designate the number of *axes* in a spicule end in the suffix *-axon* (e.g., monaxon, triaxon). Terms that designate the number of *rays* end in the suffixes *-actine* or *-actinal* (e.g., monactinal, hexactinal, tetractinal). In addition, there is a detailed nomenclature specifying shape and ornamentation of various spicules (Figure 6.12).

A spicular skeleton may be viewed as a supplemental supporting structure. If the amount of inorganic material is increased in relation to organic material, the sponge becomes increasingly solid until the texture approaches that of a rock, as it may in some members of the demosponge order Tetractinellida and a few others (e.g., the "lithistid" sponges). In contrast to discrete spicules, the massive calcareous skeletons of some species (the coralline, or sclerosponges) have a polycrystalline microstructure; they are composed of needles ("fibers") of either calcite or aragonite embedded in an organic fibrillar matrix. The advantage of incorporating organic matter into the calcareous framework has been compared to lathe-and-plaster, or reinforced concrete. The mix of organic and inorganic materials probably yields fibrous calcites and aragonites that are less prone to fracture while also producing substances that are more easily molded by the organism. In some demosponges (e.g., Lithistida) and many Hexactinellida, the spicules may be linked or fused into such a rigid framework that it is capable of fossilizing.[7]

Nutrition, Excretion, and Gas Exchange

Although sponges lack the complex organs and organ systems seen in the higher Metazoa, they are nevertheless a hugely successful group of animals. As noted above, their success seems partly due to their very "ancientness"—the flexibility inherent in their developmental programming, cellular pluripotency, highly versatile aquiferous system, and the general plasticity of their body form.

Unlike most Metazoa, nearly all sponges rely on intracellular digestion, and thus on phagocytosis and pinocytosis as means of food capture. The aquiferous system has already been described; with it, sponges more or less continuously circulate water through their bodies, bringing with it the microscopic food particles upon which they feed. They are size-selective particle feeders, and the arrangement of the aquiferous system creates a series of "sieves" of decreasing mesh size (e.g., inhalant ostia or dermal pores → canals → prosopyles → choanocyte villi → intertentacular mucous reticulum). The upper limit of the diameter of incurrent openings is usually around 50 μm, so larger particles do not enter the aquiferous system. A few species have larger incurrent pores, reaching diameters of 150 to 175 μm, but in most species the incurrent openings range from 5 to 50 μm in diameter. Internal particle capture in the 2 to 10 μm range (e.g., bacteria, small protists, unicellular algae, organic detritus) is by choanocytes and by phagocytic motile archaeocytes that move to the lining of the incurrent canals. As in the choanoflagellate protists, the propagation of the flagellar wave in sponge choanocytes is thought to draw water in through the microvilli of the collar, which then slows or blocks food particles, allowing them to be phagocytized. The smallest particles, large organic molecules and small bacteria in the 0.1–0.2 μm

[7]The order Lithistida has long been recognized as polyphyletic, but kept mainly as a matter of convenience, essentially because it is used by paleontologists. However, as with the former taxon Sclerospongiae, it is clearly time to abandon the name "Lithistida" and begin reassigning its component species

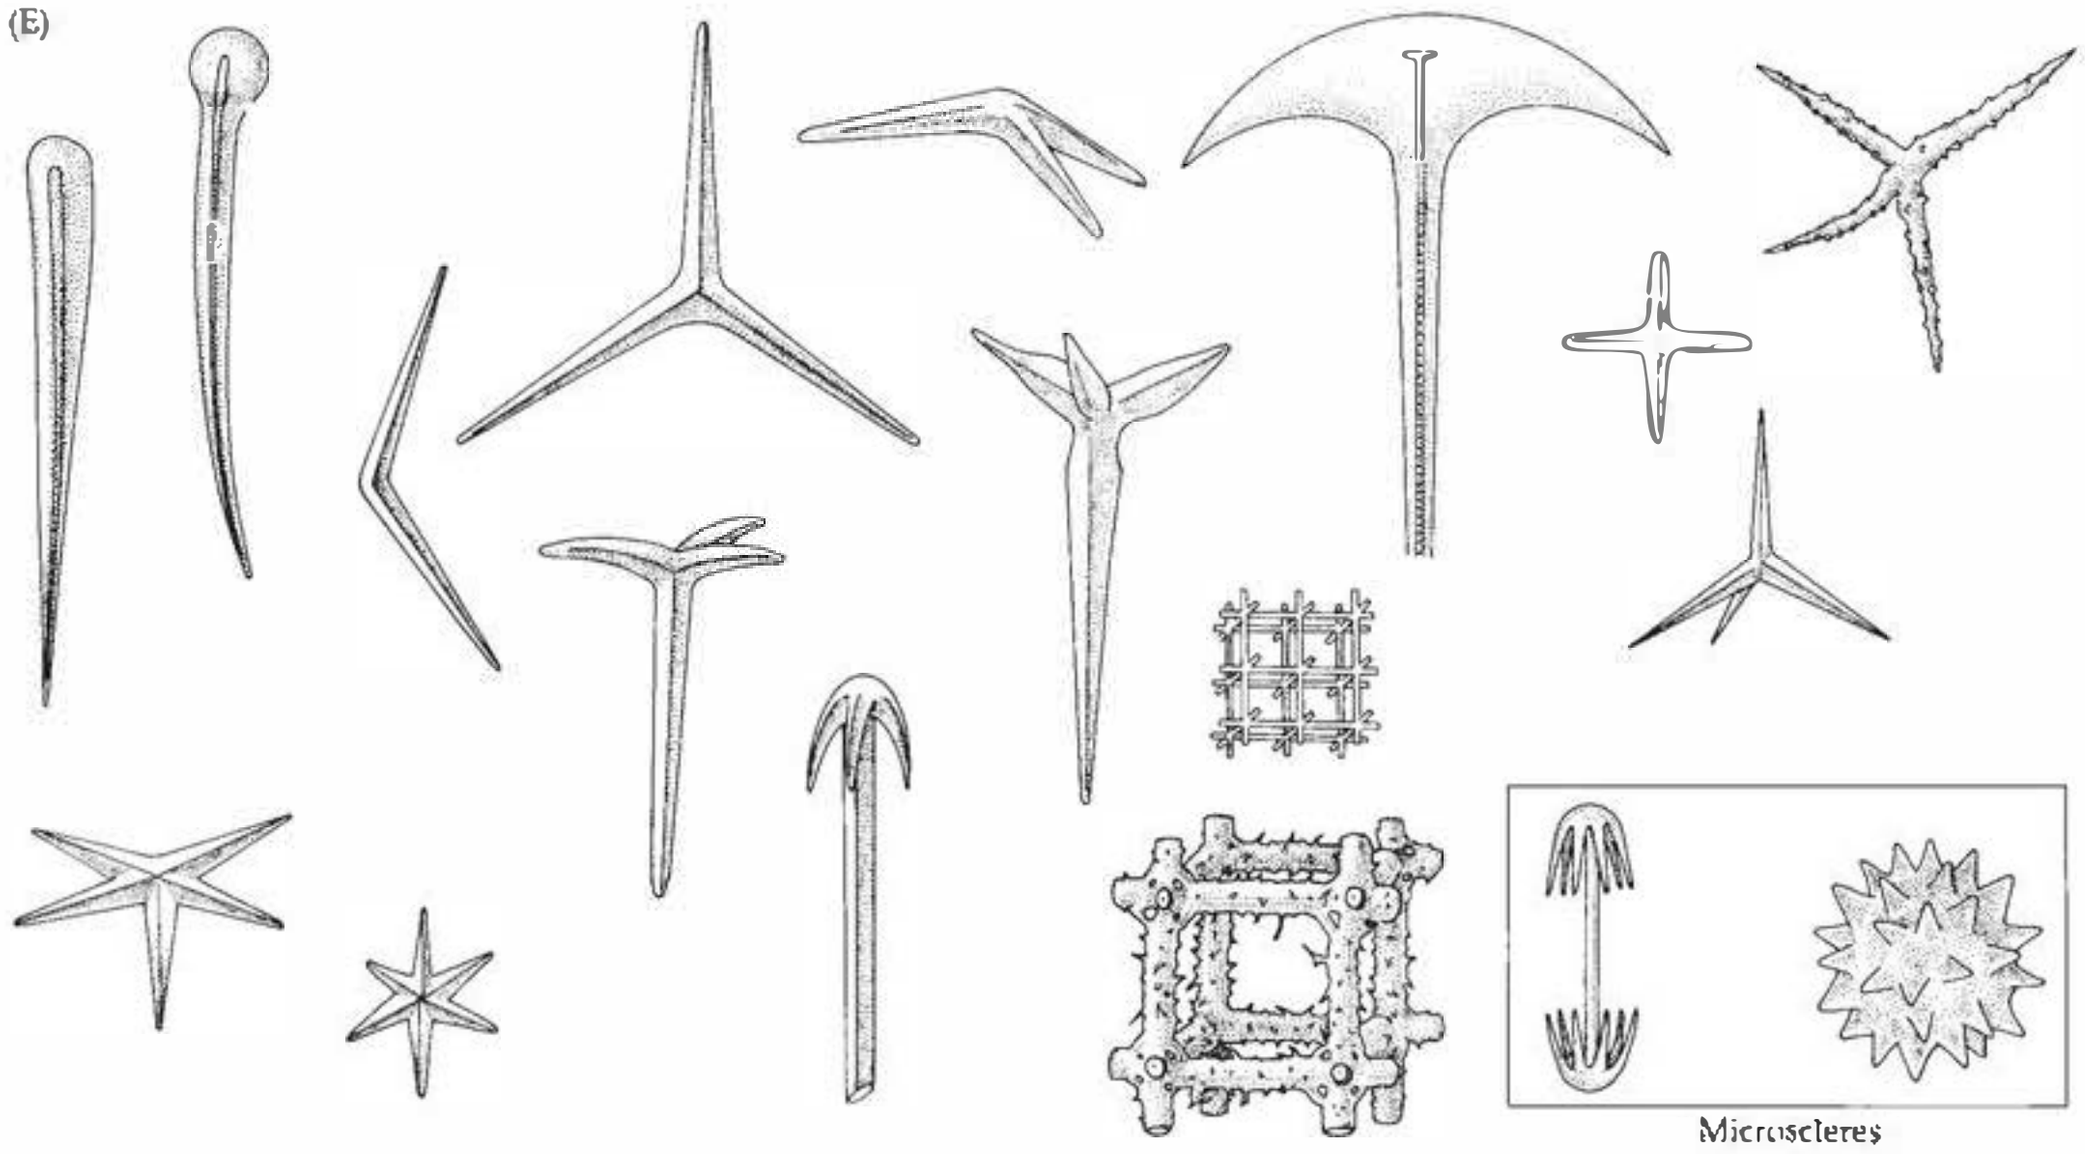


Figure 6.12 Sponge skeletal systems. (A) Photomicrograph of the superficial dermal spongin–fiber skeleton typical of the demosponge family Callyspongiidae. range (the distance between adjacent villi is ~1.5 μm or less), may be trapped on the collar itself. Larger particles, up to ~3 μm, adhere to the body of the choanocyte only to be engulfed by "pseudopodial" extensions (phagocytosis) that may be longer than the collar villi themselves. Undulations of the collar might move some trapped food particles down to the choanocyte cell body, or stalled food might be captured by long

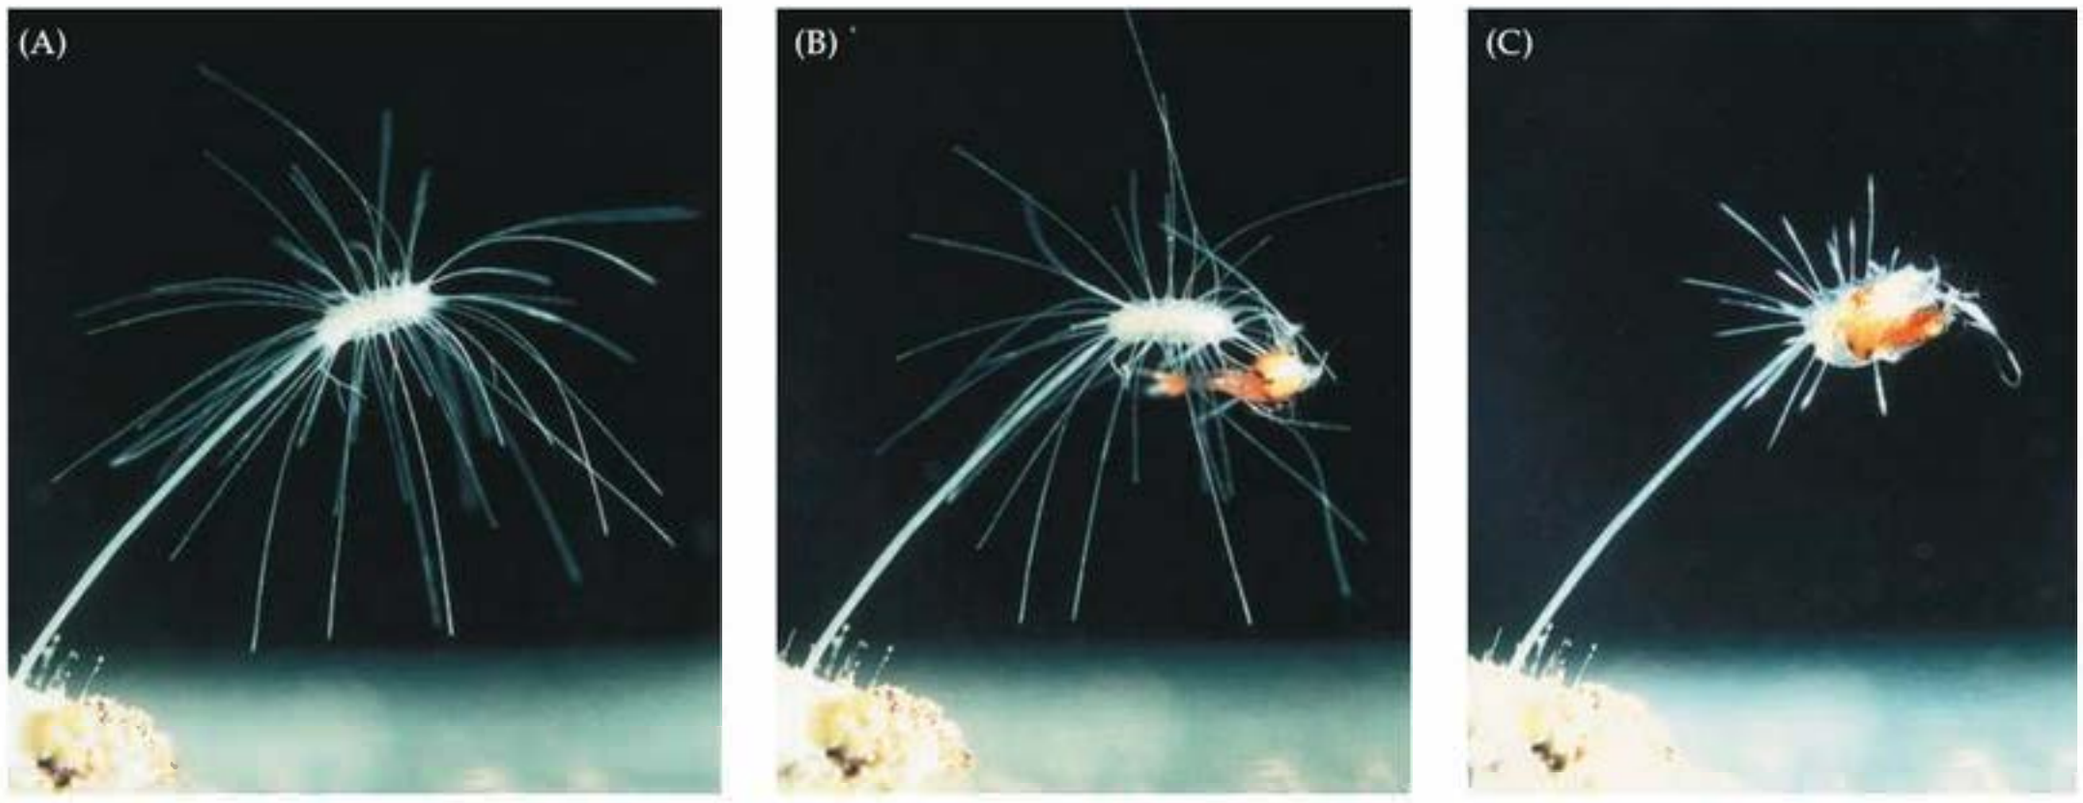
phagocytizing pseudopods that form from the collar microvilli and migrate from the base of the collar (as in Choanoflagellates) or by pseudopods from the choanocyte cell body itself

Interestingly, it would seem that food particle capture can take place almost anywhere on the surface of a sponge. Even pinacocytes are known to be capable of phagocytizing particles as large as 6 μm on the surface of a sponge. It has been estimated that the pinacocytes lining canals can take particles as large as 50 μm.

In the case of archaeocyte phagocytosis, digestion takes place in the food vacuole formed at the time of capture. In the case of choanocyte capture, food particles are partly digested in the choanocytes and then quickly passed on to a mesohyl archaeocyte (or other wandering amebocyte) for final digestion. In both cases, the mobility of the mesohyl cells assures transport of nutrients throughout the sponge body.



The efficiency of food capture and digestion was dramatically shown in an elegant study long ago, by Schmidt (1970), using fluorescence-tagged bacteria fed to the freshwater sponge *Ephydatia fluviatilis*. By monitoring the movement of the fluorescent material, Schmidt determined that 30 minutes elapsed from the onset of feeding until the bacteria had been captured by choanocytes and moved to the base of the cells. Transfer of the fluorescent material to the mesohyl commenced 30 minutes later. Twenty four hours later, fluorescent wastes began to be discharged into the water, and no fluorescent material remained in the sponges after 48 hours. Additional studies on this same species led to an estimate of 7,600 choanocyte chambers per cubic millimeter of sponge body, each chamber pumping a phenomenal 1,200 times its own volume of water daily More complex leuconoid sponges have as many as 18,000 choanocyte chambers per cubic millimeter. In some thin walled asconoid and simple syconoid sponges, a distinctive mesohyl is hardly present. In these sponges the choanocytes assume both capture and digestive/assimilative functions. More recent studies have shown that sponges are capable of removing up to 95% of the bacteria and heterotrophic protists from the water they filter.

Many sponges appear to also take up significant amounts of dissolved organic matter (DOM) by pinocytosis from the water within the aquiferous system, and there is some evidence that this is needed by the microbial symbionts within the sponge. Studies have shown that 80% of the organic matter taken in by some shallow water marine sponges can be of a size below that resolvable by light microscopy. The other 20% comprises primarily bacteria and dinoflagellates. On the other hand, some sponges appear to rely very little on DOM for nutrition (e.g., some hexactinellids that have been studied). Recent studies show that at least some sponges form simple fecal pellets. Experiments on the widespread North Atlantic species *Halichondria panicea* have revealed that undigested material is expelled as discrete pellets coated with a thin layer of mucus. Exactly how these pellets are formed is unclear.

Figure 6.13 These remarkable SEMs and color photographs show predation in the carnivorous sponge *Asbestopluma* (family Cladorhizidae). (A–D) *Asbestopluma* in ambush posture (A), followed by capture of a mysid. (E) Fifteen minutes after capture of a mysid on its tentacle-like feeding filaments. (F–H) The mysid prey has been partly engulfed by the sponge. (I) The prey is entirely engulfed.

Although the phylum Porifera is characterized by filter feeding, members of the deep-sea demosponge family Cladorhizidae display an entirely different and unique mode of feeding. Species in this group have lost most or all of the characteristic choanocyte-lined aquiferous system and instead feed as macrophagous carnivores; in fact, they are passive suspension-feeding predators, spending a minimal amount of energy during long periods between rare feeding opportunities! They feed by trapping small prey on hook-shaped spicules that protrude from the surfaces of tentacle like structures (Figure 6.13 and 6.14). Trapped prey are gradually enveloped by migrating feeding cells that undertake digestion and absorption. Most cladorhizids live at great ocean depths, and *Asbestopluma occidentalis* is the deepest known sponge. Most cladorhizids probably remain undescribed and, unfortunately, they are common on the tops of seamounts—a habitat threatened by fishing and mineral extraction interests. However, one species of *Asbestopluma* (*A. hypogea*) lives in shallow caves in the Mediterranean, where it has been the subject of considerable study. One of the more bizarre cladorhizids is *Chondrocladia lyra* (the lyre sponge), which has a series of vanes extending from the central body, each vane in turn with a series of upright side branches, creating a lyre- or harp-like structure that works for passive suspension capture of small zooplankters, especially crustaceans. Cladorhizids apparently lack oscula, ostia, and a canal system, and some may even lack choanocytes! Another of the remarkable cladorhizid sponges, *Cladorhiza methanophila*, has been discovered to harbor methanotrophic bacterial symbionts in its cells, such as seen in many animals inhabiting hydrothermal vents and cold seeps. The sponge thus feeds both by predation and by direct consumption of its microbial symbionts. Recently, species in several other deep sea families have shown evidence of carnivory, suggesting that this habit has perhaps evolved several times among the Demospongiae.

Sponges continuously excrete waste from their body via the osculum. Occasionally, they also undergo a stereotypic series of whole body contractions, sometimes called a "sneeze." It appears that these contractions are stimulated by a reduction in water flow through the oscula, which would typically be caused by obstruction

from an excessive accumulation of particulates that can clog the aquiferous system. The decrease in oscular flow is registered by special short cilia that line the inner osculum epithelium. Unlike most cilia, that possess the classic 9+2 anatomy, these oscular cilia lack the central pair of microtubules and are nonmotile. Their

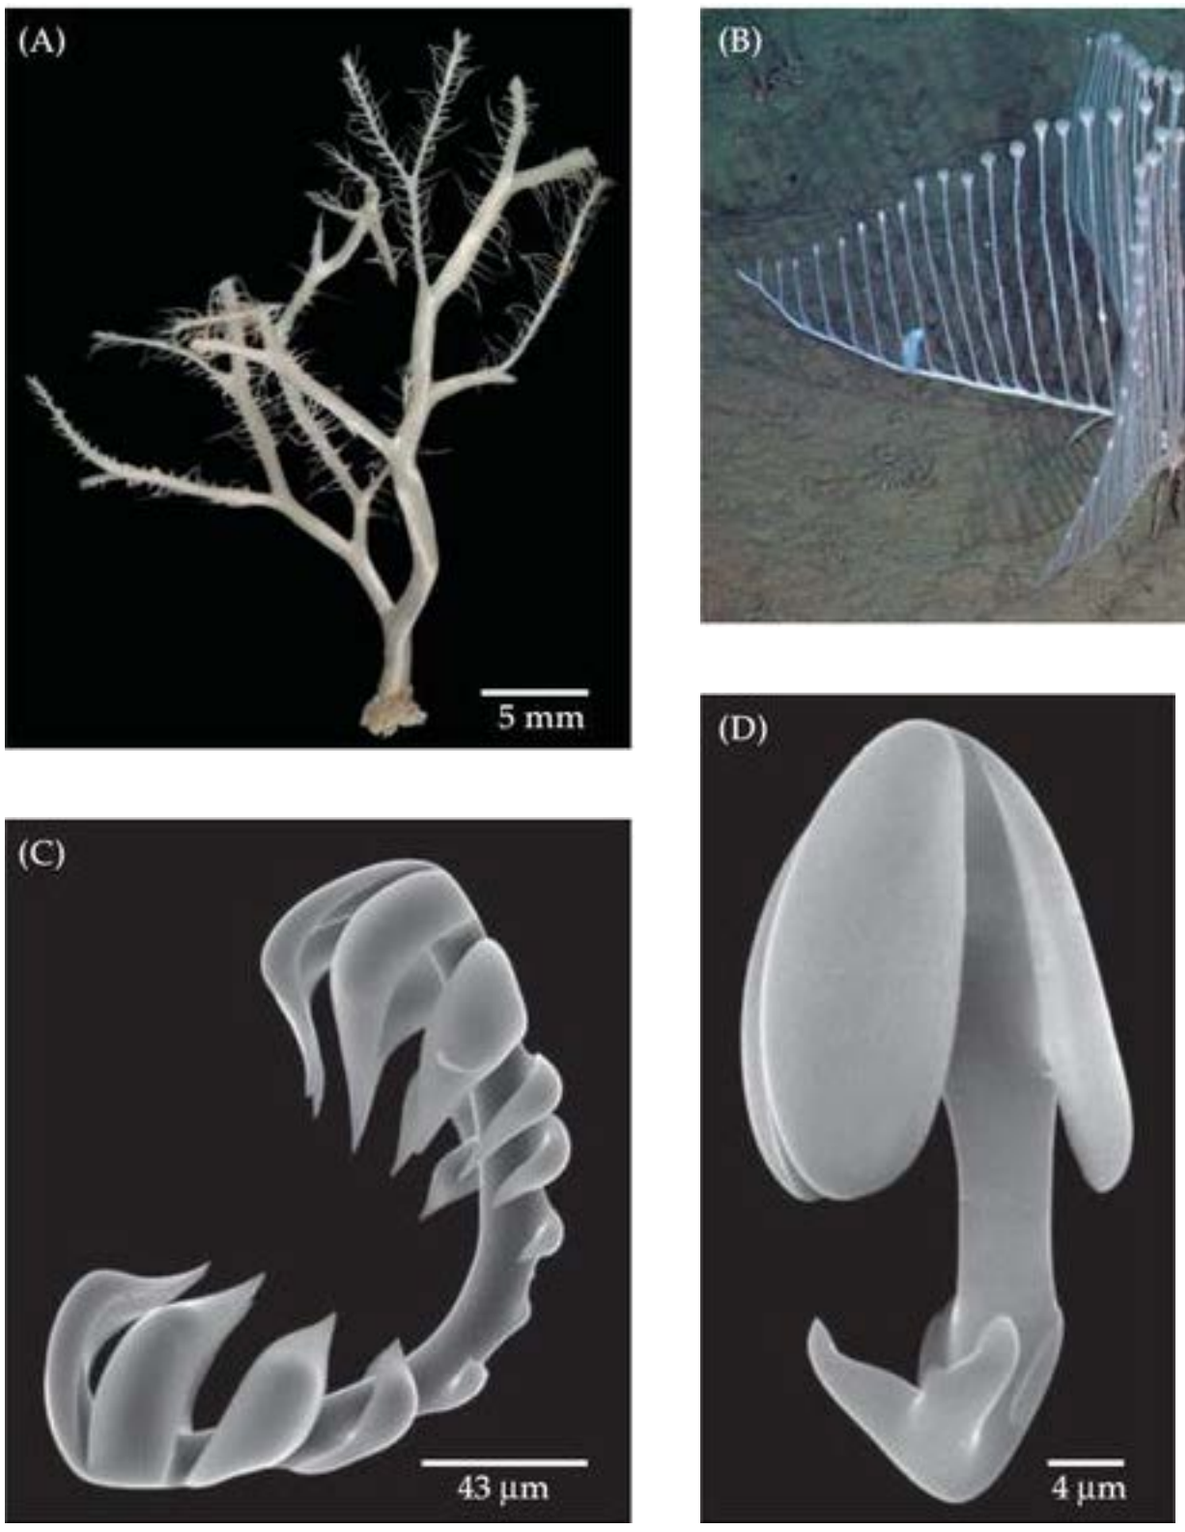


Figure 6 14 More carnivorous sponges (family Cladorhizidae). (A) *Asbestopluma desmophora*, a tree-like carn vorous sponge from New Zealand. Large clear megascleres are aligned vertically a ong the main "trunk," twisting around t to give a s lky sheen to the creature. The small, thin, side branches are covered in microscleres that snare passing prey. (B) The remarkable lyre sponge, *Chondrocladia lyra*, from a depth of 3.5 km off the coast of Monterey, Californ a, reaches 36 cm in height and has up to s x long vanes that grow from the m a n body, each vane with a parallel series of side branches that are used for passive suspension feeding of smal invertebrates, particu ar y crustaceans, using Velcro-like barbed hooks (microscleres). (C) A microsclere from *Abyssocladia car charias*, named for the remarkable shape of the "abyssochelae" microscleres, which resemble the jaws of the great wh te shark *Carcharodon carcharias*. (D) Microsclere ("anisochelae') of *Asbestopluma agglutinans*. In carnivorous sponges, microscleres are involved in snaring prey and typically line the sponge's su face.

function seems strictly to be the detection of flow rates through the oscula. Such cilia, called "primary cilia" are known from other metazoans, where they typically sense changes in fluid movement. Thus, the sponge osculum can be viewed as a true sense organ—the only one known in this phylum! Experimentally de-osculated sponges cannot be triggered to sneeze

Excretion (primarily ammonia) and gas exchange are by simple diffusion, much of which occurs across the choanoderm. We have already seen how folding of the body, combined with the presence of an aquif erous system, overcomes the surface-to-volume dilemma posed by an increase in size. The efficiency of the poriferan body plan is such that diffusion distances never exceed about 1.0 mm, the distance at which gas exchange by diffusion becomes notably inefficient. In addition, water expulsion vesicles (contractile vacu oles) occur in freshwater sponges and presumably aid in osmoregulation

Activity and Sensitivity

Sponges do not possess neurons, a nervous system, or discrete adult sense organs (except for the oscula, see above), and nothing resembling the synaptic connections (or gap junctions) of higher Metazoa is known in these animals. Neuronal synapses, which provide for chemically-mediated and directional nerve impulse transmission, do not occur in sponges (these occur in every metazoan phylum except Porifera and Placozoa).

Despite the absence of a nervous system, sponges are capable of responding to a variety of environmental stimuli by closure of the ostia or oscula, canal

constriction, backflow, body contractions that flush the aquiferous system ("sneezing"), and reorganization of flagellated chambers. Acetylcholinesterase, catecholamines, and serotonin have all been shown to be present in sponges and these probably play roles in coordinating "tissue" contractions, although electrophysiological evidence of a conducting mechanism is still lacking. Sponge larvae show both positive and negative phototaxis, depending on whether they are in their planktonic or settling phase. In the demosponge *Reniera*, larval photoreceptors are thought to be a posterior ring of columnar monociliated epithelial cells that possess cilia and pigment-filled protrusions In addition, the ability to conduct electrical impulses (when stimulated by an electrical probe) has been shown to exist in some Hexactinellida, where the absence of cellular membranes within the syncytium presumably allows action currents to spread in any direction from sites of depolarization. When the action currents reach choanocytes within the trabecular network, choanocyte activity is suppressed. In all sponges, the "default" behavior seems to be active pumping by the choanocytes to keep the aquiferous system functioning; and the usual effect of environmental stimuli is to reduce or stop the flow of water through the aquiferous system. For example, when suspended particulates become too large or too concentrated, sponges will respond by closing the incurrent openings and immobilizing the choanocyte flagella. Indeed, sponges have long been known to contract their ostia and oscula, and portions of their canal system, although the rates of propagation are very slow. Direct physical stimulation will also elicit this reaction, which is easily observed by simply running one's finger across a sponge surface and observing the dermal pore or oscular contractions with a hand lens or low power microscope. In addition, the mesohyl of some species has been shown to react to mechanical stimulation by stiffening.

Choanocyte pumping activity also varies with certain endogenous factors. For example, during a major growth phase, such as canal or chamber reorganization, choanocyte pumping activity typically decreases. Periods of reproductive activity also cause a substantial decrease in water pumping, in part because many choanocytes are expended in the reproduction process (see next section). Even under normal conditions, variations in pumping rates occur. Some sponges cease pumping activity periodically, for a few minutes or for hours at a time; others cease activity for several days at a time—reasons for these changes in activity are not always apparent.

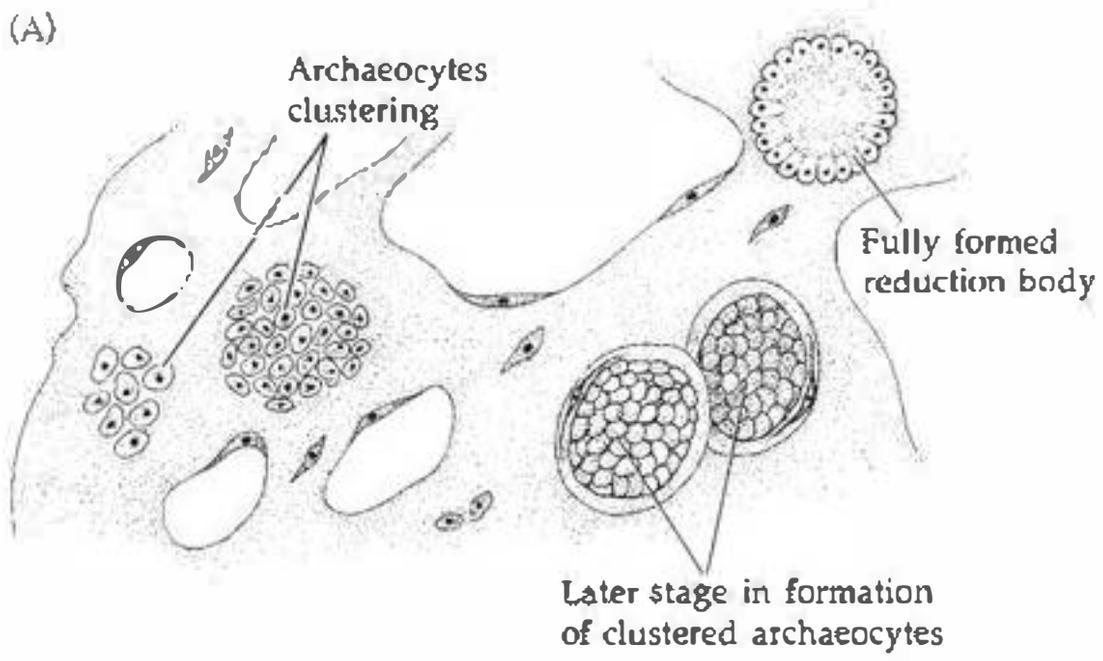
The switch from full pumping activity to complete cessation requires at least several minutes; considering the organism, however, this is a fairly fast response time. The spread of stimulation and response in most sponges appears to be by simple mechanical action (stimulation from one cell to the adjacent cells) and perhaps also by diffusion of certain chemical messengers (hormones, or other kinds of signaling molecules) released by cells. The process by which cells communicate with other cells by secreting specific chemicals released into the surrounding extracellular matrix is called a **paracrine signaling**, or a **paracrine system**, and some workers consider sponges to use this kind of cell-cell signaling.

The contractile myocytes of sponges act as independent effectors; they are organized into a network formed by contacts between filopodial extensions of adjacent myocytes and pinacocytes. Response time of myocytes is relatively slow. Latency periods average 0.01 to 0 04 seconds, and conduction velocities are typically less than 0.04 cm/sec (except in the hexactinellids, where velocities of 0.30 cm/sec have been recorded).[8] Conduction is unpolarized and diffuse, and it may rely on both hormones (or other signaling molecules) and direct mechanical action of one cell on the next. Considerable research once focused on the myocytes in attempts to shed light on the possible presence of a sponge nervous system analogous or homologous to that in higher Metazoa. But, in spite of these efforts, there has been no verification of such a system.

Reproduction and Development

All sponges are capable of sexual reproduction, and several types of asexual processes are also common. Many of the details of these processes are unknown, however, largely because sponges lack distinct or localized gonads (gametes and embryos can generally occur throughout the mesohyl). All hexactinellids, homoscleromorphans, and calcareous sponges are probably viviparous, as are most demosponges.

Asexual reproduction Probably all sponges are capable of regenerating viable adults from fragments. Many species "pinch off" buds of various types (Figure 6.15) by a process of cellular reorganization, whereas in others (especially branching species) pieces of the sponge body are simply broken off by storm surges. Either way, the dislodged pieces fall off and regenerate into new individuals. This regenerative ability was once commonly used by commercial sponge farmers, who propagated their sponges by attaching "cuttings" to submerged rocks or cement blocks. Even today, in Pohnpei (Federated States of Micronesia) sponge farmers string cuttings of *Coscinoderma mathewsi* on lines in lagoons, growing them into large bath sponges. Additional asexual processes of poriferans include formation of gemmules and reduction bodies, budding, and possibly formation of asexual larvae.



[8] It has been suggested that, in hexactinellids, the syncytium serves as an electrical conduction pathway, propagating impulses along its membranes that trigger flagellar arrests in the flagellated chambers

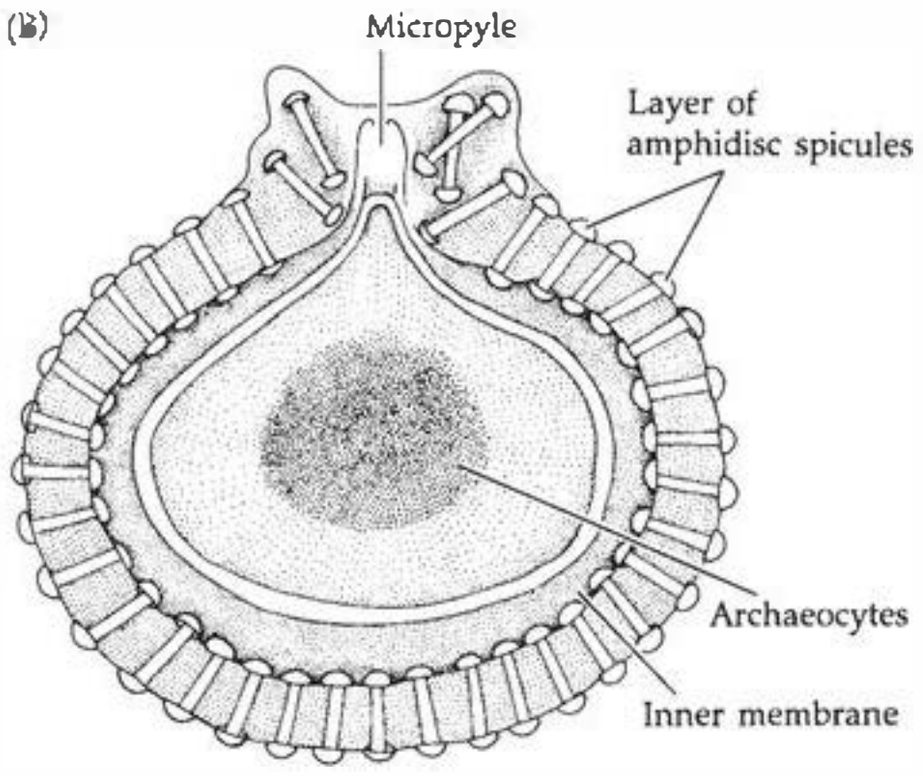


Figure 6.15 Budding in three demosponge species from New Zea and. (A) *Tethya burtoni* (B) *Stelletta* sp. (C) *Tethya bergquistae*

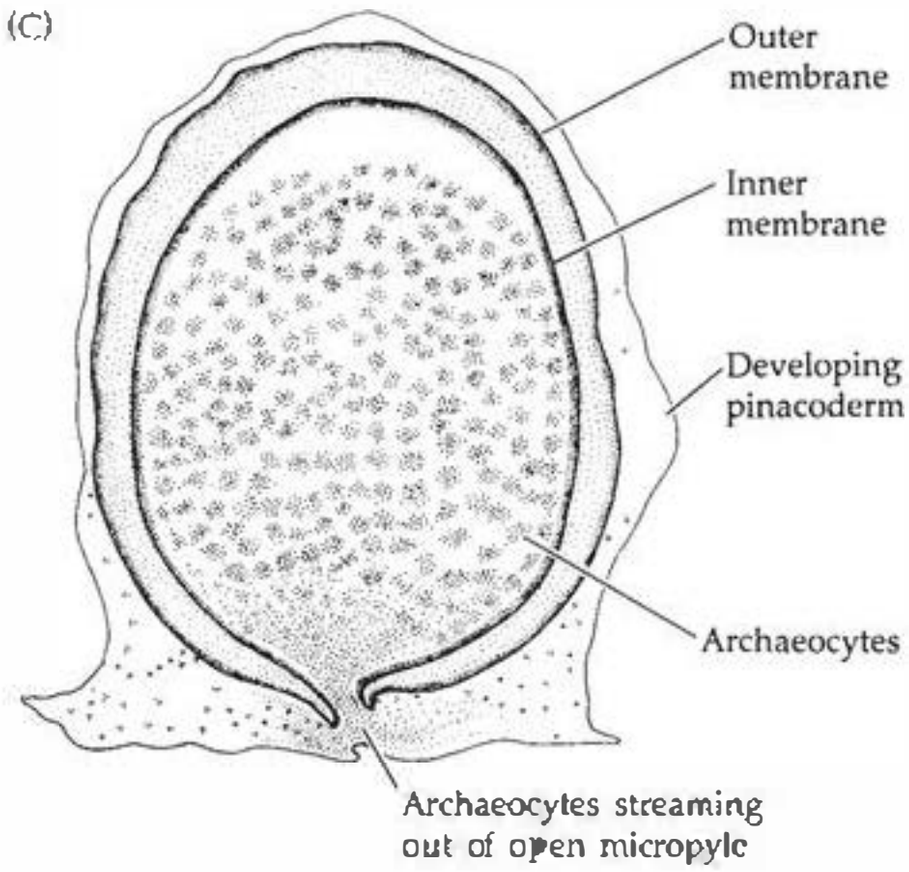
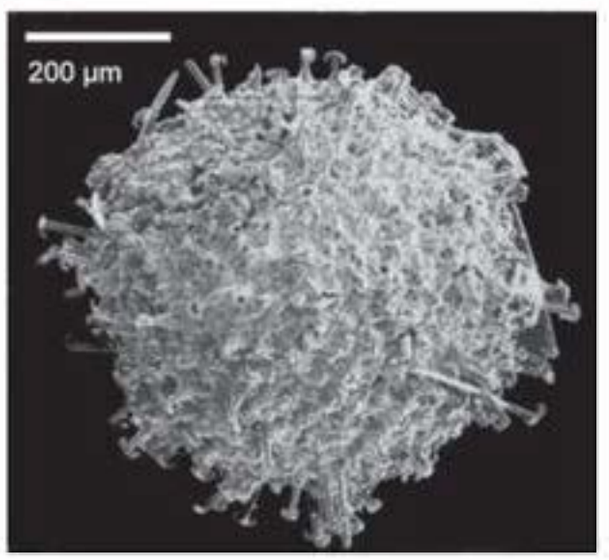
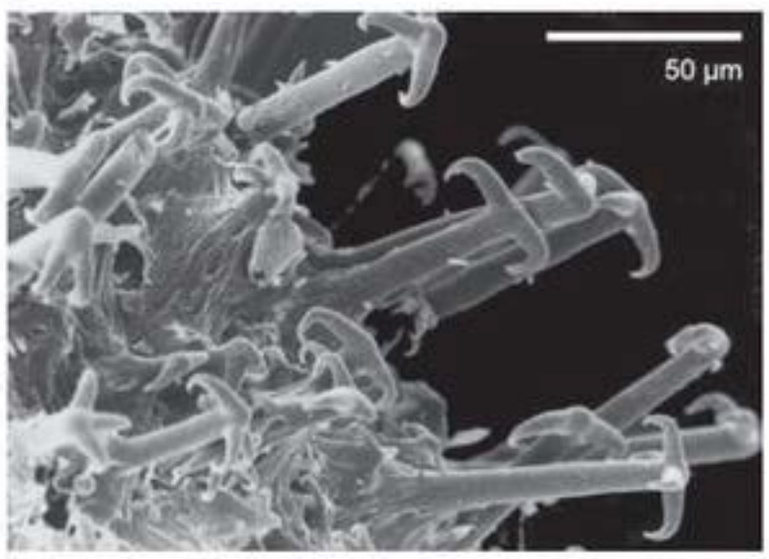


In freshwater sponges, small spherical structures called gemmules are produced at the onset of winter (Figure 6.16). These dormant, overwintering bodies are invested with a thick collagenous coating in which supportive siliceous microscleres (gemmoscleres) are embedded. Gemmules are highly resistant to both freezing and drying. The gemmules of some species can withstand exposure to 70°C for up to an hour, whereas others experience mortality at 10°C. Experiments suggest that gemmules of at least of some species can also withstand seasonal anoxic conditions. Fossil gemmules have been found as far back as the Cretaceous, and these ancient forms are very similar to modern ones. Gemmule morphology is highly specific and is used diagnostically at the family, genus, and even species levels. Three of the six freshwater sponge families do not produce gemmules: Lubomirskiidae and Metschinkowiidae (both known only from the Caspian Sea and Lake Baikal), and Malawispongiidae (from the ancient lakes of the Great African Rift Valley, through the Middle East, and to Sulawesi Island in the Indian Ocean).



The formation and eventual growth of gemmules are remarkable examples of poriferan cell totipotency. As winter approaches, archaeocytes aggregate in the mesohyl and undergo rapid mitosis. "Nurse cells," called trophocytes, stream to the archaeocyte mass and are engulfed by phagocytosis. The result is a mass of archaeocytes containing food reserves stored in elaborate vitelline platelets. This entire mass eventually b e comes surrounded by a three layered spongin cover ing. Developing gemmoscleres, amphidisc spicules (spicules having a stellate disk at each end) in most species, are transported by their parent cells to the growing geminule and incorporated into the spongin envelope. The final bit of the gemmule to be enclosed by the spongin case is covered only by a single layer of spongin that is devoid of spicules; this single layered patch is the micropyle. Thus formed, hibernation of the gemmule commences, while the parent sponge usually dies and disintegrates—such species can be thought of as "annuals."

When environmental conditions are again favor able, the micropyle opens and the first archaeocytes begin to flow out (Figure 6.16C). They immediately flow onto the substratum, whereupon they begin to construct a framework of new pinacoderm and choanoderm. The second wave of archaeocytes to leave the gemmule colonizes this framework. In the course of gemmule "hatching," and in an impressive example of cellular totipotency, archaeocytes quickly give rise to every cell type of the adult sponge. Gemmule dor mancy appears to be of two types, a quiescence and a true diapause. Quiescence is imposed by generally



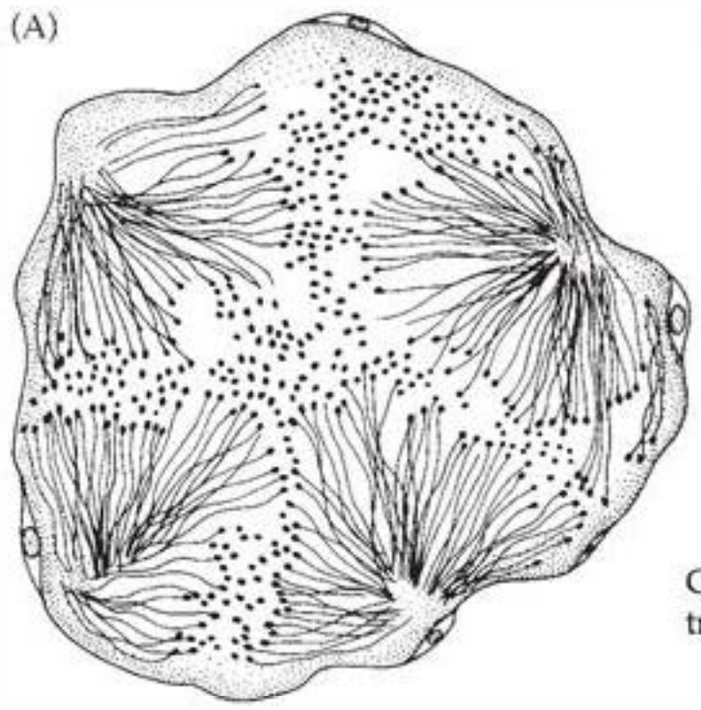


Figure 6.16 Gemmules and reduction bodies in sponges. (A) Reduction bodies forming in a marine sponge. (B) A gemmule (in section) of a freshwater sponge (Spongillidae). (C) A gemmule (in section) of the freshwater sponge *Spongilla* in the process of hatching. (D,E) Gemmule (SEMs) of *Anheteromeyenia argyrosperma* (Spongillidae).

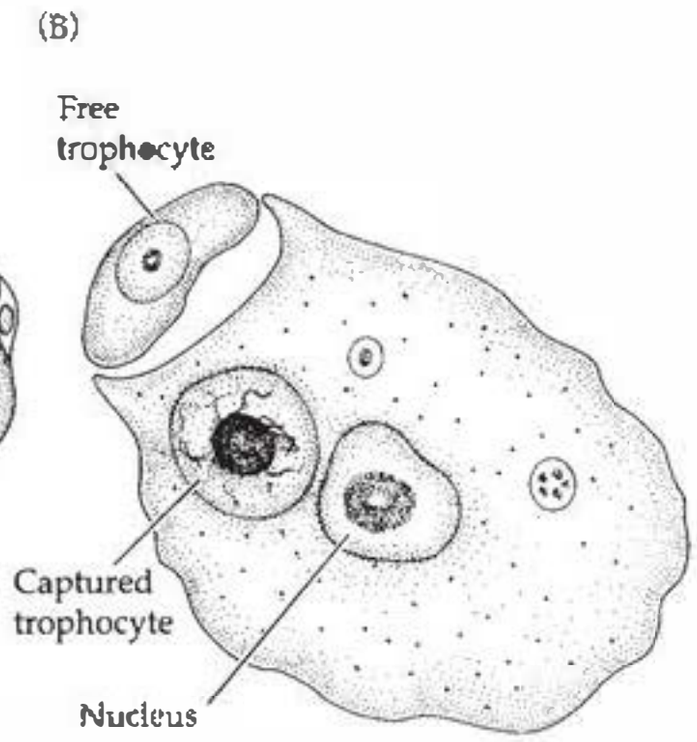

unfavorable conditions, including low temperatures, and it ends when suitable conditions return. Diapause, on the other hand, typical of annual species, is imposed by a combination of endogenous mechanisms and adverse environmental conditions. The breaking of a diapause state typically requires exposure to very low temperatures for a prescribed number of days.

Many marine species produce asexual reproductive bodies (called reduction bodies) that are roughly similar to freshwater gemmules, though much simpler in design and cell wall structure, and these incorporate a variety of amebocytes. And, in several genera of marine sponges (e.g., *Haliclona, Chalinula*) asexual reproductive bodies very similar to gemmules are formed, with a spongin coat containing spicules (oxeas).

Sexual processes The ancient origin of sponges is reflected in their extreme variability of reproductive and developmental strategies. Many are hermaphroditic, but they typically produce eggs and sperm at different times. This sequential hermaphroditism may take the form of protogyny or protandry, and the sex change may occur only once, or an individual may repeatedly alternate between male and female. In some species, individuals appear to be permanently male or female. In still other species, some individuals are permanently gonochoristic, whereas other individuals in the same population are hermaphroditic. In all cases, cross-fertilization is probably the rule.

Although sponge embryogenesis shares many cardinal features with higher Metazoa, including the

Inside the oocyte is a trophocyte that was recently ingested. (C) The unusual armored "hoplitomella larva" typical of boring sponges in the genus *Thoosa*. The armoring consists of flat plates that are actually highly modified spicules (called discotrienaenes). The long fibers emerging from the larva are also modified spicules that presumably aid in flotation. (D) Sperm release from *Xestospongia muta*, Florida. (E) Oocyte release in *Xestospongia muta*, Florida.

uniquely metazoan process of programmed cleavage and tissue layering through the process of embryonic morphogenesis that we regard as true gastrulation, it also expresses great variability. In fact, the range of ontogenetic adaptation among sponges is so broad that it is difficult to generalize about their development. The same cleavage pattern and blastula type may lead to several different larval types, and the same larval types may develop from different cleavage patterns. Overall, sponges appear to have remained at an "experimental grade" of development, in which fixed cleavage patterns and modes of gastrulation are not yet well established, and a variety of developmental processes are exploited among various lineages. This extreme developmental variation is described below.

Sperm appear to arise primarily from choanocytes; eggs from choanocytes or archaeocytes. Spermatogenesis usually occurs in distinct **spermatic** cysts (= sperm follicles), which form either when all the cells of a choanocyte chamber are transformed into spermatogonia, or when transformed choanocytes migrate into the mesohyl and aggregate there (Figure 6.17A). During oogenesis, solitary oocytes typically develop within cysts surrounded by a layer of follicle cells and, sometimes, nurse cells (**trophocytes**) (Figure 6.17B).

In Demospongiae and Calcarea, mature sperm and (in the case of demosponge oviparity) oocytes are released into the environment through the aquiferous system. The rapid release of sperm from sponge oscula can be highly visible and quite dramatic, and such individuals are often referred to as "smoking sponges" (Figure 6.17D). Sperm release may be synchronized in a local population or restricted to certain individuals. Fertilization takes place in the water (oviparity) leading to planktonic larvae, or within the female sponge itself (viviparity). In the viviparous coral-boring sponge *Cliona vermifera*, each zygote inside the sponge body becomes encapsulated; these are eventually released into the water in a series of rapid pulsations of the aquiferous system. In viviparous species, sperm

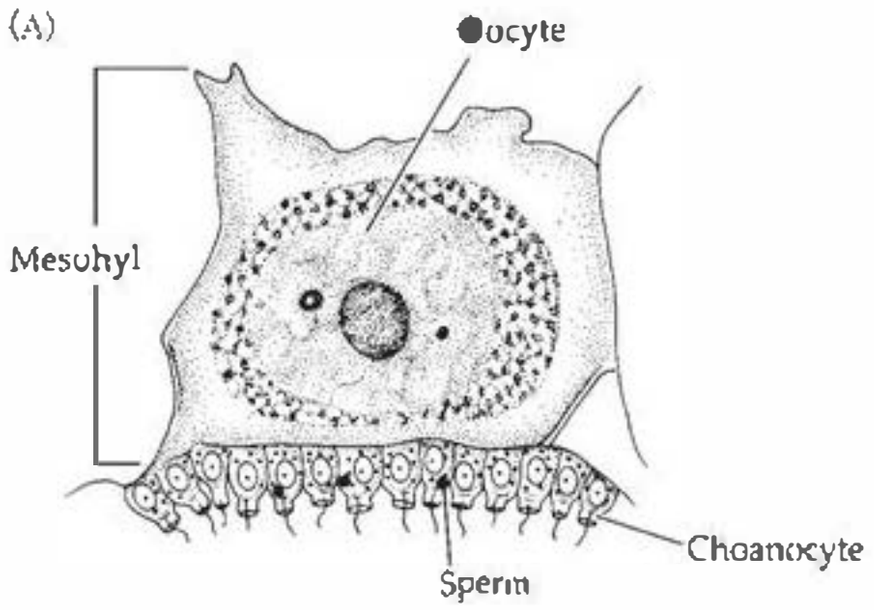

Figure 6.18 Fertilization in the calcareous sponge. (A) Sperm are trapped by choanocytes; an egg is lying in the mesohyl adjacent to the choanoderm. (B) A transfer choanocyte gives up its sperm to the egg; note that the egg lies next to the choanoderm and that the choanocyte has lost its flagellum.

(probably from a different individual) are taken into the aquiferous system and then must then cross the cellular barrier of the choanoderm, enter the mesohyl, locate the oocytes, penetrate the follicular barrier, and finally fertilize the egg. In all studied species of the subclass Calcaronea, this impressive feat involves sperm capture by choanocytes and enclosure in an intracellular vesicle (somewhat like the formation of a "benign food vacuole"). The choanocyte then loses its collar and flagellum and migrates through the mesohyl as an ameboid cell, transporting the sperm to the oocyte (Figure 6.18A). The migratory choanocyte is called a carrier cell, or transfer choanocyte (Figure 6.18B). Choanocytes no doubt regularly consume and digest the unlucky sperm of different species of sponges and other benthic invertebrates but, by some as yet undescribed recognition mechanism, they respond with a remarkably different behavior to sperm of their own kind. Presumably this process is directed by cell surface proteins/glycoproteins.

In viviparous species, embryos are typically released as mature swimming larvae via the excurrent plumbing of the aquiferous system, or through a rupture in the parent's body wall. Larvae may settle directly, they may swim about for several hours or a few days before settling, or they may simply move about the substratum until ready to attach. In all sponge species that have been studied, the larvae are lecithotrophic. In general, littoral sponges tend to produce planktonic larvae, whereas the larvae of subtidal species tend to settle directly or move about on the ocean floor for a few days before beginning to grow into a new adult individual.

Embryogenesis and larvae Until fairly recently, larval development in sponges was surrounded by a great deal of mystery, partly because it had not been well studied and partly because huge variation exists. The broad array of blastulation/gastrulation processes and larval types seen in sponges is mind boggling, and many different, but distinct larval types have been described. In fact, a number of embryogenic pathways occur in sponges that do not occur in any other Metazoa (e.g., multipolar egression in Homoscleromorpha, polarized delamination in some demosponges). Since the 1990s, significant new work has altered our view of development in this phylum although many questions still remain. The diversity of sponge developmental pathways is remarkable, and in some instances the same cleavage pattern and blastula type may be characteristic of several different larval types. On the other hand, the same larval type may arise from very different cleavage patterns. For example, the parenchymella larva of *Reniera* (Demospongiae: Haplosclerida) develops as a result of chaotic (seemingly unpatterned) cleavage and multipolar delamination, whereas the parenchymella larva of *Halisarca* (Demospongiae: Halisarcida) arises by polyaxial cleavage and multipolar ingression.

Much of the confusion surrounding sponge embryogenesis has centered on the question of when gastrulation occurs. Many older studies had reported that, during larval development, the external ciliated cells lost their cilia and migrated internally, whereupon they differentiated into adult choanocytes. These studies suggested that larvae formed in such a way represented the blastula stage, with later gastrulation coinciding with larval metamorphosis. Such an embryonic processes, producing blastular larvae, would make sponges unique among metazoans. However, recent work suggests that this migration/inversion of cell layers during larval development was probably a misinterpretation in most if not all cases, and in fact sponge larvae probably represent post-gastrulation stage individuals (as with most other metazoan larvae). Cell migrations such as these do occur in some poriferans, but only *after* embryogenesis has formed a fully differentiated bi- or tri-layered larva, and such cell movements are thus not related to gastrulation. It now seems that most, if not all, sponge larvae derive from cellular reorganization that can be equated (though not necessarily

directly homologized) with gastrulation processes seen in other metazoans. Thus, gastrulation precedes the larval stage, and probably no sponge larvae represent blastula stages.[9]

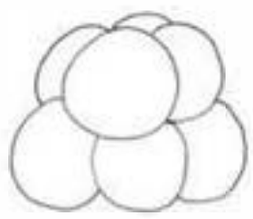
Specialists have long wondered what the original, or ancestral cleavage pattern in sponges (and Metazoa) might be—most researchers would probably vote for radial cleavage, and indeed this form of cleavage is seen in many demosponges, although it is not known from any other sponge class. At least three other forms of holoblastic cleavage have been described: chaotic (also known as "anarchic") cleavage, table palintomy, and polyaxial cleavage. Chaotic cleavage (seemingly random, or unpatterned) is characteristic of many demosponges. In table palintomy, the cleavage furrows pass obliquely relative to the egg's animal–vegetal axis; this form of cleavage occurs in some calcareous sponges (Calcaronea) It is also reminiscent of the green algal genus *Volvox* and several other colonial protists. However, the Calcaronea also undergo an utterly unique process of inversion of the blastula, and this has led some workers to suggest that palintomy is an aberrant cleavage process. Polyaxial cleavage is characteristic of the genus *Halisarca* and possibly also the Calcinea (Calcarea). It is characterized by cleavage furrows that form perpendicular to the surface of the embryo during the transition from the 8 to 16-cell stage, with axes of symmetry that radiate at certain angles from the center of the embryo; however, after the 16-cell stage division becomes chaotic.

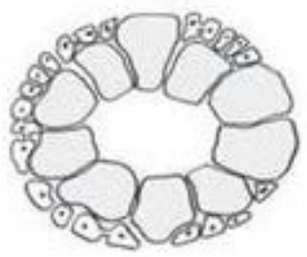
Although sponge embryogeny is highly variable, all species go through an ordered sequence of blastomere divisions and movements leading to morphogenesis of larval tissue structures (which we consider to be gastrulation) and formation of a larval axis that is often referred to as an anterior posterior axis. Spongologists have so far recognized at least seven types of sexual development in sponges, recognized by their resultant larval forms, but continued research may reveal even more: (1) trichimella larva (Hexactinellida), (2) calciblastula larva (Calcarea: Calcinea), (3) amphiblastula larva (Calcarea: Calcaronea), (4) cinctoblastula larva (Homoscleromorpha), (5) disphaerula larva (Demospongiae: Halisarcidae), (6) direct development (Demospongiae, Tetractinellida, *Tetilla*), and (7) parenchymella larvae (most Demospongiae). These seven developmental pathways are depicted in Figure 6.19 and described below. The anterior flagellated pole of swimming sponge larvae (e.g., amphiblastula, cincto blastula, parenchymella; Figure 6.20) putatively corresponds to the animal pole of other metazoan larvae, and it is this pole that gives rise to the internal choanoderm, while ameboid cells at the posterior pole generate the outer layer (pinacoderm) of the adult sponge.

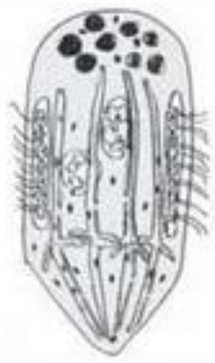
Homologues of metazoan developmental genes are just beginning to be described from Porifera, but many more should be revealed soon with the recent completion of a "complete genome" for the demosponge *Amphimedon queenslandica*. Already, a diversity of metazoan homeobox genes have been identified in sponges, and in *A. queenslandica* a broad range of transcription factor gene classes, many of which appear to be metazoan specific, are expressed during development. However, the possible homologies of adult sponge tissues to metazoan endoderm and ectoderm remain quite uncertain, and for this reason the terms "gastrodermis" and "epidermis" are used for sponges to avoid implications of embryological homology (and the inner mesohyl layer certainly does not appear to

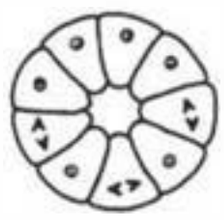
[9] The question of whether or not, and when, gastrulation occurs in sponges has long been debated. In fact, it depends on how one defines "gastrulation." Some workers define gastrulation simply as the epithelialization of embryos, thus clearly indicating sponges undergo gastrulation. Other workers define it as the embryogenic process through which metazoan ectoderm and endoderm, and a gut are derived, but, of course, sponges have no guts and their inner and outer cell layers appear not to be homologous to the epithelia of higher metazoans, and on this basis one could argue that gastrulation does not occur in Porifera. Spongologists following this line of logic refer to "embryonic morphogenesis" rather than "gastrulation." Still others have defined poriferan gastrulation as the process of metamorphosis from larva to adult, when the choanocyte chambers are formed. In this book, we define gastrulation (in the general sense) as the reorganization of cells of the blastula to form multiple embryonic germ layers—the tissues upon which all subsequent development depends. Gastrulation, in most cases, creates the separation of those cells that must interact directly with the environment, and those that process materials taken in from the environment. Thus, gastrulation is a keystone, defining feature of the Metazoa. By our definition then, gastrulation in sponges takes place during formation of the larva, when the first germ layers are laid down, regardless of the process. It is worth noting, however, that the absence of solid cell–cell adhesion, and the ability of sponge cells to become mobile, might argue against true gastrulation in sponges because there is not necessarily conservation of cells in specific germ layers.

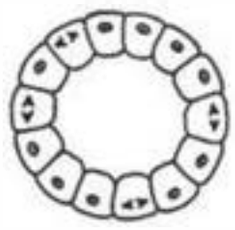
Interestingly, the term "gastrulation" derives from the name given by Ernst Haeckel (in 1872) to a stage in the development of calcareous sponges, his gastrula stage, a ciliated egg shaped larva that settles to the benthos and, according to Haeckel, formed a "mouth and a gut." Haeckel claimed that the gastrula stage could be found in the development of all animals, and thus represents the recapitulation of the ancestral metazoan, a hypothetical ancestor he called the gastraea—a diploblastic animal with a ciliated gut This recapitulation, he argued, was proof that the Metazoa are monophyletic. Until recently, only one other observation of Haeckel's "gastrula" stage in calcareous sponges had been made, by the German philosopher and biologist Ernst Hammer, in 1908. And yet, "gastrulation by invagination" has been widely conceived, for over a hundred years, to be the ancestral mode of germ layer formation in animals. The conundrum, of course, is that we now know sponges don't form a typical metazoan gut, so the transient cavity formed by invagination during settlement cannot represent a future gut An outstanding sponge biologist by the name of Sally Leys has recently shown that what Haeckel (and later Hammer) witnessed was a very brief transitory stage in which the anterior cells of a settled calcareous sponge larva invaginate into the posterior half of the larva. However, the "invagination hole" closes completely and it is not until some days later that the sponge forms an osculum (not a gut!) at its apical pole Hence, there is no reason to assume that this transitory "gastrula" stage is a precursor for formation of a gut via invagination in higher animals Further, it is the earlier formation of the two cellular regions of the larva that comprises the actual gastrulation event (whereas metamorphosis upon settlement involves the reorganization of these already differentiated regions).

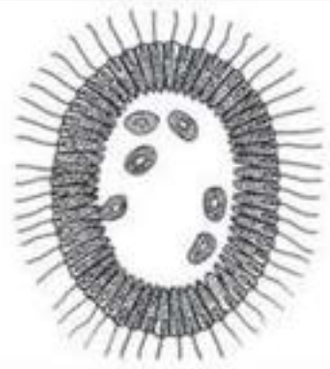


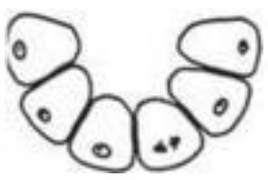


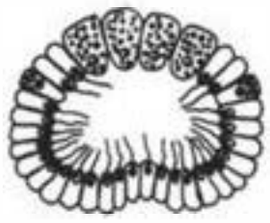


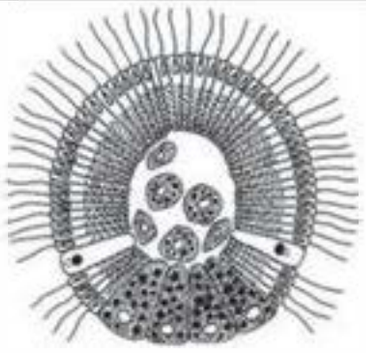


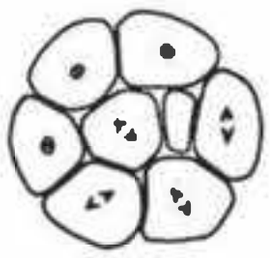


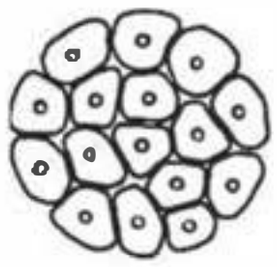


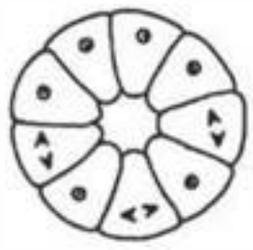


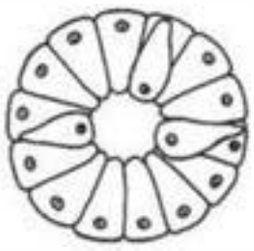


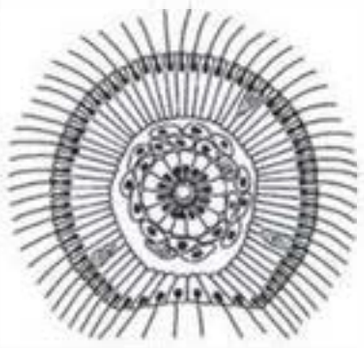


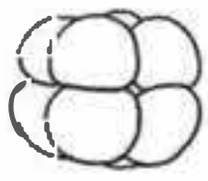


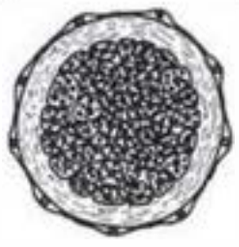


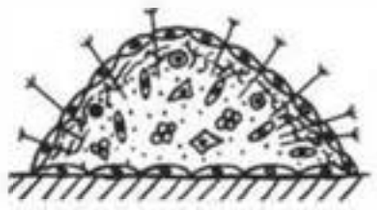


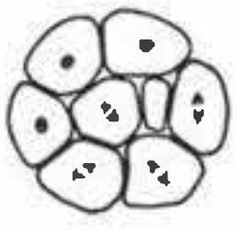


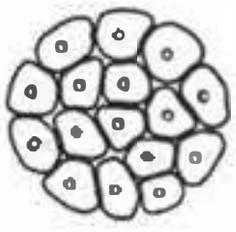


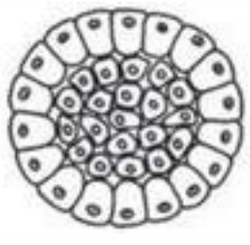












Type of development	Cleavage	Blastula	Morphogenesis	Larvae

be homologous to the mesoderm of higher Metazoa). This inability to directly homologize sponge tissues with those of higher Metazoa is one of the reasons some workers reject using the term "gastrulation" for Porifera. With the exception of the homoscleromorph demosponges, typical epithelial anatomy (with underlying basal lamina) appears to be lacking in sponges. The ability of pinacocytes to migrate into the mesohyl and convert to other cell types has also argued against considering this layer to be true ectodermally-derived epithelium (the motility of pinacocytes has been ascribed to the general absence of specialized desmosomal junctions among these cells).

Because there is so much variation in sponge developmental processes, each class is reviewed separately below.

Calcarea So far as is known, all calcareous sponges are viviparous. In the subclass Calcinea, oocytes develop within the mesohyl and grow in size (by phagocytizing neighboring amebocytes). Embryos also develop in the mesohyl and cleavage is total and equal to produce a hollow blastula larva (coeloblastula). The coeloblastula of some species has two types of cells: ciliated outer cells, and one or two posterior granular cells. After larval release, and just prior to larval attachment to the substrate, in some species, some cells loose their cilia and ingress into the blastocoel via ingression.

In the subclass Calcaronea, oocytes differentiate from choanocytes and move into the mesohyl. After a period of growth they migrate to the periphery of the sponge. Cleavage is total and equal, and the first three are meridional. The fourth division (at least in *Leucosolenia*) is oblique, almost exactly like the cleavage in the colonial green alga *Volvox*—a type of cleavage referred to as table palintomy. The resulting embryo is a cup-shaped blastula, with a small opening at the side closest to the choanoderm. While most of the cells continue to cleave in the same manner, forming a single-layered epithelium, a few that lie directly under the choanoderm do not; these remain much larger than the other cells, with their cytoplasm filled with large yolk granules. The most unusual feature of the calcaronean embryo is that cilia, which differentiate on the micromeres, project into the center of the blastocoel (inverted, compared with those in all other sponge embryos); this stage is called a stomoblastula (Figure 6.21B–D). To reach the final orientation, the embryo

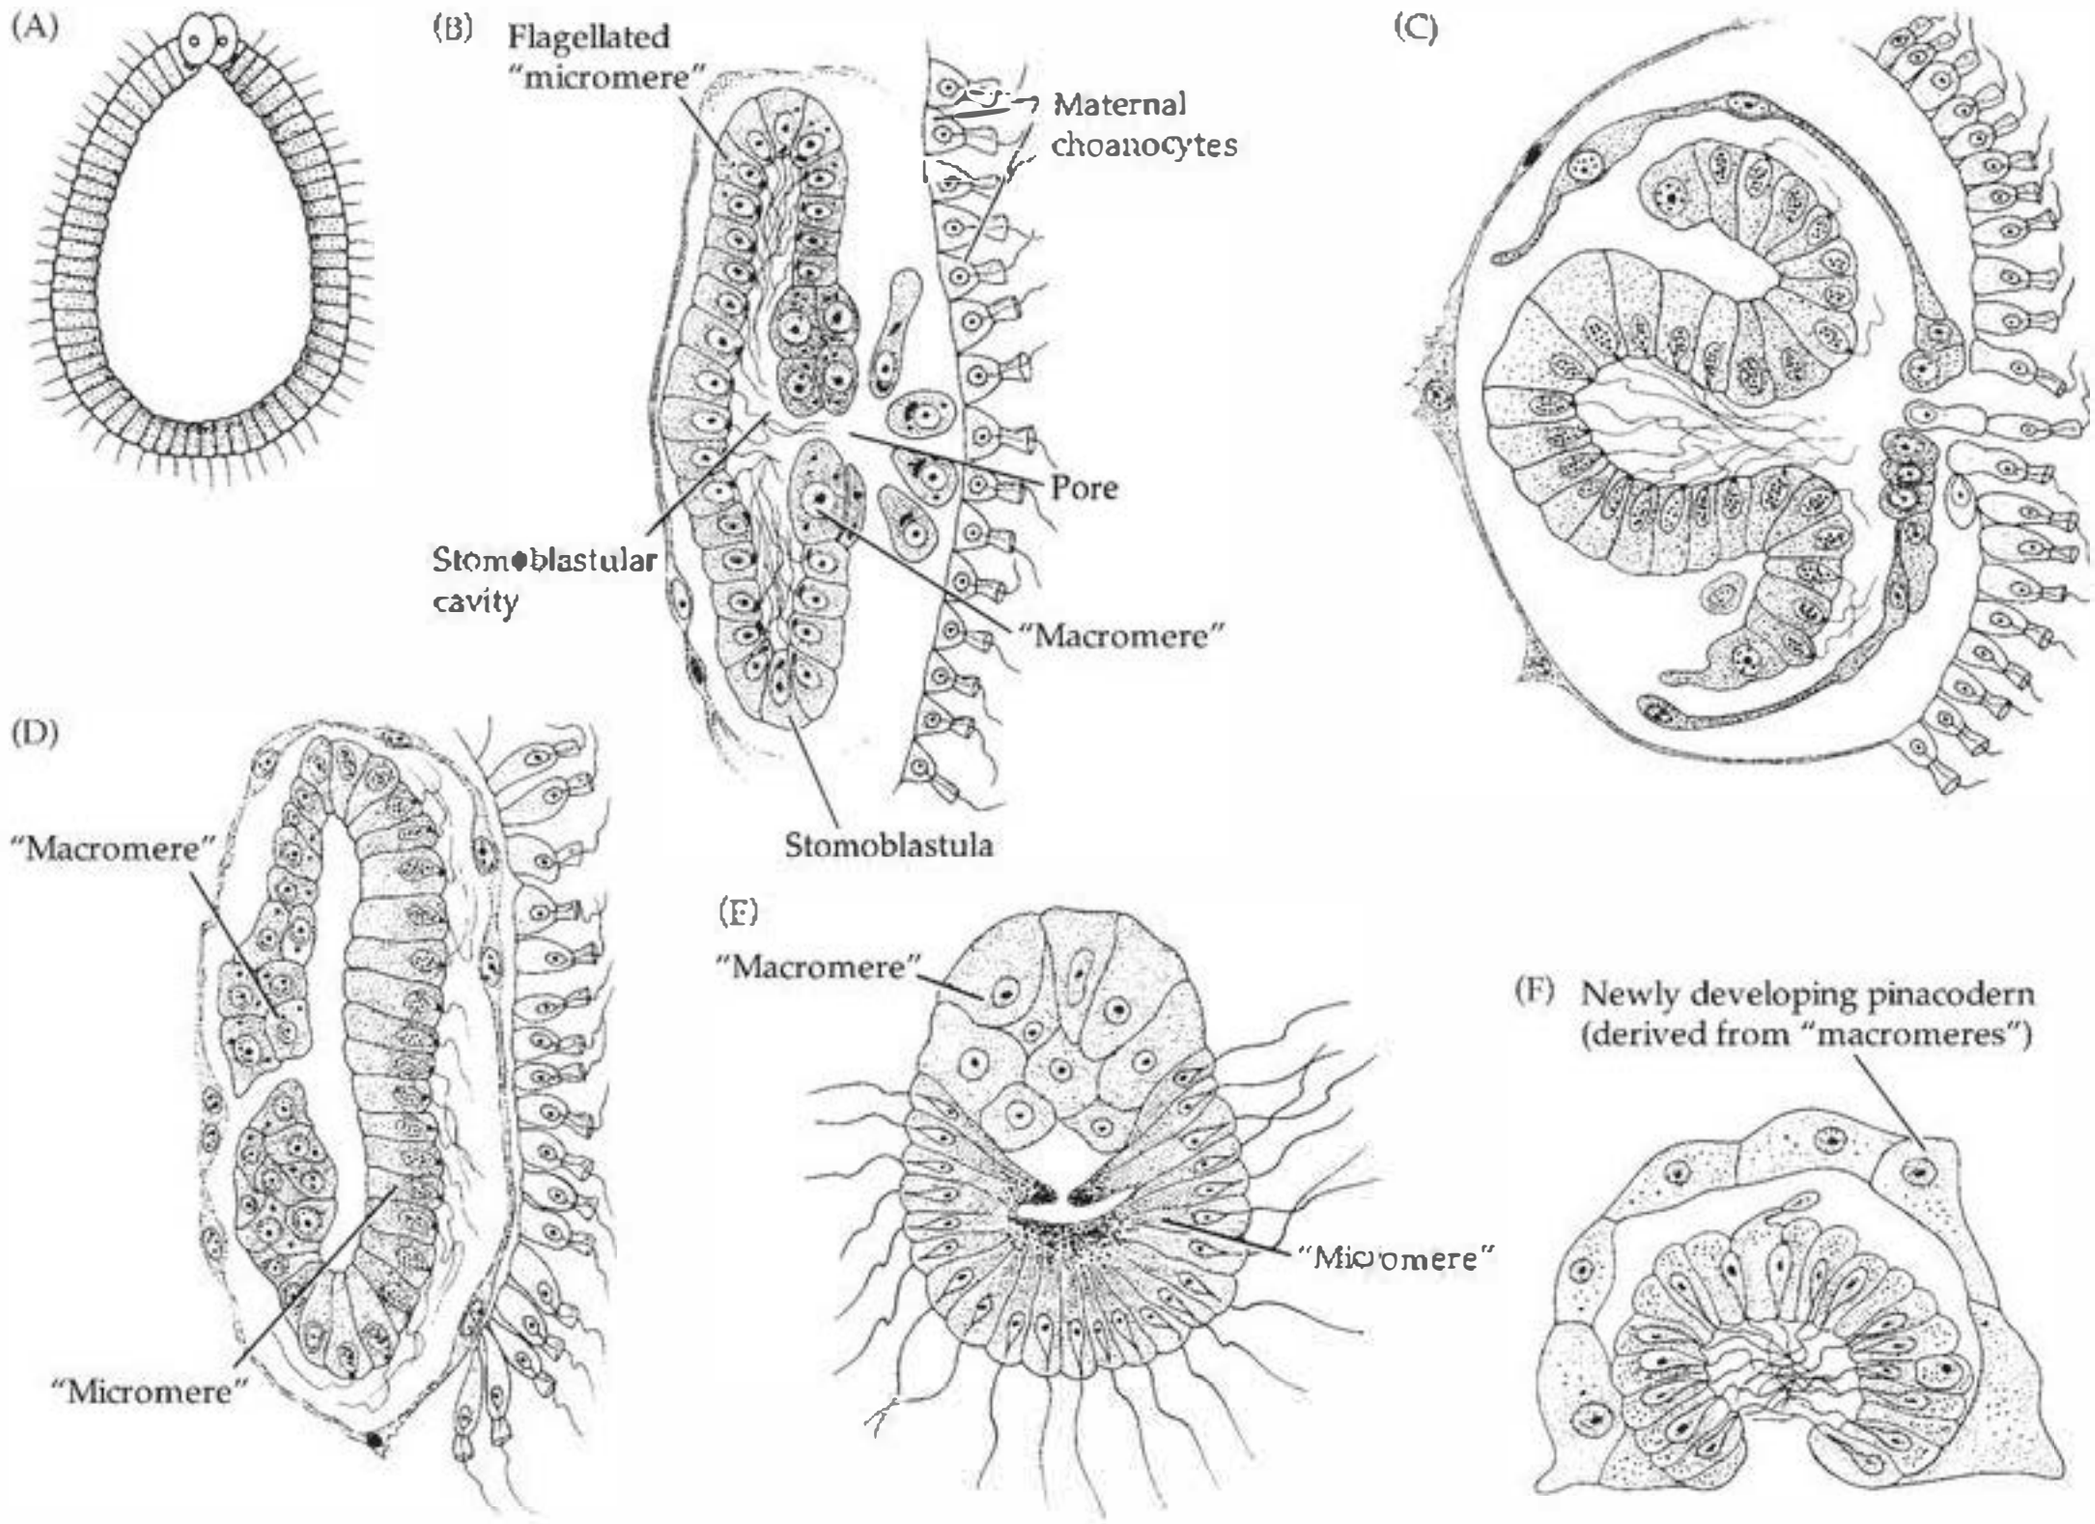

Figure 6.21 "Coeloblastula" and amphiblastula larvae (in section). (A) Typical "coeloblastula" larva with its posterior "macromeres." (B–D) During the remarkable process of inversion in *Sycon* (= *Scypha*), the stomoblastula turns itself inside out to form an amphiblastula larva with externally directed flagella. (E) A typical amphiblastula larva (*Sycon*). (F) Settled young sponge (*Sycon*) after invagination of flagellated cells.

actually turns itself inside out. To do this, the ciliated blastomeres move upwards and through the opening as a "single epithelium," into the choanocyte chamber (much as a bag is turned inside out). The resulting larva is an amphiblastula (Figure 6.21E), composed of anterior ciliated cells, posterior granular cells, and inner nutritive amebocytes.

The free-swimming amphiblastula larvae of *Sycon* (class Calcaronea) exit the parent sponge via the osculum and settle within 12 hours, attaching by their cilia, which are thought to be adhesive (probably via glycoproteins on the cell surface). In some cases, larvae settle on their anterior end, on the hole left from the earlier invagination event. The hole is thus unrelated to the future osculum (nor is it a primitive "mouth" of any kind); it is, in fact, engulfed by the newly forming epithelium of the metamorphosing larva. Thus, the transient cavity that is formed by invagination is not the future osculum of the sponge, as Ernst Haeckel long-ago intimated, and this invagination does not represent gastrulation. Once settled, they quickly undergo metamorphosis into a juvenile (sexually immature) sponge.[10] During metamorphosis, the anterior cells loose their cilia and migrate in to form an inner cell mass; some of these cells differentiate into choanocytes, while others remain amoeboid. Metamorphosis of these larvae seems to involve a rapid proliferation of the "macromeres" to form pinacoderm that overgrows the flagellated hemisphere. The flagellated cells pocket inward to form a chamber lined with cells destined to become choanocytes (Figure 6.21F). An osculum breaks through, and the tiny asconoid-like sponge becomes capable of circulating water and feeding. This

[10] This is the stage that Ernst Haeckel focused upon as the root of gastrulation. Haeckel, however, mistook the amphiblastula for a bilayered planula larva and claimed a number of observations that have never been repeated. It is likely that the microscopical tools that Haeckel had were simply insufficient to resolve the rapidly unfolding changes during embryogenesis and metamorphosis in *Sycon*.

initial functional stage is called an olynthus (Figure 6.5A). After further growth, it will become an asconoid, syconoid, or leuconoid adult, depending upon the species.

Hexactinellida Because reproductive individuals in this class are rarely encountered, and most species live in deep water, almost all of our knowledge on development comes from a few small cave dwelling species that are accessible by SCUBA. Although based upon studies of only a few species, a general overview of glass sponge development is as follows. Hexactinellids are probably all viviparous. Gametes arise from groups of archaeocytes that are suspended within the trabecular reticulum. Each archaeocytes cluster is called a congery, and all the cells are connected by cytoplasmic bridges (although mature oocytes are independent cells). It is not yet known how sperm find oocytes or how fertilization occurs. Cleavage to the 32 cell stage is total, equal, and asynchronous. The first cleavage is generally meridional, and the second either equatorial or rotational. By the 16- and 32-cell stage, the embryo is a hollow blastula. The following cleavages are unequal, producing smaller micromeres that lie on the outside and larger yolkrich macromeres on the inside. Even the earliest micromeres are connected to one another by cytoplasmic bridges. The macromeres divide unequally, gradually filling the center of the blastocoel, and eventually they envelop the micromeres with massive filopodia. Uniquely, these cells then fuse to form a single multinucleated giant tissue, the new trabecular syncytium, which completely envelops the micromeres. In this way, the embryo gains its outer epithelium. The formation of micromeres was originally considered to represent gastrulation by cellular delamination. However, the epithelialization of the larva—the enveloping of the micromeres by the incipient trabecular reticulum is probably better viewed as the true gastrulation event. The fully differentiated hexactinellid larva is a trichimella (Figure 6.19). The major tissue of the larva is the syncytial trabecular reticulum, continuous throughout the larva including its surface "epithelium." After swimming for one to several days, the larva settles on its anterior, lipid-filled pole and undergoes metamorphosis. The flagellated cells of the trichimella are multiciliated cells, which is unique among the sponges.

Demospongiae The class Demospongiae is large and diverse—without an easily characterized or uniform developmental pattern. Detailed recent embryological studies have been accomplished for only a dozen or so species. Both viviparity and oviparity occur in this class. Development is highly varied among the orders, families, genera, and in some cases even within single species. Spermatocytes may develop in special cysts within the mesohyl, and in most demosponges, notably in freshwater species, these derive from choanocytes. Oocytes may be isolecithal or telolecithal, and they usually arise from archaeocytes in the mesohyl—although in the family Lubomirskiidae (freshwater sponges in Lake Baikal) they are thought to derive from choanocytes—and they may be accompanied by yolk-rich nurse cells, or follicular cells, that form a thick coating around them, the yolk being incorporated into the cytoplasm of the oocytes. Spawning of eggs and sperm has been linked to lunar cycles in some species, as in many higher invertebrates Fertilization is usually external.

Cleavage appears to be complete, equal or unequal, often chaotic, and (at least in some species) produce micromeres and macromeres. The former develop a cilium, and eventually both types segregate out until the ciliated micromeres cover the periphery of the embryo (a process termed multipolar delamination). At this point, the embryo may be a solid blastula (stereoblastula), or a coeloblastula (although the central cavity may be filled with bacteriocytes and small granular cells of the follicle layer). Many species appear to produce parenchymella larvae that are polarized and possess a ciliated outer layer. Settlement seems to occur quickly, and in some species the eggs are released in a mucus mass and a planktonic larval stage is absent (larvae develop upon the substratum near the parent sponge).

Among the Demospongiae, the genus *Halisarca* stands out in several ways. It completely lacks a skeleton, and has mixed developmental pathways (that have been studied for over 100 years). Most, or all species are gonochoristic and viviparous. Spermatocytes originate from choanocytes via spermatic cysts. Oocytes also derive from choanocytes, and during vitellogenesis symbiotic bacteria characteristic of the mesohyl of adults are incorporated into the oocyte. Cleavage is total and equal, producing a hollow blastula. In many cases, cells invade the blastocoel by both multipolar and unipolar ingression. Cilia appear on the external cells of the 32 to 64 cell stage blastula, while internal cells differentiate to become archaeocytes. At this point, things get strange, because three very different kinds of larvae can now develop, even within the same individual parent sponge. The first is a coeloblastula, with a single layer of surface cells surrounding a small lumen. The second is a parenchymella that has an outer layer surrounding an inner cell mass of amoeboid cells. The third has two layers of epithelial cells, one external and the other internal, that line a small lumen; this type of larva is called a disphaerula. All three types are polarized by external patterns of ciliation, and all swim by rotating in a left-handed direction.

Homoscleromorpha The eggs of homoscleromorphs are isolecithal, rich in yolk inclusions, and completely

surrounded by a follicle formed of parental endopinacocytes. Cleavage is holoblastic and equal. At the third division, cleavage becomes irregular and asynchronous, and proceeds to form a solid morula of undifferentiated yolk-rich blastomeres. At about the 64-cell stage, the outer layer of the morula begins to differentiate. The blastomeres close to the surface divide more actively, while the internal cells migrate to the periphery of the embryo to gradually form a monolayered larva with a central cavity that contains symbiotic bacteria and maternally secreted cells. The resulting embryo is a hollow coeloblastula, and as the outer layer differentiates the cells grow cilia. So far as is known, the centrifugal migration of cells from the center to the periphery of the morula, to form the coeloblastula, is unique not only within Porifera but for all of Metazoa. This unusual process has been termed **multipolar egression**. The ciliated cells of the outermost layer become elongate (columnar) and are closely linked by desmosome like junctions.

Loose collagen fibrils fill most of the internal cavity as the coeloblastula matures into a larva. However, immediately below the outermost cell layer there develops a tough extracellular matrix of consolidated collagen fibrils, and beneath that there is a second layer of more loosely consolidated collagen fibrils. These two layers of collagen constitute a basement membrane similar to the one found below the pinacoderm and choanoderm of adult homoscleromorphs. (A similar network of extracellular matrix has been described from beneath the larval epithelium of one demosponge larva.) The outermost cell layer of homoscleromorph larvae is a true epithelium, homologous to that seen in adult sponges and in other Metazoa, its cells being columnar and producing a basement membrane/basal lamina.

As development continues, the central cavity is progressively filled by collagen fibrils (along with the symbiotic bacteria) and the larval epithelium becomes regionally differentiated, giving the larva a symmetry that most regard as truly anteriorposterior. The homoscleromorph larva was originally called an "amphiblastula" because it was thought to possess two fairly distinct regions, one ciliated and the other not However, morphogenesis in sponges of this group is not at all like that of sponges in the Calcaronea (a group for which the amphiblastula larva is characteristic), and the larvae are in fact completely ciliated. Thus it was suggested that the homoscleromorph larva be called a **cinctoblastula**, a term which more accurately describes its distinctive feature of paracrystalline intranuclear inclusions that from a belt around the posterior pole. The free-swimming cinctoblastula larva is ovoid or pear shaped, wider at the anterior pole than the posterior pole, and the entire surface is ciliated. All larvae that have been observed swim with a left-handed rotation.

Some Additional Aspects of Sponge Biology

Some basic sponge ecology has been presented in the previous sections of this chapter. However, because sponges play such important roles in so many marine habitats, and because they are intrinsically interesting in their phylogenetic "primitiveness," we add here some additional aspects of their natural history.

Distribution and Ecology

Certain distributional patterns are evident among the four classes of sponges Calcareous sponges (and coralline demosponges) are far more abundant in shallow waters (less than 200 m), although they are not uncommon at slope depths, and a few species (particularly *Sycon;* Figure 6 21) have even been reported from depths to 3,800 m. Hexactinellids, which were common in shallow seas of past eras, are now largely restricted to depths below 200 m, except in extremely cold environments (such as western Canada and Alaska, New Zealand, and Antarctica), where some species occur in shallow waters. Demosponges live at all depths, whereas homoscleromorphs occur from the continental shelf to around 1,000 m depth. Calcareous sponges may be restricted largely to shallow waters because they require a firm substratum for attachment On the other hand, many demosponges and hexactinellids grow on soft sediments, attaching by means of rootlike spicule tufts or mats. The coralline sponges, once a predominant group on shallow tropical reefs, are now largely restricted to shaded crevices and caves, to subreef depths, or to warm temperate waters where their potential competitors (the hermatypic corals) cannot grow (Figure 6.2L). They are thought to be relicts of major reef constructing sponge clades of Mesozoic and Paleozoic seas.

Although sponges are very sensitive to suspended sediment in their environment, they seem to be quite resistant to hydrocarbon and heavy metal contamination. Many species can actually accumulate these contaminants without apparent harm, and may be seen, for example, in the ferric granules on the spongin skeleton of fibrous bath sponges from intertidal regions. The capacity of certain species to accumulate metals at far higher levels than that of the ambient environment has been suggested as a possible defense mechanism (anti-predation, antifouling). Detergents also do not appear to affect many sponges, and in fact may even serve as a source of nutrition for these amazingly adaptable animals.

Sponges are the dominant animals in a great many benthic marine habitats. Most rocky littoral regions harbor enormous numbers of sponges, and they often occur in vast numbers (and large sizes) around Antarctica. Although many animals prey on sponges,

the amount of serious damage they do is usually slight. Some tropical fishes (e.g., some angelfish) and turtles (e.g., hawksbill turtles) crop certain kinds of sponges, a number of sea stars and shelled gastropods are sponge predators, and smaller predators (mainly opisthobranchs that closely match the prey sponge's color) consume limited amounts of living sponge material in both warm and temperate seas. Overall, however, sponges appear to be very stable and long-lived animals, perhaps in part due to their spicules and toxic or distasteful compounds that discourage would be predators.

Biochemical Agents

Seashore explorers and SCUBA divers quickly notice that sponges are just about everywhere, except on shallow sandy habitats. Most grow on open rock or occasionally mud surfaces where they are obviously exposed to potential predation. Clearly, some mechanism(s) must be working to prevent these animals from being cropped excessively by predators. The primary defense mechanisms in sponges are mechanical (skeletal structures) and biochemical. Studies have also show that sponges manufacture a surprisingly broad spectrum of biotoxins, some of which are quite potent. A few, such as *Tedania* and *Neofibularia*, can cause painful skin rashes in humans.

Research in sponge biochemistry has also revealed the widespread occurrence of antimicrobial agents in sponges. Sponges appear to use "chemical warfare" not only to reduce predation and prevent infections, but also to compete for space with other invertebrates such as ectoprocts, ascidians, and even other sponges. Different species have evolved chemicals (allelochemicals) that may be species-specific deterrents or actually lethal weapons for use against competing sessile and encrusting organisms. For example, the coral inhabiting sponge *Siphonodictyon* releases a toxic chemical into the mucus exuded from its oscula, thus preventing potential crowding by maintaining a zone of dead coral polyps around each osculum (Figure 6.22).

Many of the chemicals produced by sponges and other marine invertebrates are being closely studied by natural products chemists and biologists interested in their potential as pharmaceutical agents. Compounds with respiratory, cardiovascular, gastrointestinal, anti inflammatory, antitumor, cytotoxic, and antibiotic activities have been identified from many marine sponges. One study found that 87% of the temperate sponges, and 58% of the tropical species examined in New Zealand produced extracts with specific antibacterial activity. One New Zealand sponge (*Halichondria moorei*) has long been used by native Maoris to promote wound healing and was recently discovered to contain remarkably high concentrations (10% of the sponge dry weight) of the potent anti-inflammatory agent potassium fluorosilicate. In the 1950s, compounds belonging to a class of chemicals called arabinosides, that

Figure 6.22 *Siphonodictyon coralliphagum* infests the hermatypic coral *Siderastrea siderea* on a Caribbean reef. Note the "dead zone" between the oscular chimneys of the sponge and the coral polyps.

are active against viruses, were found in the tropical sponge *Tectitethya* (= *Tectya*) *crypta*. This led to the development of a number of important drugs that are in use today, including AraC (Citarabina®), sold under the trade name Cytosar-U®, by Pharmacia & Upjohn. Cytosar-U® was approved for treatment of certain leukemias in 1969, making it the first such approved marine-derived drug for use in cancer chemotherapy. Other drugs, also derived from natural products in *T. crypta*, include AZT (Zidovudine), manufactured under the trade name Retrovir® by the drug company GlaxoSmithKline, which was the first drug licensed for the treatment of HIV infection, and Ara-A (sold as Acyclovir/Zovirax®), an antiviral compound commonly prescribed for treating herpes.

Some sponges, including the west Pacific species *Luffariella variabilis*, produce a remarkable terpenoid compound called manoalide that is not only an extremely powerful antibacterial compound but also acts as both an analgesic and anti-inflammatory agent. Sponges of the genera *Halichondria* and *Pandaros* are known to produce potent antitumor compounds belonging to a group of chemicals called halichondrins. For example, eribulin mesylate (sold under the trade name Halaven®), a powerful treatment for metastatic breast cancer, is a synthetic analogue of halichondrin B, a product isolated from the marine sponge *Halichondria okadai*.

Growth Rates

Little is known regarding growth rates in sponges, but rates appear to vary widely among species. Some species are annuals (especially small-bodied calcareous sponges of colder waters); hence, they grow from larvae or reduction bodies to reproductive adulthood in a matter of months. Most, however, appear to be perennials and often grow so slowly that almost no

change can be seen from one year to the next; this growth pattern is especially true of tropical and polar demosponges. Until recently, age approximations of perennial species ranged from 20 to 100 years. However, research on the Caribbean giant barrel sponge *Xestospongia muta*, which can exceed two meters in height, suggests that this species might be capable of living more than 2,000 years. Radiocarbon dating of several hexactinellid *Rossella* species from Antarctica recently revealed growth rates of about 3 mm per year, aging the sponges at about 440 years old. Even more impressive, the west Pacific species *Monorhaphis chuni* has giant SiO_2 spicules that can reach lengths of nearly 3 m, representing the largest biogenic silica structures in the animal kingdom; the lifespan of the spicule is estimated to be 11,000 (±3,000) years, making this the longest-lived animal species on Earth!

Some sponges are capable of very rapid growth, and they regularly overgrow neighboring flora and fauna. For example, the tropical encrusting sponge *Terpios* is known to overgrow both living and nonliving substrata. In Guam, this sponge grows at rates averaging 23 mm per month, over almost every live coral species in the area as well as over hydrocorals, mollusc shells, and many algae. Experiments have shown that *Terpios* is toxic to living corals, and presumably to many other animals. However, in most cases of observed sponge overgrowth of living corals, the corals have been stressed (by temperature, sediment, pollution) or damaged and presumably weakened.

Still another physiological trick of some sponges is the ability to rapidly produce copious amounts of mucus when disturbed. On the west coast of North America, the beautiful red orange *Antho* (= *Plocamia*) *karykina* covers itself with a thick layer of mucus when injured or disturbed. Yet the little red sea slug *Rostanga pulchra* has evolved the ability to live and feed inconspicuously on this and other red-colored sponges, and even lays its camouflaged red egg masses on the sponge's exposed surface without eliciting the mucous reaction.

Symbioses

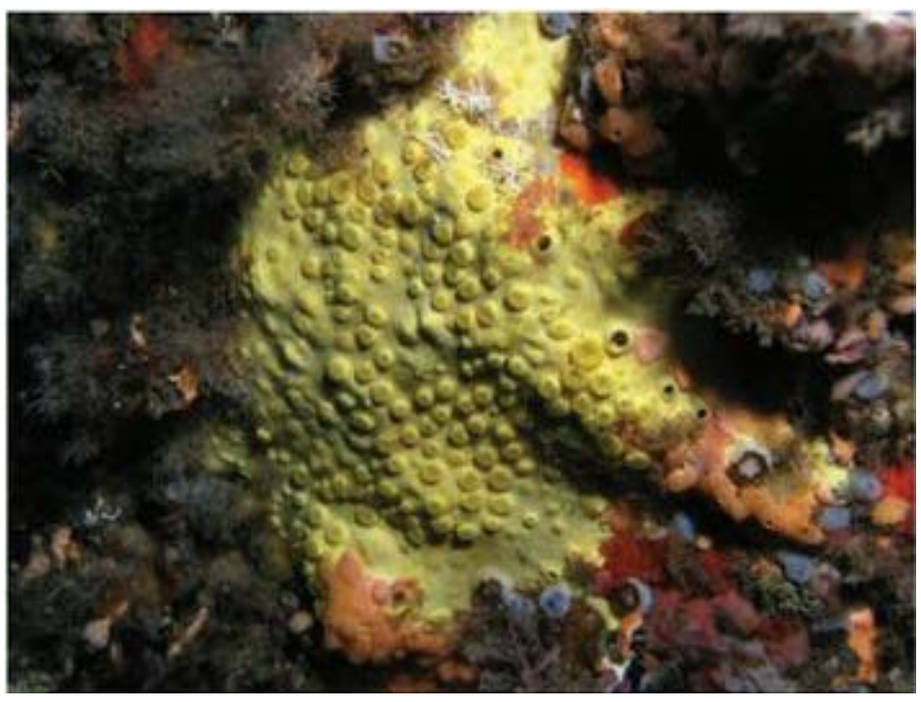
Symbiosis is common among sponges of all kinds. It would be difficult to find a marine sponge that is not utilized by at least some smaller invertebrates and often by fishes (e.g., gobies and blennies) as refuge. The porous nature of sponges makes them ideally suited for habitation by opportunistic crustaceans, ophiuroids, molluscs (e.g., scallops, mussels), and various worms. A single specimen of *Spheciospongia vesparia* from Florida marine waters was found to have over 16,000 alphaeid shrimps living in it, a study from the Gulf of California found nearly 100 different species of plants and animals on and in a 15 × 15 cm *Geodia mesotriaena*, and an examination of eight sponge species off the coast of South Carolina and Georgia (at depths of 18 to 875 m) recorded 236 symbiotic invertebrate species. The last study concluded that sponge symbiont assemblages can constitute legitimate ecological communities harboring complete food webs as well as gravid and juvenile individuals. Even freshwater sponges host abundant symbionts, and most freshwater invertebrate phyla have been recorded with sponges (e.g., Hydrozoa, Nematoda, Oligochaeta, Polychaeta, Gastropoda, Bivalvia, Isopoda, Amphipoda, Ostracoda, Copepoda, Hydracarina, Bryozoa).

Most symbionts of sponges use their hosts only for space and protection, but some rely on the sponge's water current for a supply of suspended food particles. A classic example of this phenomenon is the male–female pair of shrimp (*Spongicola*) that inhabit the globally distributed, deep-water hexactinellid sponges known as Venus's flower baskets (*Euplectella*; Figure 6.2O,P). The shrimp enter the sponge when they are young, only to become trapped in their host's glasslike case as they grow too large to escape. Here they spend their lives as "prisoners of love." Appropriately, this sponge (with its guests) is a traditional wedding gift in Japan—a symbol of the lifetime bond between two partners.

Other, far more intimate symbiotic relationships with sponges are also common. Some snails and clams characteristically have specific sponges encrusting their shells, and many species of crabs (hermits and brachyurans) collect certain sponges and cultivate them on their shell or carapace (Figure 6.2M). Demosponges, such as *Suberites*, are commonly involved in these commensalistic relationships. The sponge serves primarily as protective camouflage for its host, and it perhaps benefits by being carried about to new areas. The sponge also no doubt feeds off small bits of organic material dislodged during the feeding activities of its host. Evidence suggests that scallops and oysters with their shells overgrown by sponges (frequently *Halichondria panicea*) experience reduced predation from seastars. Certain dromiid crabs carry sponges on their carapace, probably also as a predator avoidance adaptation, and numerous species of decorator crabs stick pieces of sponge on their carapace as camouflage. A particularly odd symbiosis occurs in the Mediterranean Sea, where most colonies of the bryozoan *Smittina cervicornis* are overgrown by the thinly encrusting sponge *Halisarca harmelini*; somehow, the feeding currents actually appear to be strengthened for both partners by this collaboration. On the other hand, the Indonesian sponge *Mycale vansoesti* seems to rely on a coralline alga (*Amphiroa* sp.) as its skeleton; the alga completely invests the sponge and holds it erect, the sponge itself having almost no spicular skeleton of its own.

Other spectacular examples of poriferan symbioses are sponge–Bacteria/Archaea and sponge–algae associations, some of which appear to be mutualistic

whereas others are not. For example, a typical member of the demosponge order Verongida contains a mesohyl bacterial population accounting for some 38% of its body's volume, far exceeding the actual sponge-cell volume of only 21%. Presumably, the sponge matrix provides a rich medium for bacterial growth, and the host benefits by being able to conveniently phagocytize the bacteria for food. Similar relationships are common between poriferans and various Cyanobacteria. The Indian Ocean demosponge *Tethya orphei*, and other haplosclerid sponge species, have been shown to harbor an ectosome permeated by filamentous cyanobacteria (probably *Oscillatoria spongeliae*). Vertical transmission of symbiotic bacteria (from the parent sponge to the next generation) is a specific trait of poriferan development. The bacteria are transmitted to the buds or gemmules when the sponge reproduces asexually. During sexual reproduction the bacteria are transmitted through eggs (in oviparous species) or through larvae (in ovoviviparous forms). It has been suggested that in *Tethya seychellensis* the green alga *Ostreobium* sp. grows exclusively along the siliceous spicule bundles in order to capture sunlight via these natural optical fibers, and other evidence from *T. aurantium* also suggests that silicious spicules act like optical fibers to channel light to photosynthetic microbes living deep inside their bodies. Recent evidence suggests that some products of normal cyanobacterial metabolism (e.g., glycerol and certain organic phosphates) are translocated directly to the sponge for nutrition. In many sponges, both regular bacteria and Cyanobacteria co-occur, the former in deeper cellular regions, the latter closer to the surface where light is available. On the far-offshore regions of the Great Barrier Reef, 80% of the sponge individuals harbor commensal cyanobacteria. In one remarkable study, C. R. Wilkinson (1983) showed that 6 of the 10 most common sponge species on the forereef slope of Davies Reef (Great Barrier Reef) are actually net primary producers, with three times more oxygen produced by photosynthesis (by their symbionts) than consumed by respiration. Such relationships also exist with certain dinoflagellates, filamentous green algae, and red algae.



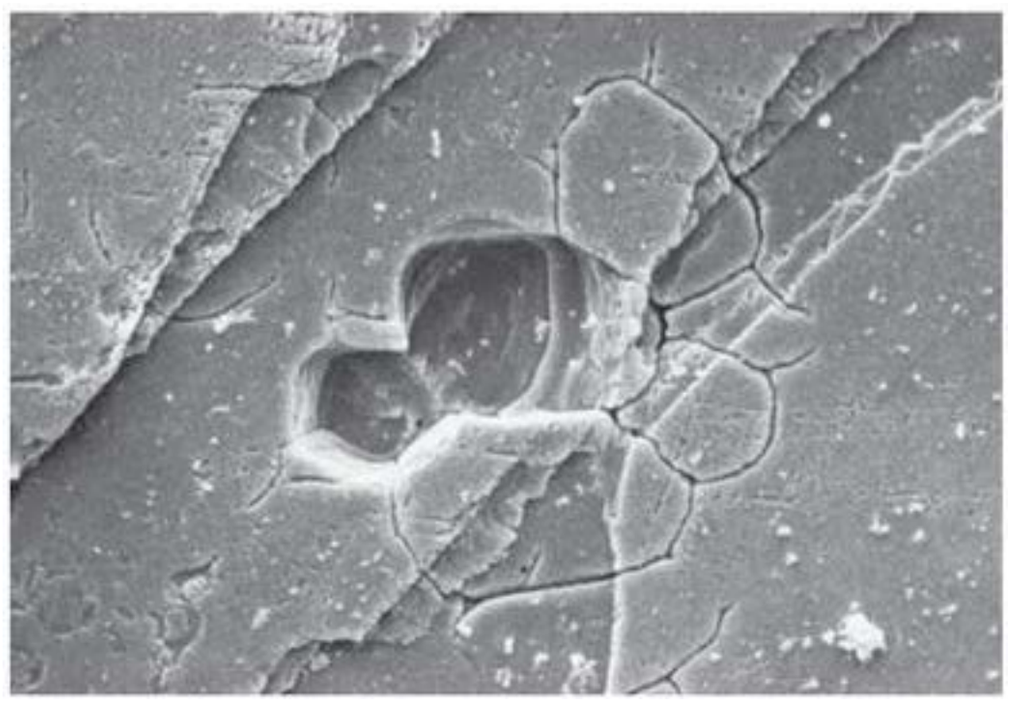
Recent studies of the Caribbean giant barrel sponge (*Xestospongia muta*) have provided evidence of two very different cyanobacterial symbionts in the *Synechococcus* group, both of which are implicated in "sponge bleaching" events in this species (similar to coral bleaching). There is no evidence that either species of *Synechococcus* maintains a mutualistic relationship with *Xestospongia muta*. One species seems to be a commensal, benefiting from the relationship but doing nothing positive or negative to the sponge. This species dies back on a cyclical basis (as do about 25% of the sponges off southern Florida), probably in association with abnormally warm seawater temperatures, and the cyanobacterial death causes a temporary bleaching (whitening) of the host sponge, but it does not kill it. The other species of *Synechococcus*, which also dies back with warmer than normal waters (and perhaps under other conditions), may be a pathogen and it kills its host sponge as it dies. Similar deaths, which are often associated with a distinctive orange "death band" that moves across the sponge body, have been recorded for several species of *Aplysina* in the Caribbean.

In some areas of the Caribbean and Great Barrier Reef, sponges are second only to corals in overall biomass, and they appear to owe their rapid growth to the presence of large populations of symbiotic Cyanobacteria. Most freshwater spongillids maintain similar relationships with zoochlorellae (symbiotic green algae, or Chlorophyta). These sponges grow larger and more rapidly than specimens of the same species that are kept in dark conditions. Some marine sponges (e.g., the boring sponges *Cliona* and *Spheciospongia*) harbor commensal zooxanthellae similar to those of corals.

Many species of sponges prefer to grow on the roots of mangrove trees in littoral habitats, and experiments have shown that sponge infested roots elongate much faster than those without sponges. Stable isotope studies have suggested transfer of dissolved inorganic nitrogen from sponge to mangrove, and transfer of carbon from mangrove to sponge! However, this unusual sponge–plant symbiosis is not well understood.

One of the most intriguing examples of poriferan symbiosis is the rare case of intimate association between two different sponge species. In North America, for example *Halichondria poa* is almost always overgrown by *Hymeniacidon sanguinea*, while in Europe *Haliclona cratera* almost always overgrows *Ircinia oros*. And, in the Gulf of California (Mexico) *Haliclona sonorensis* overgrows *Geodia media*. It is not known how the covered species of sponge obtains sufficient water flow to survive, or what the cost/benefit relationships are of these unusual symbioses.

The boring demosponges (e.g., *Cliona*, *Spheciospongia*) excavate complex galleries in calcareous material such as corals and mollusc shells (Figure 6.23). This phenomenon, known as bioerosion, causes significant damage to commercial oysters as well as to natural coral, bivalve, and gastropod populations. In fact, in the Caribbean the boring sponge *Cliona delitrix* has been shown to undercut entire coral heads by their excavations, resulting in a collapse of the head. The active boring process involves chemical and mechanical removal of fragments or chips of the calcareous coral or shell material by specialized archaeocytes called etching cells, which release acid phosphatase. The coarse silt-sized excavated chips are expelled in the excurrent canal system and can actually contribute significantly to local sediments. Many species in the remarkable boring genus *Cliona* (family Clionaidae) have two or three different growth forms (e.g., *C. californiana* of the



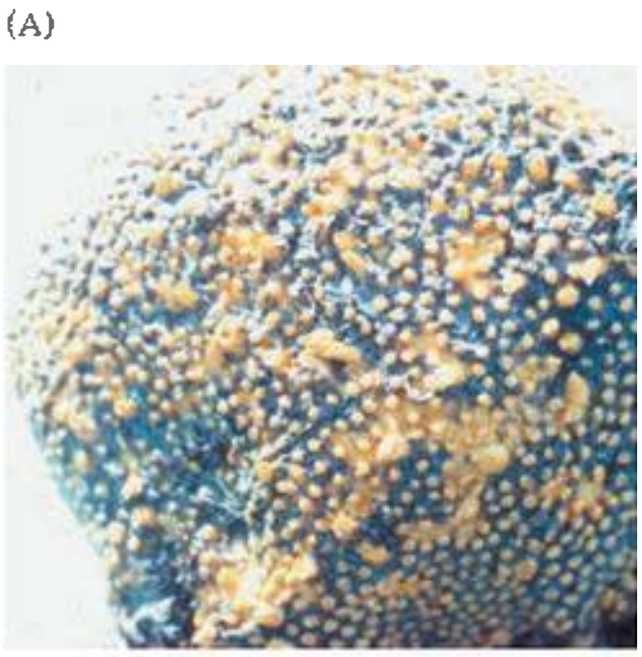


Figure 6.23 Boring sponges. (A) Surface of a cora infected by the yellow boring sponge *Cliona*. (B) A close view (SEM) of the surface of a clam shell, showing six eroded "chips," two of which have been entire y removed and four that are only partly etched by *Cliona*.

eastern Pacific region). The alpha stage (Figure 6.24A) is purely boring (living internally within the "host"), the beta stage (Figure 6.24B) is eruptive (having "escaped" to overgrow the surface of the calcareous substratum), and the gamma stage is "free living" (i.e., has given up the boring stage of its life history) (Figure 6.24C,D).

Sponge bioerosion has a significant impact on coral reefs. Perhaps even more important than actual erosion is the weakening of attachment regions of large corals. This action can result in considerable coral loss during heavy tropical storms, and it is increasing as corals are weakened by bleaching events and ocean acidification resulting from increased atmospheric CO_2. Boring sponges do not appear to gain any direct nourishment from their host coral; rather, they use it as a protective space in which to reside If you carefully examine the shells of dead bivalves along any shoreline, you will

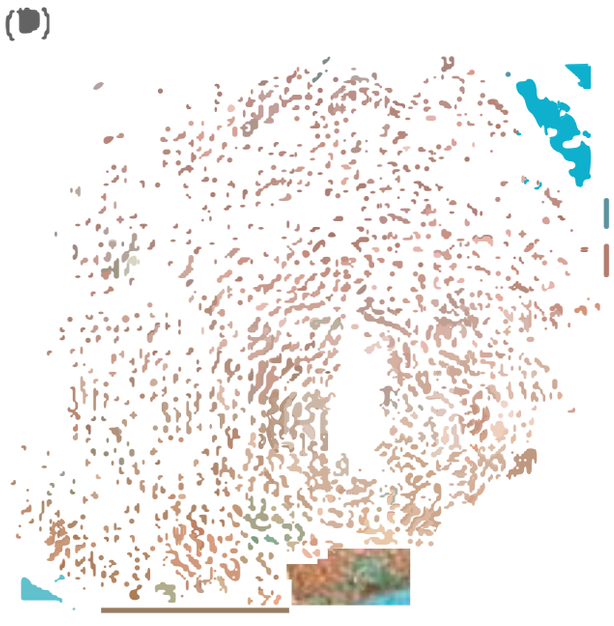

Figure 6 24 The three life history stages of the Pac fic boring sponge *Cliona californi ana*. (A) In the alpha stage, the sponge lives primar ly within the shell (or other ca careous structure) in which it bores. (B) In the beta stage, the sponge erupts from its ca careous home and begins to overgrow the substratum. (C,D) In the gamma stage, the sponge is entirely free living. (E) On most beaches in the wor d, cast-ashore shells show ev dence of boring sponge act vity

discover that most of them are perforated with minute holes and galleries from boring sponges (Figure 6.24E). Bioeroding sponges are responsible for a major portion of the initial breakdown of such calcareous structures, and thus they set the stage for their eventual decomposition and recycling through Earth's biogeochemical cycle

Poriferan Phylogeny

The Origin of Sponges

Being the living descendants of what might have been the first multicellular animals on earth, sponges are a key group in which to look for innovations that form the basis of the metazoan body plan. But sponges are an ancient group, and the important events in their origin and early evolution lie hidden in the Proterozic eon of the Precambrian. Both the ancient and the unique nature of the poriferan body plan are strikingly revealed by the aquiferous system, cellular pluripotency, and reproductive flexibility; and by the lack of a gut, fixed reproductive organs, nervous system, muscles, cell gap junctions, or strong adult body polarity. These features, along with the choanoflagellate-like choanocytes of sponges, suggest a protistan ancestry, as also shown in many (though not all) molecular phylogenetics Generally speaking, the poriferans seem to share as many similarities with protists as they do with the higher metazoans. At the same time, sponges clearly stand apart from all other Metazoa in their possession of such features as an aquiferous system and choanocytes with flagella bearing paired vanes (nearly identical to those of the protist phylum Choanoflagellata) (Box 6B).

Understanding sponge evolution is thus closely tied to understanding the transition from unicellular to multicellular life a phenomenon that we actually know surprisingly little about. Molecular phylogenetic dating estimates indicate that the Porifera likely arose from a common ancestor with the protist phylum Choanoflagellata more than 600 million years ago, perhaps over 700 million years ago.

Although subtle ultrastructural differences exist, the collar cells (choanocytes) of sponges are nearly identical to the collar cells of choanoflagellates, including the unique possession of two distinct winglike projections (the vanes) that arise on either side of the flagellum, and a glycocalyx sheath on the collar that joins the microvilli. In choanoflagellates, the collars are funnel shaped and the sheath forms an uninterrupted fibrous layer on the cell surface. In sponge choanocytes, the collars tend to be tubular and the glycocalyx forms a mesh that both holds the microvilli together and connects adjacent collar microvilli. The vanes, in both groups, are also formed from horizontal fibers of glycocalyx that extend from the flagellum. The vanes in sponge choanocytes appear to be wider than that described from Choanoflagellata, spanning the full width of the collar with the edges of the two wings lying against the inside of the collar (and perhaps attached to it) in sponges.

Somewhat similar collar cells (but without flagellar vanes and generally with a nonmotile cilium) have also been found in some other metazoan phyla (e.g., in certain echinoderm larvae and adults, in some corals, in the trunk epithelium of the enteropneust *Harrimania kupfferi*). The homology of these other metazoan cells to sponge choanocytes is questionable however. In addition, they do little to diminish the force of the argument for a direct relationship between Porifera and Choanoflagellata (an idea that dates back to at least 1866). Molecular data support the monophyly of both the Choanoflagellata and the Porifera.

So similar are choanoflagellates and sponges that periodically through the eighteenth and nineteenth centuries the proposal came up that sponges are no more than highly organized colonial choanoflagellates However, the presence of distinctly animal features, including metazoan developmental genes, in the Porifera argues against this idea (e.g , gastrulation during embryogenesis, spermatogenesis, adhaerens junctions in some species, type IV collagen, etc.). And, recent molecular developmental work suggests that certain genes found in sponges and other metazoans probably played critical roles in the transition from unicellularity to multicellularity. Homologues of many typical metazoan genes have now been identified in sponges, such as those encoding proteins involved in immune responses, myosin production, developmental patterning, the formation of the extracellular matrix, and other vital functions. Even the chitin synthase gene has been found in sponges, although it does not seem to be active.

The major class of transcription-factor encoding genes that regulate animal development is called Antennapedia (ANTP). The ANTP group includes the Hox, ParaHox, and NK genes, all of which are paralogues (i e , they have arisen in different animals from a shared ancestor as a result of gene duplication events). These genes, which are involved in multiple developmental processes, are often found in clusters, and in some animals their expression is temporally or spatially correlated to their position within the cluster (a phenomenon known as colinearity). Until recently, no ANTP genes had been found in the phylum Porifera, leading to the suspicion that this gene family did not evolve until the emergence of a line subsequent to sponges the name "ParaHoxozoa" was given to that lineage of phyla with ANTP class genes. But when the first sponge genome was sequenced (from a species of Demospongiae) a group of gene clusters was found, which are known to be neighbors of Hox and ParaHox genes in higher metazoans. This led to a proposal in 2012 that these developmental genes had been present in the common ancestor of all animals, but

had been secondarily lost in sponges an idea called the "ghost locus" hypothesis. A test of this hypothesis came in 2014, when researchers looked closely at sponge genomes in the class Calcarea, and it was discovered that this sponge class contained both NK and ParaHox genes remarkably similar to those of higher animals. In fact, they found that ParaHox expression in the choanoderm cell layer was very similar to that seen in the endoderm of bilaterians. Although homology in developmental genes does not necessarily equate to homology of organs, the discovery provided support for the ghost locus hypothesis, and it suggests that the first Metazoa probably had a ParaHox gene repertoire. The discovery of these ANTP genes in calcarean sponges adds further data to the recognized, considerable genetic divergence among the sponge classes, which is not too surprising given that Calcarea and Demospongiae are estimated to have diverged from one another at least 600 million years ago.

Recently, genes belonging to the cadherin family have also been identified in sponges The cadherin family of genes comprise critical mediators of metazoan cell adhesion and signaling and provide the structural basis for vital developmental processes, including tissue morphogenesis and maintenance, cell sorting, and cell polarization. Plants and fungi lack cadherins, which are so far known only from metazoans and choanoflagellates. Cadherin activity has been identified in choanoflagellates in the actin-filled microvilli that comprise the apical collar, at the basal pole of the cell, and in certain cellular bodies of unknown function. The localization of cadherins on the collar suggests that actin filaments and cadherins have been associated since before the origin of the Metazoa. In metazoan epithelial cells, recruitment of β catenin facilitates essential interactions between classical cadherins and the actin cytoskeleton to establish and maintain cell shape and polarity.

This brings us to the interesting proposal that choanoflagellates might be nothing more than "reduced" sponges. This idea derives partly from the inability, so far, to connect the Choanoflagellata phylogenetically with any other protist group. In addition, the mitochondria of choanoflagellates (which are characterized by non-discoidal flattened cristae) and their basal bodies (which bear accessory centrioles) are two other features that are shared with metazoans. On the other hand, comparison of the mitochondrial genomes of protists and metazoans yields at least 13 genes in choanoflagellates that are absent from animal mitochondria, in support of their protist roots. It is often noted that sponges, and all other metazoans, produce true gametes and have embryogenesis—hallmarks of the Metazoa that are lacking in choanoflagellates. However, several choanoflagellates with a sessile trophic stage also produce free swimming cells, called **zoospores**. They have no collar, and swim vigorously with the flagellum propelling the cell from behind, just as in animal sperm[11] Choanoflagellates and sponges are clearly closely related and reside near the point of origin of the Metazoa.[11]

The solutions that poriferans evolved to survive environmental challenges created a group of animals unlike any other. Sponges achieved multicellularity and large body size without such typically metazoan traits as fixed organs, nervous and muscular systems, extracellular digestion, or excretory organs. Taken together, these and other poriferan attributes support the notion that sponges are the earliest evolving metazoans for which living representatives exist today. However, despite this evidence several phylogenetic studies have suggested that Ctenophora, not Porifera, could be the basalmost metazoan, although those studies have been seriously questioned.

Evolution within the Porifera

Sponges comprise such an ancient and enigmatic phylum that their phylogeny largely eluded scientists until fairly recently. Although the Porifera have nearly consistently appeared at the base of metazoan molecular and morphological trees, data have been slow to resolve the relationships of sponges to the other basal metazoan phyla (e g , Cnidaria, Ctenophora, Placozoa), and as this book went to press those relationships were still unsettled, although overall evidence still supported them as basal metazoans. Recent genomic level studies strongly suggest that Placozoa arose between sponges and all other metazoans, thus clearly separating the Porifera from Cnidaria and Ctenophora. And only since the early twenty-first century have there been robust phylogenetic hypotheses of relationships among the four poriferan classes. Although fossils provide a poor record of noncalcareous sponges, first-occurrence data support a Precambrian origin of the Hexactinellida and Demospongiae, and an early Cambrian origin of the Calcarea (Figure 6.25). Estimated rates of molecular evolution place the origin of the Hexactinellida over 600 million years ago. Even considering some preservation biases in the fossil record, well over 1,000 fossil genera have been described, about 20% of which are still extant

Sponges first appear in the fossil record in the Precambrian, and the oldest known fossils are from about 600 million years ago, although a well preserved

[11] Several other enigmatic, unicellular organisms that appear to fall on the line leading to Metazoa are *Capsaspora owczaraki*, *Ministeria vibrans*, and the group Ichthyosporea. *Capsaspora owczarzaki* is a symbiont in the hemolymph of the freshwater snail *Biomphalaria glabrata Ministeria vibrans* is a free-living species that feeds on bacteria. Phylogenetic analyses suggest that these two species might form a sister group to the clade Choanoflagellata + Metazoa. The large group Ichthyosporea, which are symbionts with various animals, might be sister to that group, and this larger clade has been called Holozoa. Holozoa, in turn, is the likely sister group to Fungi, a clade known as Opisthokonta. However, the status of these creatures might well change as more information about them becomes available in the near future.

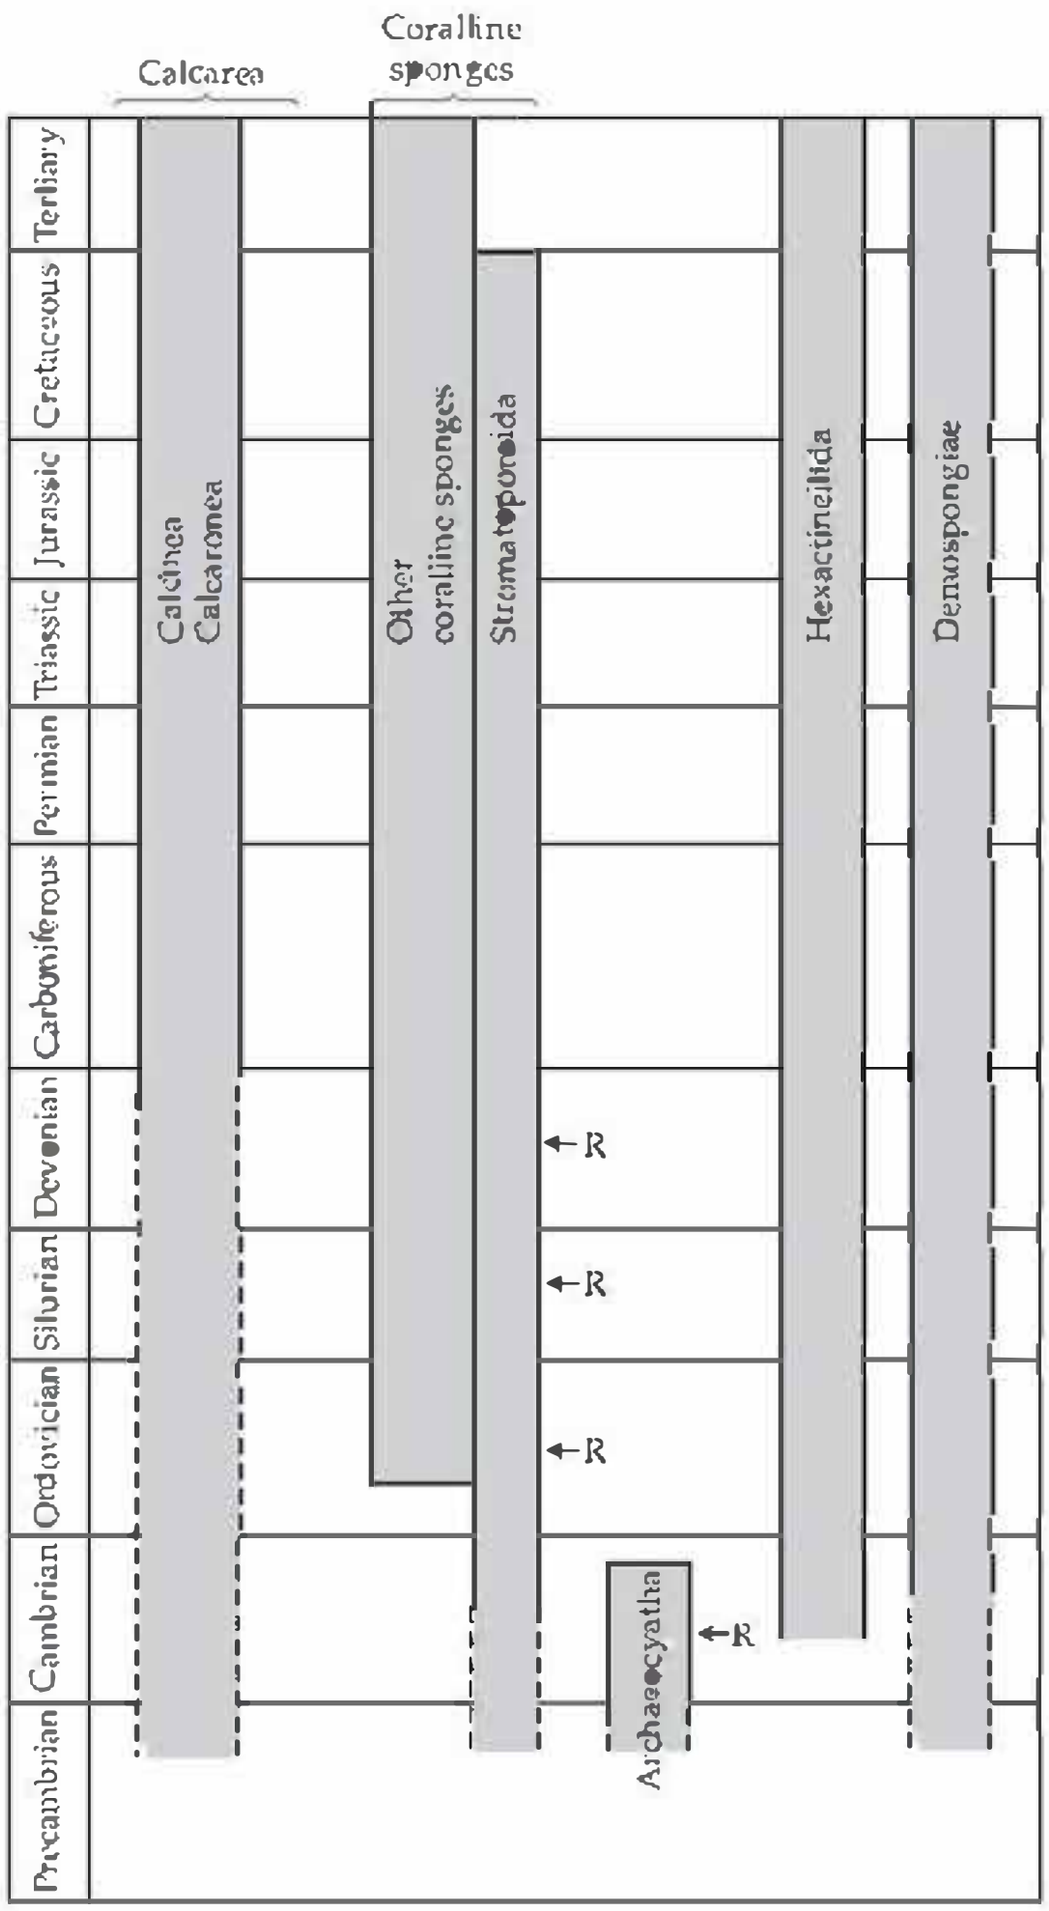

Figure 6.25 Fossil record of three sponge classes, the Archaeocyatha, and the other coralline sponges. Dashed lines indicate suggested occurrence, even though fossils have not yet been found. "R" indicates the times when the group in question is known to have been an important marine reef builder.

600-million-year-old fossil of an Ediacaran sponge was described in 2015 from the Doushantuo Formation of South China. This fossil sponge, *Eocyathispongia qiania*, is only just over one millimeter wide but composed of hundreds of thousands of cells, and it has a structure consisting of several hollow tubes sharing a common base. The external surface is covered with flattened cells resembling pinacocytes, punctuated with small pores.

The fossil record suggests that sponges might have had their ecological heyday in the Paleozoic and Mesozoic when massive tropical reefs developed

composed largely of four groups: the archaeocyathans, stromatoporoids, sphinctozoans, and chaetetids. The oldest of these, the coralline Archaeocyatha (Figure 6.26), had a short life within the Cambrian (550–500 Ma). Sphinctozoans and stromatoporids also appeared in the Cambrian (about 540 Ma), while chaetetids first appeared in the Ordovician (about 480 Ma). The affinities of these four coral-like groups have been debated for a hundred years, and various alliances with Cyanobacteria, red algae, ectoprocts, cnidarians, and foraminiferans have been proposed. However, the discovery of living coralline sponges has led most workers to believe that the majority of species in these four groups were primitive, but true, sponges. Research suggests that the calcium-carbonate secreting sponges utilize the same α-carbonic anhydrase genetic pathway as seen in higher animals that biomineralize. And it was exploitation of this gene group that led the explosion of mineralized skeletons among the Metazoa during their rapid Cambrian radiation, made possible by unique genes inherited from their poriferan "roots."

Unlike the coralline sponges, which have decreased in abundance and diversity since the Mesozoic, the Calcarea and Demospongiae appear to have increased in diversity throughout their history. The demosponges were well established by the mid-Cambrian, and there is biochemical evidence that demosponges might have been living as much as 1.8 billion years ago (e.g., sponge-specific biochemicals associated with ancient stromatolites). Several recent molecular analyses,

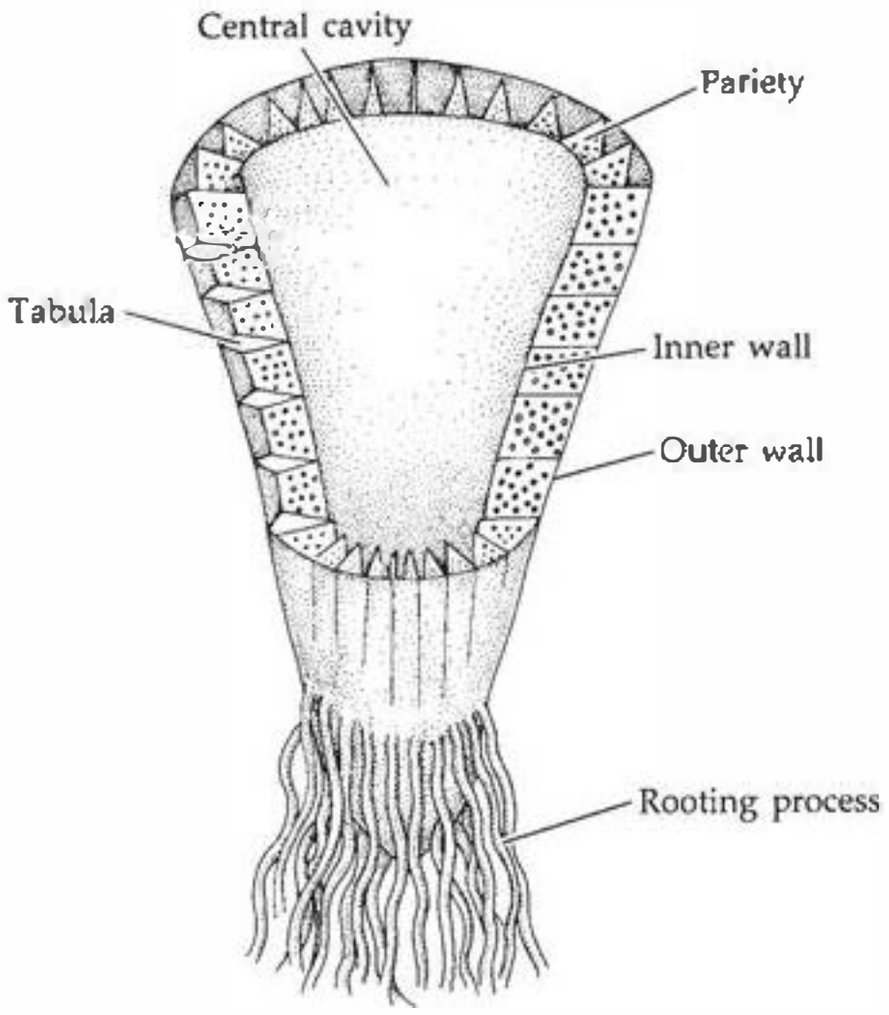

Figure 6.26 A typical archaeocyathan. A vertical section has been partly cut away to show the structure between the inner and outer walls (i.e., vertical parieties and horizontal tabula).

including an analysis of protein kinase C in sponges and some higher metazoans, favor the hypothesis that Hexactinellida were the first of the three sponge classes to appear. The Late Devonian extinction event brought many demosponge clades to an end, and the modern demosponge lineages largely appeared subsequent to that event. All known orders of modern demosponges are found in Cretaceous rocks.

Hexactinellids were most diverse and abundant during the Cretaceous. The oldest hexactinellid fossils, of the early Cambrian, were all thin-walled, saclike sponges with a dispersed surface spicule layer that probably could not support a thick body wall. During the Paleozoic, hexactinellids were common in shallow-water environments. Since then, however, they have become restricted largely to deeper oceanic regions.

Until recently, two fundamentally opposing views of sponge phylogeny existed. One hypothesis suggested that the living sponge classes that produce siliceous spicules comprise a monophyletic lineage (e.g., Demospongiae, Homoscleromorpha, Hexactinellida), with the Calcarea being phylogenetically more distant. The other view proposed that the classes of cellular sponges (Demospongiae, Homoscleromorpha, Calcarea) comprise a monophyletic clade, with the syncytial Hexactinellida standing apart from them.

The first hypothesis was proposed by de Laubenfels in 1955, who reduced the siliceous groups to a single class, Hyalospongiae. Subsequent authors renamed the two groups Silicea (or Silicispongia) and Calcarea (or Calcispongia). An obvious objection to this concept had been the profoundly different anatomies and spicule geometrys of Hexactinellida and Demospongiae/Homoscleromorpha. However, the same process of secretion of the siliceous spicules within sclerocytes around an axial filament occurs in all three groups, and that itself might be viewed as a synapomorphy of the Silicea. In addition, these three groups lack crossstriated rootlets, which are present in Calcarea and other metazoans (as well as in choanoflagellates and some other protists). Thus, *loss* of this structure may be another synapomorphy of the Silicea.

The second hypothesis of class-level relationships in Porifera suggests that the Hexactinellida stand apart from the other sponges by their unique syncytial body plan. This view recognized the two groups Symplasma (or Nuda) for hexactinellids, and Cellularia (or Gelatinosa) for demosponges and calcareous sponges. One of the arguments against this view has been that hexactinellid sponges begin their lives as cellular embryos and partly-cellular larvae, only later transitioning to the syncytial adult body form (by fusion of individual blastomeres), thus suggesting that Hexactinellida may have arisen from a demosponge-like ancestry.

As it turns out, neither of these views of sponge phylogeny is likely fully correct. DNA analyses

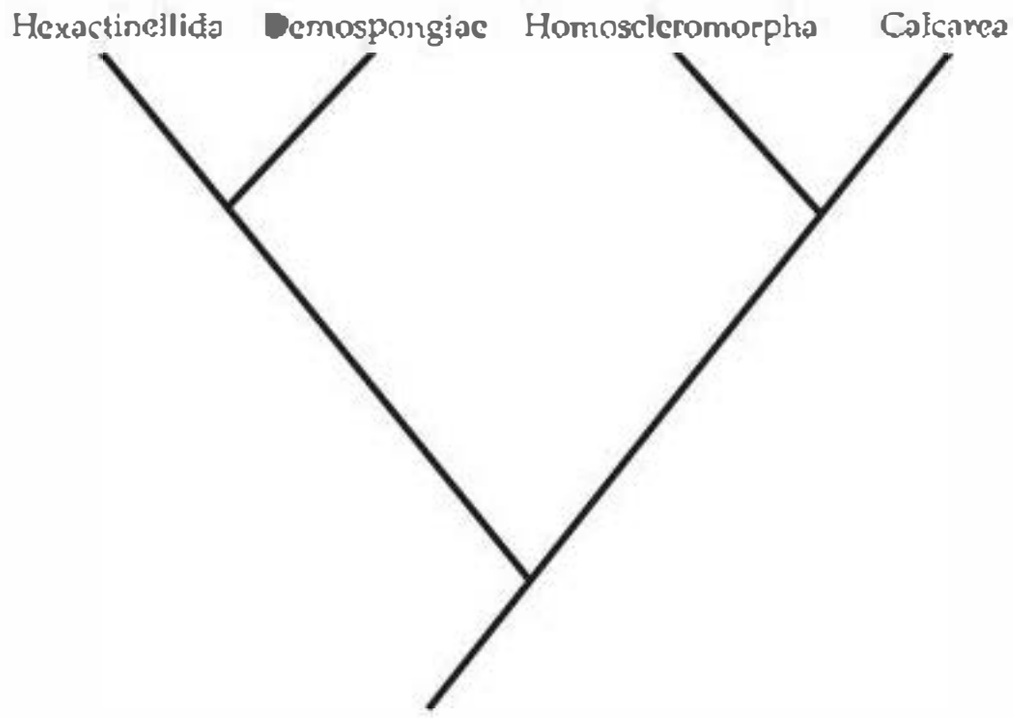

Figure 6.27 A modern view of poriferan phylogeny, based on molecular sequence analyses—18S and 28S rDNA, plus mitochondrial genes. Synapomorphies of the classes discussed in the text include the following: Hexactinellida with unique syncytial body anatomy, triaxonic spicules, and a square axial filament; Homoscleromorpha never with a spongin skeleton; Calcarea with monocrystalline calcareous spicules.

since 2009 strongly favor of the first hypothesis, but with the Homoscleromorphans removed from the demosponges (Figure 6.27). It now appears that Demosponges and Hexactinellids comprise a sister group, as possibly do Calcarea and Homoscleromorpha. All four classes appear to be monophyletic groups.

Hexactinellid sponges, with their Precambrian record, might be considered the basal extant sponges. In fact, hexactinellids are the earliest known metazoans that can be related to an extant animal group. Hexactinellids formed enormous reefs in the Jurassic and their fossilized remains crop up all round the world, but they declined in the Cretaceous and have largely disappeared. However, in 1987 the Geological Survey of Canada was engaged in routine surveys of the seafloor off British Columbia. Here, at around 200 m depth in ancient glacially-scoured seafloor troughs, they discovered massive hexactinellid sponge reefs. Since that discovery, teams of scientists have documented the extent and composition of these living sponge reefs, which appear to be about 9,000 years old. The reefs cover roughly 700 km^2, and they are composed of fewer than a dozen hexactinellid species. They are largely identical to the massive hexactinellid-lithistid sponge reefs of Mesozoic times, known to paleontolgists as "reef mounds" or "mud mounds," which culminated in the Late Jurassic when a 7,000 km-long reef existed on the northern shelf of the Tethys Sea—the largest bioconstruction ever built on Earth. Hexactinellid reefs declined after the Cretaceous.

The long fossil record of hexactinellids comprises two principal clades, the Amphidiscophora and the

Hexasterophora, differing in shape and type of their microscleres Hexactinellid synapomorphies are many, including their unique cellular and syncytial tissue organization, possession of triaxonic spicules, and an axial filament with a square section.

The key synapomorphy of the Calcarea is their monocrystalline calcareous spicules (unique among sponges). DNA analyses also support the monophyly of the two classes of Calcarea Calcinea and Calcaronea. An important proposed synapomorphy of the Calcinea is the basal position of nuclei in choanocytes, with no relation to the flagella. A proposed synapomorphy of the Calcaronea is the formation of the amphiblastula larva through the original process of eversion of the stomoblastula.

Overall, relationships within the Demospongiae remain uncertain, although there is growing support for the four subclasses used herein (although some researchers would subsume the Haploscleromorpha within the Heteroscleromorpha). For many years, Homoscleromorpha was viewed as the most primitive group of living Porifera (and deeply embedded within the Demospongiae) owing to its seemingly simple anatomic organization. One species, *Oscarella lobularis*, was even suggested as the prototype of all sponges because of its reduced mesohyl (and appearance of having only two layers, choanoderm and pinacoderm) and lack of a mineral skeleton. For a brief period of time, some workers were proposing the Homoscleromorpha be removed from the Porifera altogether, and allied with the Eumetazoa (a grouping dubbed Epitheliozoa). However, just the opposite view now prevails. The recent discovery that Homoscleromorpha are not demosponges, but should stand alone as a monophyletic fourth class of living sponges (probably most closely allied to Calcarea, on the basis of DNA sequence data and the unique crossstriated rootlet in larval ciliated cells in these two groups) was based on anatomical data, as well as 18S and 28S rDNA and complete mitochondrial DNA sequence data. In fact, Homoscleromorphs have a number of distinctly metazoan like attributes, such as apical cell junctions, flagellated exopinacoderm, a well-developed basement membrane beneath both the pinacoderm and the choanoderm (in larvae and adults), acrosomes in their spermatozoa (also known from a few other sponges), and a basal apparatus of flagellated larval cells with true cross-striated rootlets (as also seen in some Calcarea).

What is one to make of these higher metazoan-like aspects of the Homoscleromorpha, especially given that other features (including their mitochondrial genome) place them squarely within the phylum Porifera? One explanation that has been offered is that these features represent retained ancestral characteristics that have been lost in most other sponges. This would suggest that sponges are actually far more "evolved" than conventional wisdom holds, and that they have undergone a massive simplification since their origin, traces of which can be seen in the Homoscleromorpha. A simpler interpretation might be that the genetic potential for such features as basement membrane, acrosome-bearing spermatozoa, and cross-striated ciliary rootlets has existed since the dawn of the Metazoa, and was simply unevenly expressed in early animal evolution. Certainly other features of sponges, such as the wide variation in embryogenesis and larval forms, support the idea of Porifera being an ancient group that was one of the first to begin experimenting with metazoan body plans.

CHAPTER 7

Phylum Cnidaria

Anemones, Corals, Jellyfish, and Their Kin

The phylum Cnidaria is a highly diverse assemblage that includes jellyfish, sea anemones, corals, and the common laboratory *Hydra*, as well as many less familiar forms such as hydroids, sea fans, siphonophores, zoanthids, and myxozoans (Figure 7.1). There are about 13,400 living described species of cnidarians. Much of the striking diversity seen in this phylum results from three fundamental aspects of their natural history. First is the possession of cnidae—unique, tubular structures contained within cellular capsules that aid in prey capture, defense, locomotion, and attachment. No other animal group produces cnidae, and all cnidarians produce them. Second is the tendency to form colonies or assemblages of individuals by asexual reproduction; the colony can achieve dimensions and forms unattainable by single, nonmodular individuals. Third, many species of cnidarians exhibit a dimorphic life cycle that can include two entirely different morphologies: a polypoid form and an adult medusoid form. The dimorphic life cycle has major evolutionary implications touching on nearly every aspect of cnidarian biology.[1] The unique polyp form of Cnidaria, their planula larvae, and stinging or adhesive cnidae are three of the key synapomorphies that define the phylum.

Cnidarians are widely thought to be diploblastic metazoans at the tissue grade of construction. They possess radial or biradial symmetry, tentacles, cnidae, an endodermally derived incomplete gastrovascular cavity as their only "body cavity," and a middle layer (called mesenchyme, or mesoglea) derived primarily from ectoderm.[2] They lack cephalization, a centralized nervous system, and discrete respiratory, circulatory, and excretory organs (Box 7A). This basic body plan is retained in both the polypoid and medusoid forms (Figure 7.2). The primitive nature of the cnidarian body plan is exemplified by the fact that they have fewer cell types than any other animals except the sponges and mesozoans.

Classification of The Animal Kingdom (Metazoa)

Non-Bilateria*
(a.k.a. the diploblasts)

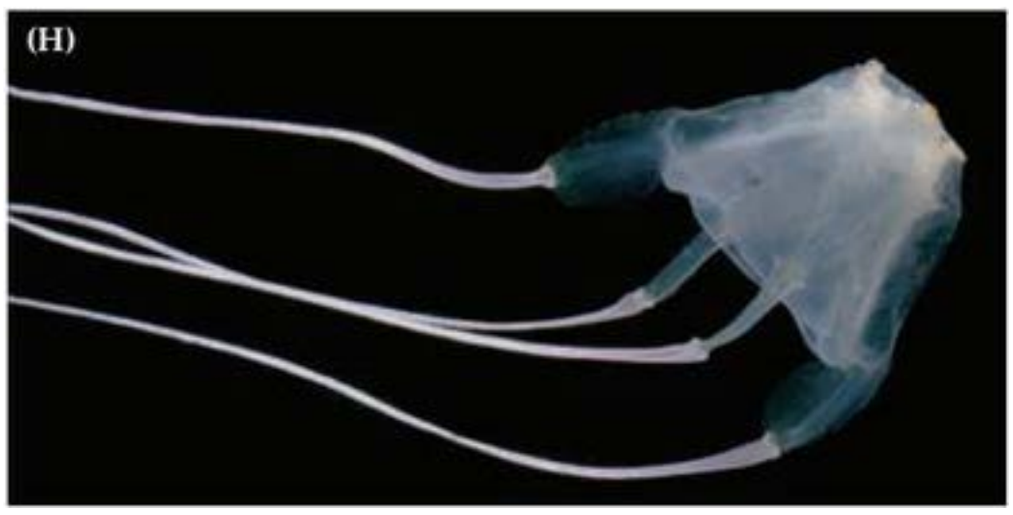
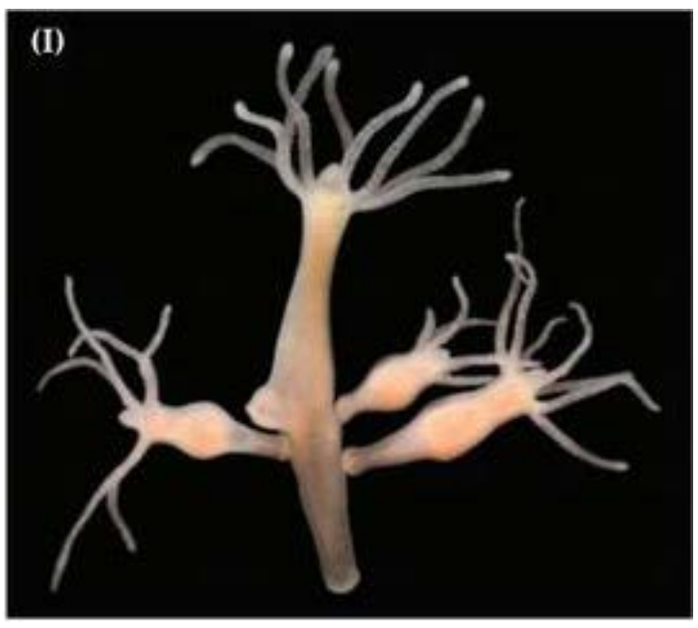
(E)

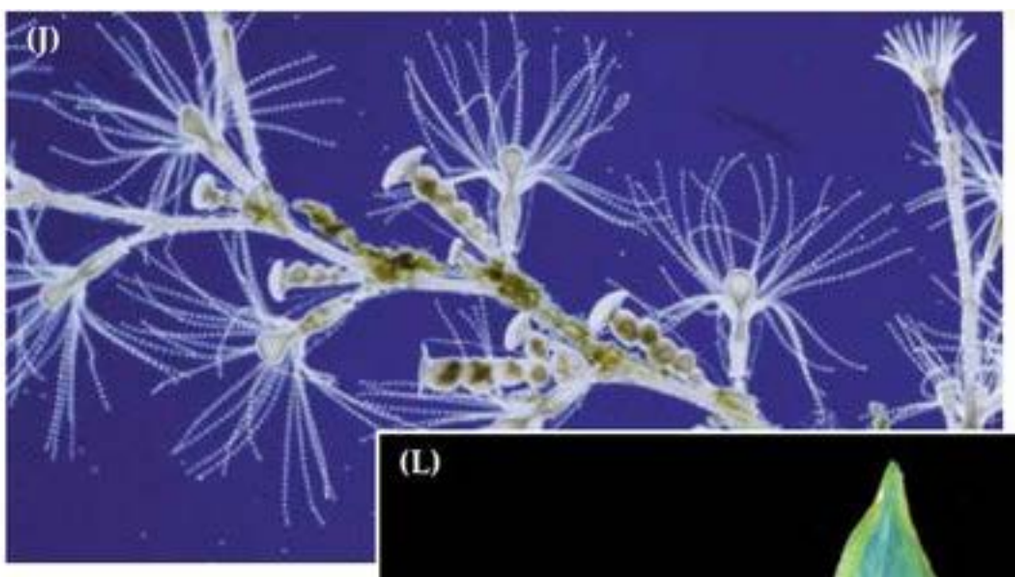
[2]There exists a suite of terms in zoological literature that apply to apparently diploblastic species that is frequently confused, misused, and generally messy These terms include mesenchyme, mesoglea, co le ıchyme parenchyme, and coenenchyme In th s book, these terms are used in the following ways Mesenchyme (Greek, literally "middle juices") refers to a primitive connec tive tissue derived wholly or in part from ectoderm and located between the epidermis and the gastrodermis (endodermis). Mesenchyme generally consists of two components a noncellular, jelly-like matrix called mesoglea, and various cells and cell products (e g , f bers). When no (or very little) cellular material is present, this layer is simply called mesoglea. Mesenchyme is the typical middle layer of sponges (where it is called the mesohyl), and of members of the phyla Cnidaria and Ctenophora. In these diploblastic groups, where no true (endo-) mesoderm ex sts, the mesenchyme is fully ectodermally derived. When cellular material is sparse or densely packed, mesenchyme may sometimes be designated as collenchyme or parenchyme respectively. The term parenchyme is also sometimes used for the mesenchymal layer of triploblastic acoelomate animals (such as platyhelminths and xenacoelomorpharıs), in which the dense layer includes tissues derived from both ecto- and endomesoderm.



In some colonial cnidarians, particularly anthozoan polyps, the individuals are embedded in and arise from a mass of mesen chyme perforated with gastrovascular channels that are continuous among the members of the colony. The term coenenchyme refers to this ent:re matrix of common basal material, which is itself covered by a layer of epiderm s



Adding to the potential confusion, the term mesenchyme is used in a second, very different way by some biologists Vertebrate embryologists sometimes use the term to refer to that part of true (endo) mesoderm from which all connective tissues, blood vessels, blood cells, the lymphatic system, and the heart are derived. Thus, to a vertebrate embryologist, the term "mes enchymal cell" often denotes any undifferentiated cell found in the embryonic mesoderm that is capab e of differentiating into such tissues. Occasionally, one a so sees the term "mesenchyme" used in this way by echinoderm embryologists and non-vertebrate chordate specialists. In these latter cases, researchers are gener ally referring to cells that are destined to become mesodermal and thus a bet:er term might be "proto-" or "incipient mesoder mal cells " Because of this confusion, some authors prefer to use the term mesoglea in lieu of mesenchyme when referring to the middle layers of sponges and diploblastic Metazoa. However, we adhere to the former definition of mesenchyme and hope that this note will lessen rather than add to the muddle.



A word of caution regarding spelling the meanings of some of these terms can be altered by changing the terminal "e" to an "a." The termination "-chyme" is preferred for animals, "-chyma" for plants. Thus, mesenchyma refers to tissue lying between the xylem and phloem in plant roots; collenchyma refers to certain primordial leaf tissues Parenchyma is a very general botanical term used in reference to various supportive tissues Unfortunately, the same spelling is occasionally (improperly) used by zoologists.

Figure 7.1 Some cnidarians (A–E) Anthozoa. (A) An actiniarian, the sea anemone *Metridium senile*. (B) The Caribbean elkhorn coral, *Acropora palmata*. (C) The sea pen, *Ptilosarcus gurneyi* (Pennatulacea). (D) The yellow gorgonian *Eunicella cavolini* (Mediterranean Sea, Italy). (E) *Renilla*, the sea pansy (Pennatulacea). (F–M) Medusozoa. (F) *Lucernaria*, a staurozoan (White Sea, Russia). (G) A lion's mane jellyfish, *Cyanea capillata*, a semaeostoman scyphozoan from the northeast Pacific Ocean. (H) *Carybdea marsupialis*, a cubozoan; (I–L) Hydrozoa. (I) *Hydra*, an aberrant freshwater anthomedusan (shown here budding). (J) A colony of the leptomedusan *Gonothyrea*. (K) The medusa of *Polyorchis*, an anthomedusan. (L) A colonial hydrozoan, *Velella* ("by-the-wind sailor"). (M) *Myxobolus cerebralis*, myxozoan spores from an infected trout

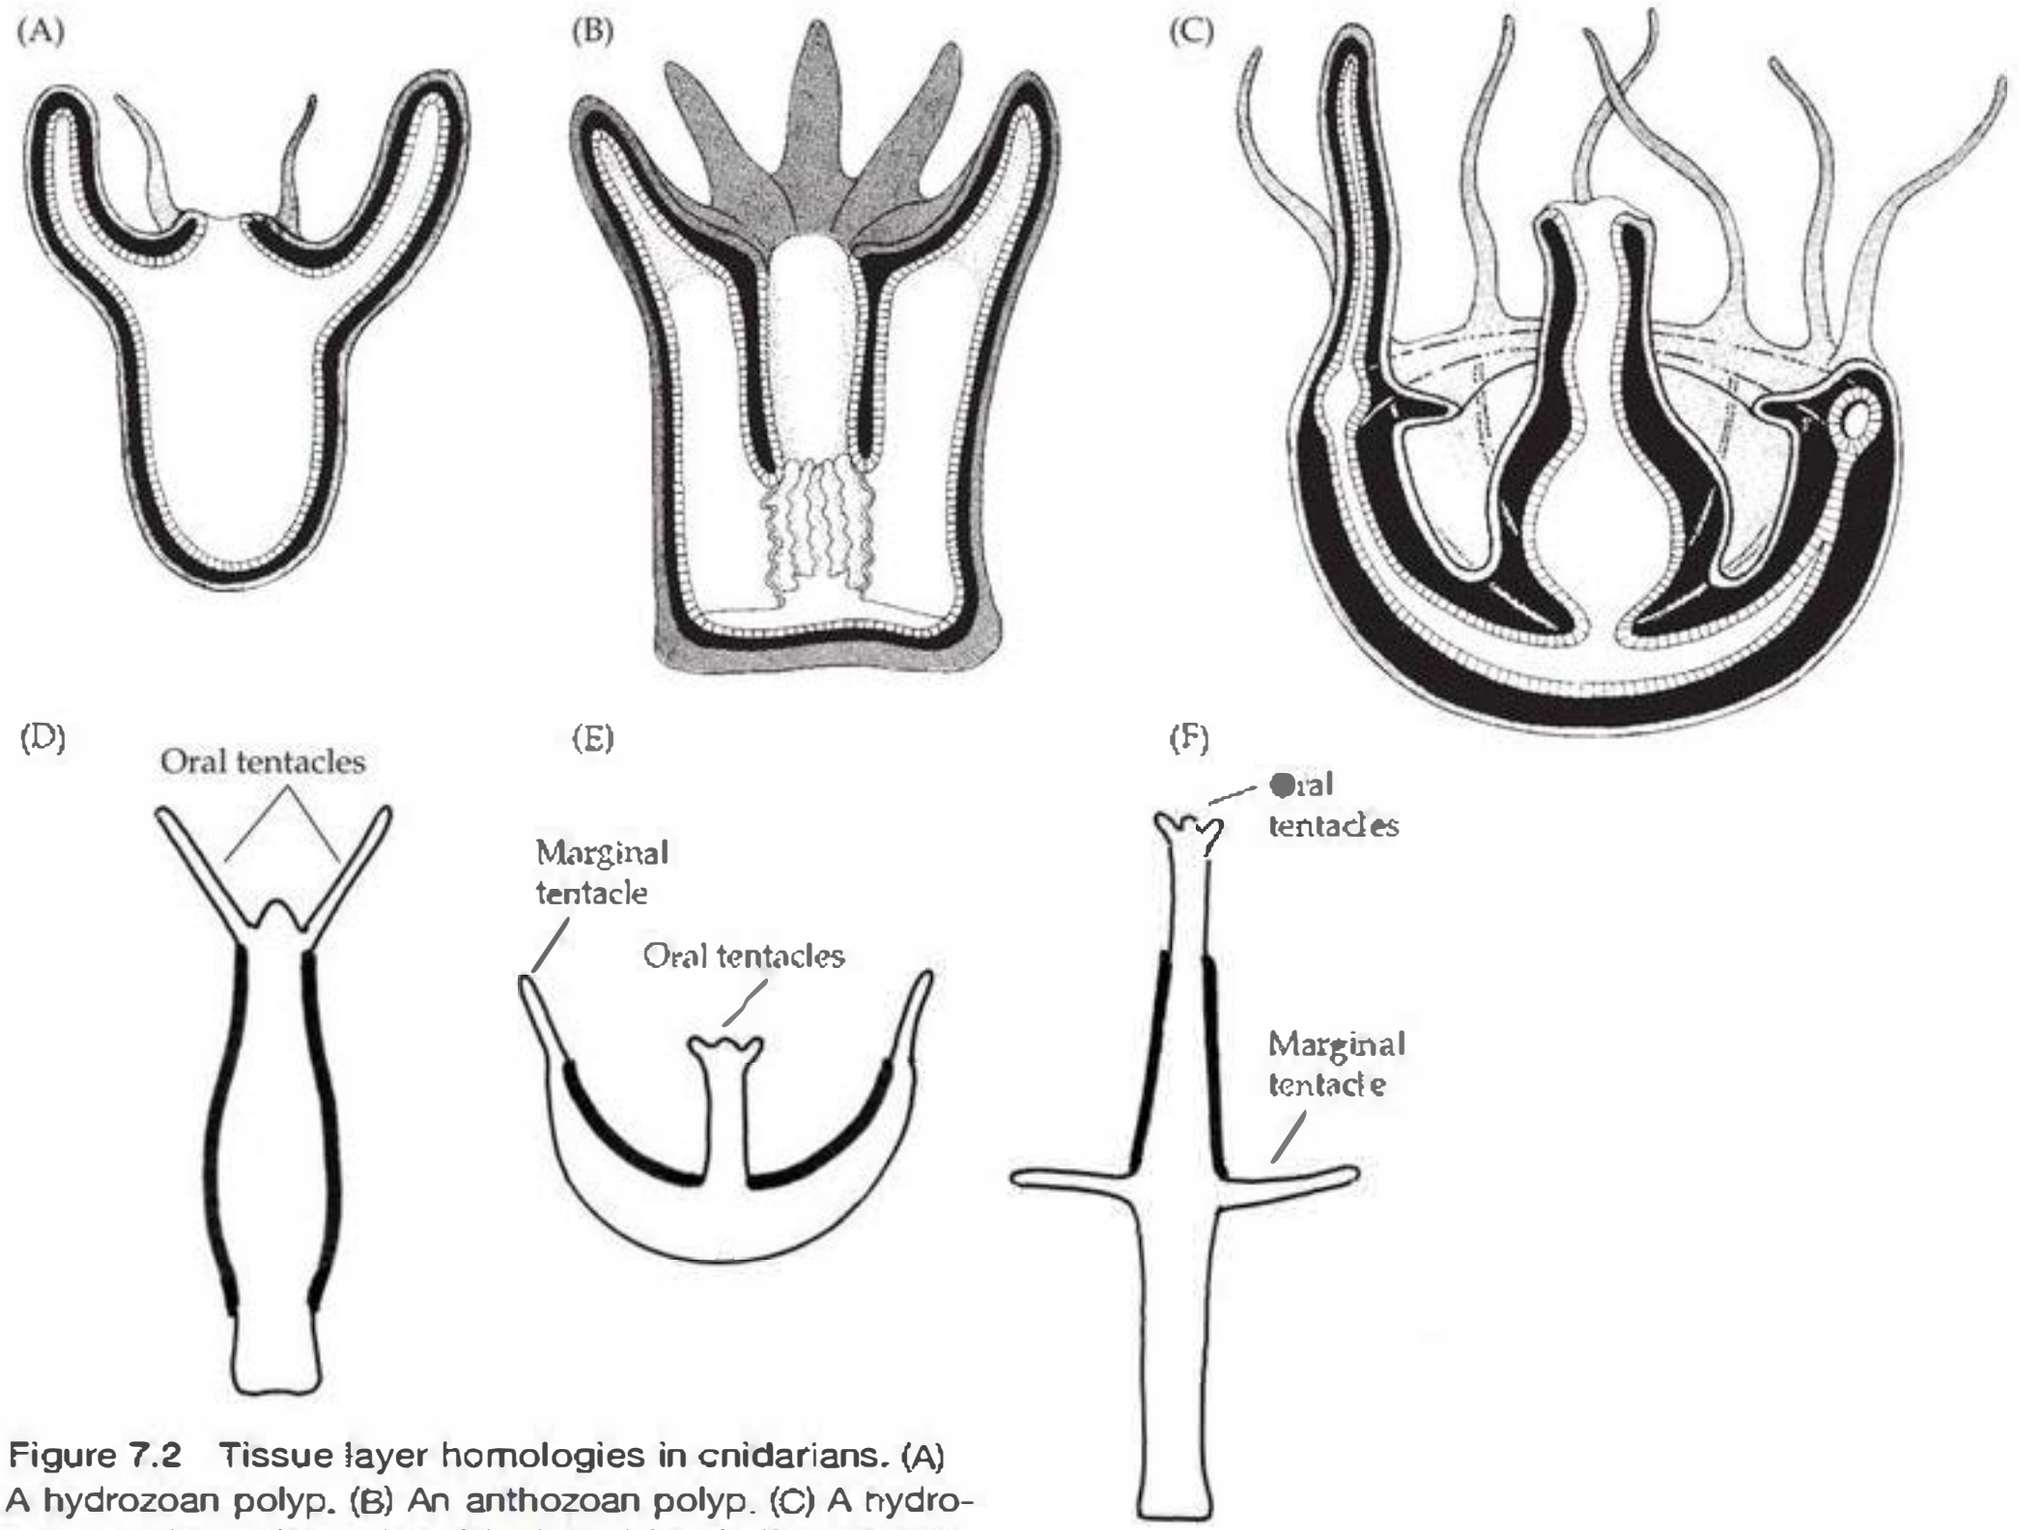

Figure 7.2 Tissue layer homologies in cnidarians. (A) A hydrozoan polyp. (B) An anthozoan polyp. (C) A hydrozoan medusa, shown "upside down" for similar orientation. The outer tissue layer is ectodermal (= epidermis); the inner tissue layer is endodermal (= gastrodermis); and the middle layer is the mesenchyme/mesoglea. Within the Hydrozoa, ectodermal tissue homologues may lie on the outer body wall as in *Hydra* (D) or within the marginal tentacles of hydromedusa and hydropolyps (E,F). OT = oral tentacles, MT = marginal tentacles.

In fact, cnidarians contain fewer cell types than does a single organ in some other Metazoa.

Cnidarians are mostly marine; only a few groups have successfully invaded fresh waters. Most cnidarians are sessile (polyps) or planktonic (medusae) carnivores, although some employ suspension feeding and many species harbor symbiotic intracellular algae from which they may secondarily derive energy. Cnidarians range in size from nearly microscopic polyps and medusae to individual jellyfish 2 m wide and with tentacles 25 m long. Colonies, such as the corals, may be many meters across. The phylum dates from the Precambrian, and its members have played important roles in various ecological settings throughout their long history, just as they do on modern coral reefs today.

Cnidarians play numerous roles in folklore around the world. In Samoa, the corallimorpharian anemone *Rhodactis howesii*, known as *mata-malu*, is served boiled as a festive holiday dish. Eaten raw, however, *mata malu* causes death and is a traditional device in Samoan suicide. Hawaiians refer to the zoanthid *Palythoa toxica* as *limu-make-o-Hana* ("the deadly seaweed of Hana"). Hawaiians used to smear their spear tips with this cnidarian, the toxin from which is called **palytoxin**. Interestingly, palytoxin may be produced by an unidentified symbiotic bacterium, not by the cnidarian itself. It is one of the most powerful toxins known, being more deadly than that of poison arrow frogs (batrachotoxin) and paralytic shellfish toxin (saxitoxin).

Taxonomic History and Classification

As is the case with sponges, the nature of cnidarians was long debated. In reference to their stinging tentacles, Aristotle called the medusae *Acalephae* (*akalephe*) and the polyps *Cnidae* (*knide*), both names derived from terms meaning "nettle." Renaissance scholars considered them plants, and it was not until the eighteenth century that the animal nature of cnidarians was widely recognized. Eighteenth-century naturalists classified them along with the sponges and a few other groups under Linnaeus's Zoophytes, a category for organisms

BOX 7A Characteristics of the Phylum Cnidaria

1. Diploblastic Metazoa with ectoderm and endoderm separated by an (primarily) ectodermally derived acellular mesoglea or partly cellular mesenchyme
2. Possess primary radial symmetry, often modified as biradial, quadriradial, or other variations on the radial theme; the primary body axis is oral–aboral
3. Possess unique stinging or adhesive structures called cnidae; each cnida resides in and is produced by one cell, the cnidocyte. The most common cnidae are called nematocysts.
4. Musculature formed largely of myoepithelial cells (= epithelomuscular cells), derived from ectoderm and endoderm (adult epidermis and gastrodermis)
5. Exhibit alternation of asexual polypoid and sexual medusoid generations; but there are many variations on this basic theme (e.g., a medusoid stage is absent in the class Anthozoa)
6. The endodermally derived gastrovascular cavity (coelenteron) is the only body cavity.* The coelenteron is saclike, partitioned, or branched, but has only a single opening, which serves as both mouth and anus.
7. Without a head, centralized nervous system, or discrete gas exchange, excretory, or circulatory structures
8. Nervous system is a simple nerve net(s), composed of naked and largely nonpolar neurons.
9. Typically have planula larvae (ciliated, motile, gastrula larvae)

deemed somewhere between plants and animals. Lamarck instituted the group Radiata (or "Radiaires") for medusoid cnidarians, ctenophores, and echinoderms.

In the early nineteenth century the great naturalist Michael Sars demonstrated that medusae and polyps were merely different forms of the same group of organisms. Sars also demonstrated that the genera *Scyphistoma*, *Strobila*, and *Ephyra* actually represented stages in the life history of certain jellyfishes (scyphozoans). The names have been retained and are now used to identify these stages in the life cycle. Rudolph Leuckart eventually recognized the fundamental differences between the two great "radiate" groups, the Porifera/Cnidaria/Ctenophora and the Echinodermata, and in 1847 created the name Coelenterata (Greek *koilos*, "cavity"; *enteron*, "intestine") for the former group in his recognition of the "intestine" as the sole body cavity. In 1888 Berthold Hatschek split Leuckart's Coelenterata into the three phyla recognized today: Porifera, Cnidaria, and Ctenophora. Although some workers have been inclined to retain the cnidarians and ctenophores together within the Coelenterata, these two groups are universally recognized as distinct phyla, a view upheld by recent molecular analyses. Recently, some molecular analyses have suggested that Cnidaria and Ctenophora might be sister-groups, encouraging the resurrection of the name "Coelenterata," but other studies have failed to produce this sister relationship.

An important recent major advance in cnidarian systematics is the realization that the myxozoans, formerly classified as protists, are in fact, highly derived, parasitic cnidarians. Myxozoans had been considered protists until a century ago when Antonín Štolc (1899) proposed they should be considered reduced cnidarians because of the nematocyst-like architecture of their spores. Over time, the multicellular nature of Myxozoa, and the structural and developmental similarity of their **polar capsules** to cnidarian nematocysts, came to be recognized. Since the early 2000s, molecular data have supported the classification of Myxozoa as cnidarians. In 2002, the enigmatic metazoan *Buddenbrockia plumatellae*, first discovered in 1850, was reinterpreted as a myxozoan. *Buddenbrockia* is a motile vermiform creature that inhabits the body cavities of freshwater ectoprocts. It possesses four bands of longitudinal muscle cords, a cuticle like body surface, no digestive tract, a cnidarian like complement of polar capsules, and myxozoan-like infective spores (including polar capsules) that are formed inside the body cavity. Shortly after its rediscovery, it became clear that *Buddenbrockia plumatellae* is the same creature as *Tetracapsula bryozoides*, a known malacosporean (also described as *Myxosporidium bryozoides*), and furthermore, that another myxozoan, *Tetracapsula bryosalmonae* (later *Tetracapsuloides bryosalmonae*) was responsible for proliferative kidney disease (PKD) in salmonid fish. Clearly, malacosporeans are, in fact, Myxozoa

While some molecular and developmental evidence based on the structure of the striated muscle has suggested that the diploblastic condition shared by Cnidaria and Ctenophora could in fact be derived from triploblastic states, most researchers agree that cnidarians are basal to triploblastic taxa. The Cnidaria appear to comprise three major lineages: Anthozoa, a polypoid lineage lacking medusae; Medusozoa, a diverse clade including species exhibiting primarily motile medusoid forms as well as forms with medusoid and polypoid life stages; and Myxozoa, a clade whose relationship to the other two lineages remains uncertain.

Within the Anthozoa, two main lineages appear to exist—the subclasses Octocorallia and Hexacorallia—but within these groups considerable revision has occurred, mainly involving consolidation of taxa previously considered distinct. Near the base of the medusozoan clade, the Staurozoa have been identified as a new cnidarian class, and the classes Scyphozoa and Cubozoa are identified as sister taxa. A possible sister taxon to the Hydrozoa is the class Polypoidozoa, an intracellular parasite of acipenceriform fish so far

known from a single species Hydrozoans themselves appear to include two major lineages, the subclasses Trachylina and Hydroidolina. As within the Anthozoa, considerable taxonomic revision within each hydrozoan subclass seems likely for some time to come.

PHYLUM CNIDARIA

SUBPHYLUM ANTHOZOA Class Anthozoa. Anemones, sea pens, soft corals, gorgonians, organ-pipe corals, and stony corals (Figure 7.1A–E).[3] Exclusively marine; solitary or colonial; without a medusoid stage (individuals all polypoid); cnidae epidermal and gastrodermal, composed of spirocysts and ptychocysts; coelenteron divided by longitudinal (oral–aboral) mesenteries, the free edges of which form thick, cordlike mesenterial filaments; mesenchyme thick; tentacles usually number 8 (Octocorallia) or occur in multiples of 6 (Hexacorallia), and contain extensions of the coelenteron; stomodeal pharynx (= actinopharynx) extends from the mouth into the coelenteron and bears one or more ciliated grooves (siphonoglyphs); polyps may reproduce both sexually and asexually; gametes arise from gastrodermis. About 6,225 described living species divided into two subclasses.

SUBCLASS HEXACORALLIA (= ZOANTHARIA) Anemones and stony corals. Solitary or colonial; naked, or with calcareous skeleton or chitinous cuticle, but never with isolated sclerites; mesenteries usually paired and in multiples of six; mesenteries bear longitudinal retractor muscles arranged so that those of each pair either face toward each other or away from each other; mesenterial filaments typically trilobed, with two ciliated bands flanking a central one bearing cnidocytes and gland cells; one to several circles of hollow tentacles arise from endocoels (the spaces between the members of each mesenteric pair) and exocoels (the spaces between two mesenteries of different pairs); pharynx may have 0, 1, 2, or many siphonoglyphs; cnidae very diverse; endodermal zooxanthellae may be profuse.

ORDER CERIANTHARIA Cerianthids or tube anemones. Mesenteries complete, but with feeble musculature; mesenteries complete, with six primary mesenteries. Large, solitary, elongate polyps living in vertical tubes in soft sediments; tube constructed of interwoven specialized cnidae (ptychocysts) and mucus; aboral end lacks a pedal disc and possesses a terminal pore; long thin tentacles arise from margin of oral disc, fewer shorter abental tentacles encircle mouth; mesenteries complete; gonads occur only on alternate mesenteries; protandric hermaphrodites; some species possess long-lived pelagic larva stages (e.g., *Arachnanthus*, *Botruanthus*, *Cerianthemomorphe*, *Cerianthopsis*, *Cerianthus*, *Pachycerianthus*).

ORDER ZOANTHIDEA Zoanthids. Colonial polyps arise from a basal mat or stolon containing gastroderma solenia or canals; new polyps bud from gastroderma solenia of stolons; pharynx flattened, with one siphonoglyph; mesenteries numerous, but with weak musculature; without intrinsic skeleton, but many species incorporate sand, sponge spicules, or other debris into the thick body wall; most with a thick cuticle; zooxanthellae abundant in some species; many species epizootic (e.g., *Epizoanthus*, *Isaurus*, *Isozoanthus*, *Palythoa*, *Parazoanthus*, *Thoracactus*, *Zoanthus*).

ORDER ACTINARIA The sea anemones. Solitary or clonal; calcareous skeleton lacking, although some species secrete a chitinous cuticle; some harbor zooxanthellae; column often with specialized structures, such as warts or verrucae, acrorhagi, pseudotentacles, or vesicles; oral tentacles conical, digitiform, or branched, usually hexamerously arrayed in one or more circles; typically with two siphonoglyphs. A highly successful group with at least 1,000 living species in 41 families, the largest being the Actiniidae (e.g., the order includes *Actinia*, *Adamsia*, *Aiptasia*, *Alicia*, *Anthopleura*, *Anthothoe*, *Bartholomea*, *Bunodactis*, *Calliactis*, *Diadumene*, *Edwardsia*, *Epiactis*, *Halcampa*, *Haliplanella*, *Heteractis* (= *Radianthus*), *Liponema*, *Metridium*, *Nematostella*, *Peachia*, *Phyllodiscus*, *Ptychodactis*, *Stichodactyla*, *Stomphia*, *Triactis*).

ORDER ANTIPATHARIA Black or thorny corals. Upright, branched or whip-like colonies up to 6 m tall; calcareous axial skeleton, usually brown or black and covered by a thin coenosarc bearing small polyps, usually with 6 (but up to 24) nonretractable tentacles; with feeble mesenteries; skeleton produces thorns on its surface (e.g., *Antipathes*, *Bathypathes*, *Leiopathes*).

ORDER CORALLIMORPHARIA Solitary polyps, without a skeleton; lacking siphonoglyphs, ciliated bands on mesenterial filaments, and muscles in the pedal disk (e.g., *Amplexidiscus*, *Corynactis*, *Rhodactis*, *Ricordea*).

ORDER SCLERACTINIA (= MADREPORARIA) Stony corals. Colonial or solitary; polyp morphology almost identical to that of Actiniaria, except corals lack siphonoglyphs and ciliated lobes on the mesenterial filaments; zooxanthellae present in about half the known species; colony forms delicate to massive calcareous (aragonite) exoskeleton, with plate like skeletal extensions (septa). Over 1,300 extant species, in 24 families[4] (e.g., *Acropora*, *Agaricia*, *Astrangia*, *Balanophyllia*, *Dendrogyra*, *Flabellum*, *Fungia*,

[3] We use the term "anemone" in a general sense for any solitary anthozoan polyps, but restrict the term "sea anemone" to the anemones of the order Actiniaria.

[4] The taxonomy of the Scleractinia is in a state of confusion; many higher taxa appear to be nonmonophyletic. About 700 coral species live in deep water and do not form symbiotic relationships with zooxanthellae, and about two dozen of these build reef structures

Goniopora, *Letepsammia*, *Meandrina*, *Montipora*, *Oculina*, *Pachyseris*, *Porites*, *Psammocora*, *Siderastraea*, *Stylophora*).

SUBCLASS OCTOCORALLIA (= ALCYONARIA) Octocorals. Polyps with 8 hollow, marginal, pinnate tentacles, and 8 complete (perfect) mesenteries, each with retractor muscle on the sulcal side, facing the single siphonoglyph; most species with free or fused calcareous sclerites embedded in mesenchyme, although sclerites lacking in some species; stolons or coenenchyme connect the polyps. Three orders are currently recognized but considerable revision of subordinal groups is key, particularly within the Alcyonacea.

ORDER HELIOPORACEA (= COENOTHECALIA) Heliporaceans. Colonies produce massive, rigid calcareous skeletons of aragonite crystals (not fused sclerites) similar to those of milleporid hydrozoans and stony corals; polyps monomorphic. Two families (Lithotelestidae and Helioporidae) and two genera (*Epiphaxum* and *Heliopora*, "blue coral").

ORDER ALCYONACEA Soft gorgonian and organ-pipe corals. Colonies encrusting or erect, often massive; usualy fleshy and flexible, although the coenenchyme is sclerite-filed; polyps monomorphic or dimorphic; fleshy distal portions of polyps usually retractable into more compact basal portion; skeletal elements comprised of calcite and gorgonin. Twenty-nine recognized families, classified in 6 heterogeneous suborders that may be little more than morphological grades.

SUBORDER PROTOALCYONARIA Protoalcyonarians are deep-water octocorals with solitary polyps that reproduce exclusively by sexual means, (e.g., *Taiaroa* and possibly *Haimea*, *Hartea*, *Monoxenia*, *Psuchastes*). The status of this suborder is uncertain because phylogenetic studies suggest that it is nested deeply within the Octocorallia (its name is therefore misleading).

SUBORDER STOLONIFERA Stoloniferans. Simple polyps arise separately from ribbon-like stolons that forms an encrusting sheet or network; oral disc and tentacles retractable into a calyx (stiff proximal portion of polyp); mesenchyme with or without sclerites; in some (e.g., Cornulariidae) a thin, horny external skeleton may cover polyps and stolons (e.g., *Bathytelesto*, *Clavularia*, *Coelogorgia*, *Cornularia*, *Pseudogorgia*, *Sarcodictyon*, *Telesto*, *Tubipora* [organ-pipe or pipe-organ "coral," a monotypic genus, *T. Musica*, in which sclertes fuse to from a calcareous skeleton]).

SUBORDER ALCYONIINA Soft corals. Polyps united within a mass of fleshy coenenchyme; coenenchyme usually with sclerites, but lacking an axis (e.g., *Alcyonium*, *Nidalia*, *Sarcophyton*, *Studeriotes*, *Umbellulifera*, *Xenia*).

SUBORDER SCLERAXONIA Encrusting or upright, branched colonies with an inner axis (or axa-like layer) consisting mainly of fused sclerites Includes *Corallium*, one of the precious coras used to make jewelry (also *Brianeum*, *Melithaea*, *Paragorgia*, *Parisis*).

SUBORDER HOLAXONIA Gorgonians. Upright, branched colonies with an inner axis consisting of scleroproteinous gorgonin without free spicules, with hollow cross-chambered central core, often with small amounts of embedded nonsclerotic $CaCO_3$ (e.g., *Acanthogorgia*, *Eugorgia*, *Eunicea*, *Gorgonia*, *Ideogorgia*, *Muricea*, *Pseudopterogorgia*, *Swiftia*).

SUBORDER CALCAXONIA Gorgonians. Upright, branched or unbranched colonies with an inner axis consisting of scleroproteinous gorgonin without hollow cross-chambered central core, with large amounts of nonsceritic $CaCO_3$ as internodes or embedded in the gorgonin. Mostly found in the deep sea (e.g., *Australogorgia*, *Chrysogorgia*, *Dendrobrachia*, *Fanellia*, *Helicogorgia*, *Isis*, *Plumarella*, *Plumigorgia*, *Primnoa*, *Verrucella*).

ORDER PENNATULACEA Sea pens and sea pansies. Colonies complex and polymorphic; adapted for life on soft benthic substrata; often bioluminescent; elongate primary axial polyp extends length of the colony (to 1 m) and consists of a basal bulb or peduncle for anchorage and a distal stalk, the latter giving rise to dimorphic secondary polyps; coelenteron of axial polyp with skeletal axis of calcified horny material in canals (e.g., *Anthoptilum*, *Balticina*, *Cavernularia*, *Funiculina*, *Halipteris*, *Pennatula*, *Ptilosarcus*, *Renilla*, *Sarcoptilus*, *Stylatula*, *Umbellula*, *Virgularia*).

SUBPHYLUM MEDUSOZOA Medusozoans. Free swimming and sessile forms; medusae produced through lateral budding and growth of the entocodon; epiderma gonads; loss of intramesogleal muscles associated with 4 peristomial pits; loss of primary polyp tentacles transformed into hollow structures; gastric filaments and corona muscle absent. About 4,775 described living species in 5 classes.

CLASS STAUROZOA Stalked jellyfish. Small, sessile individuals that develop from benthic, non-ciliated planula larvae and have complex but poorly-understood life cycles; the planula develops into a sessile stauropolyp, and this into a stauromedusa with a stalked adhesive disc by which individuals attach to substratum (a highly motile medusa stage does not exist); stauromedusae have eight tentacle-bearing "arms"; sexual reproduction may be dominant in most species although asexual reproduction is known in at least one (*Haliclystus antarcticus*); ovaries with follicle cells Occur many in shallow water at high latitudes (e.g., *Haliclystus*, *Lucernaria*; although *Kishinouyea* spp. are tropical). Molecular phylogenetic analyses indicate that despite considerable morphological convergence with trachyline hydrozoans, the minute Antarctic species, *Microhydrula limopsicola*, formerly identified within the Limnomedusae, is in fact a life stage within the life cycle of *H. antarctica*.

CLASS CUBOZOA Sea wasps and box jellyfish (Figures 7.1H; 7.15A). Medusae 1–30 cm, largely colorless; polyps each produce a single medusa by complete metamorphosis (strobilation does not occur), medusa bell nearly square in cross section; rhopalia with complex visual structures; hollow interradial tentacle(s) hang from bladelike pedalia, one at each corner of umbrella; unfrilled bell margin drawn inward to form a velum-like structure (the velarium) into which divert cula of the gut extend. Cnidae of the nematocyst type only; the sting is very toxic, in some cases fatal to humans, hence the name "sea wasps." Cubozoans are strong swimmers that occur in all tropical seas (and a few temperate regions, e.g., the west coast of South Africa and Namibia) but are especially abundant in the Indo-West Pacific region.

ORDER CHIRODROPIDA Pedalia branch into handlike structure with each branch giving rise to a tentacle; externally fertilizing species including known deadly genera, although toxicity is variable within this order due to differences in tentacle surface area and means of venom delivery (e.g., *Chironex*, *Chiropsalmus*, *Chiropsella*).

ORDER CARYBDEIDA Viviparous species; venom can induce Irukandji syndrome, a usually nonlife threatening but physically and psychologically uncomfortable set of symptoms following envenomation. Five families, including the pelagic Alatinidae (*Alatina*, *Keesingia*), whose rhopalial openings are T shaped; two families that lack rhopalial horns, and have rhopalial openings that are crown-shaped, the Carukiidae (*Carukia*, *Gerongia*, *Malo*, *Morbakka*), and the Tamoyidae (e.g., *Tamoya*) which also lack gastric filaments; the Carybdeidae, *Carybdea*), whose ropalial openings are heart-shaped; and the Tripedaliidae (*Tripedalia*, *Copula*), which engage in courtship and "copulatory" behavior.

CLASS SCYPHOZOA Jellyfish (Figure 7.1G). Medusoid stage predominates; polypoid individuals (scyphistomae) are small and inconspicuous but often long lived; polyps lacking in some species; polyps produce medusae by asexual budding (strobilation); coelenteron divided by four longitudinal (oral–aboral) mesenteries; medusae acraspedote (without a velum), typically with a thick mesoglea (or collenchyma) layer, distinct pigmentation, filiform or capitate tentacles, and marginal notches producing lappets; sense organs occur in notches and alternate with tentacles; gametes arise from gastrodermis; cnidae present in epidermis and gastrodermis, nematocysts only; mouth may or may not be on a manubrium; usually without a ring canal. Scyphozoans are exclusively marine; planktonic, demersal, or attached. About 200 species are divided into three orders.

ORDER CORONATAE High bell divided into upper and lower regions by a coronal groove encircling exumbrella; margin of bell deeply scalloped by gelatinous thickenings termed pedalia, which give rise to tentacles, rhopalia, and marginal lappets; gonads present on the four gastrovascular septa. Small to moderate in size; primarily bathypelagic; some contain zooxanthellae (e.g., *Atolla*, *Linuche*, *Nausithoe*, *Periphylla*, *Stephanoscyphus*).

ORDER SEMAEOSTOMEAE Corners of mouth drawn out into four broad, gelatinous, frilly lobes; stomach with gastric filaments; hollow marginal tentacles continuous extensions of radial canals; without corona, furrow, or pedalia; gonads on folds of gastrodermis. This order contains most of the typical jellyfish of temperate and tropical seas; moderate to very large forms (some with bells reaching several meters in diameter) (e.g., *Aurelia*, *Chrysaora*, *Cyanea*, *Pelagia*, *Phacellophora*, *Sanderia*, *Stygiomedusa*).

ORDER RHIZOSTOMEAE Lacking a central mouth; frilled edges of the four oral lobes are fused over the mouth so that many suctorial "mouths" (ostioles) open from a complicated canal system on eight branching armlike appendages; bell without marginal tentacles or pedalia; stomach without gastric filaments; gonads on folds of gastrodermis. Small to large jellyfish that swim vigorously using a well developed subumbrellar musculature; primarily occur in low latitudes (e.g., *Cassiopea*, *Cephea*, *Eupilema*, *Mastigias*, *Rhizostoma*, *Stomolophus*).

CLASS POLYPOIDOZOA Intracellular parasites of the oocytes of acipencer form fish (e.g., sturgeons); binucleate cells within fish oocytes develop into inverted planuaform larvae which evert during host spawning into tentaclate stolons that possess cnidae and fragment when released into fresh water, dispersing as asexually reproducing medusoids whose gametes infect host fish. A single species, *Polypodium hydriforme*, currently defines this class.

CLASS HYDROZOA Hydroids and hydromedusae (Figure 7.1I–L and chapter opener photo). Alternation of generations occurs in most genera (typically asexual benthic polyps alternate with sexual planktonic medusae), although one or the other generation may be suppressed or lacking; medusae produced through lateral budding of the endocodon; medusoids often retained on the polyp; polyps usually colonial, with interconnected coelenterons; often polymorphic, individual polyps modified for various functions (e.g., gastrozooids feed, gonozooids are reproductive, dactylozooids are for defense and prey capture); exoskeleton when present usually of chitin or occasionally calcium carbonate (hydrocorals); coelenteron of polyps and medusae lacks a pharynx and mesenteries; mesoglea acellular; tentacles solid or hollow; cnidae occur only in epidermis; gametes arise from epidermal cells; medusae mostly small and transparent, nearly always craspedote (with a velum) and with a ring canal; mouth typically borne on pendant manubrium; medusae lack rhopalia. About 3,500 described species are contained in 6 orders, including some freshwater groups. Although the taxonomy of Hydrozoa is currently in a state of revision (and debate), there is considerable support

for the existence of two monophyletic subclasses, the Trachylina and the Hydroidolina. The Siphonophora has previously been regarded as a subclass, but it now appears likely to be part of subclass Hydroidolina.

SUBCLASS TRACHYLINA Trachyne medusae. Polypoid generation minute or absent; medusae produce planula larvae that usually develop directly into actinula larvae, which metamorphose into adult medusae; medusae craspedote, with tentacles often arising from exumbrellar surface, well above bell margin; medusae mostly gonochoristic; currently including three suborders and over 150 known species.

ORDER LIMNOMEDUSAE (Figure 7.13A-C). Freshwater and marine hydromedusae with ectodermal statocysts, hollow tentacles, and 4 (rarely 6) radial canals. The close relationships among freshwater genera (e.g., *Astrohydra Craspedacusta*, *Limnocnida*) suggests that freshwater species share a common ancestor these species are the only trachylines with true polyps, tiny structures that bud sexual medusae or asexual frustules which creep away to generate more polyps; families now considered within the Limnomedusae include the Olindiasidae (e.g., *Gonionemus*, *Olindias*, and the above freshwater genera), Monobrachiidae (e.g., *Monobrachium*), and Armohydridae, as well as the Geryoniidae (e.g, *Geryonia, Liriope*) which now appear to be Limnomedusae rather than Trachymedusae.

ORDER TRACHYMEDUSA Exclusively marine hydromedusae, usually with 8 radial canals and solid tentacles; includes 4 families—Halicreatidae, Petasidae, Ptychogastriidae, and Rhopalonematidae. The last family may include the actinulidans: free-living, solitary, minute (to 1.5 mm), motile, interstitial, apparently asexual polypoid hydrozoans with no medusa stage; (e.g., *Halammohydra*, *Otohydra*). This order may be polyphyletic.

ORDER NARCOMEDUSAE Pelagic or bathypelagic hydromedusae lacking radial canals, with lobed umbrella margins, broad, pouched stomachs, solid tentacles; includes 4 families: Aeginidae (e.g., *Aegina*), Cuninidae (e.g., *Cunia*), Solmarisidae (e.g., *Pegantha*), and Tetraplatiidae (e.g., the wormlike *Tetraplatia*, formerly considered a coronate scyphozoan).

SUBCLASS HYDROIDOLINA (Figure 7.13D-F). Hydroids and their medusae, and siphonophores Polypoid generation often predominant; polyps may have a chitinous exoskeleton; oral tentacles filiform or capitate, rarely branched or absent; colonies often polymorphic; many do not release free medusae but release gametes from sporosacs or sessile attached medusoids (= medusoid buds, or gonophores) on colony; colonies gonochoristic. A large group, with over 75 described families and over 3,200 species. Hydroids occur at all depths; the polypoid forms are very common in the littoral zone.

ORDER THECATA (= LEPTOMEDUSAE, CALYPTOBLASTEA, OR LEPTOTHECATA) Adverse group of hydroids with polyps always coenosarc; hydranths and gonozooids encased in exoskeleton; free medusae usually absent, but when present flattened and with statocysts; medusae form gametes on subumbrella beneath radial canals; gonozooids (= gonangia) with blastostyle that produces medusae buds. Monophyly of the Leptothecata seems likely but relationships within this order await further study These are some of the most common species of hydrozoans in the marine littoral zone (e.g., *Abietinaria*, *Aequorea*, *Aglaophenia*, *Bonneviella*, *Campanularia*, *Cuviera*, *Gonothyrea*, *Lovenella*, *Obelia*, *Plumularia*, *Sertularia*).

ORDER ATHECATA (= ANTHOMEDUSAE, GYMNOBLASTEA, OR ANTHOATHECATA) Polyps solitary or colonial; hydranths and gonozooids lack exoskeleton; gonozooids produce free or sessile medusae; some groups produce gametes in transient sporosacs; free medusae tall and bell shaped, without statocysts, with or without ocelli; medusae form gametes on subumbrella or manubrium. Current research suggests this order is polyphyletic.

SUBORDER CAPITATA Adverse group of hydroids possessing stenotele nematocysts and tentacles with rounded (capitate) tips at some stage in the life cycle; many have medusae with complex, cup-shaped ocelli. Current research suggests there are two clades, Zancleida and Corynida Zancleida includes well-known polypoid forms (e.g., *Pennaria*, the Christmas tree hydroids) and the milleporid "fire corals" (known for their potent stinging nematocysts). Milleporids are distinguished by massive or encrusting calcareous coral-like skeletons, the calcareous matrix covered by thin epidermal layer; gastrozooids with short capitate tentacles; and each gastrozooid surrounded by 4–8 dactylozooid-like tentacles, each tentacle in a separate skeletal cup; gonophores housed in pits (ampullae) in skeleton; and, the small free medusae lack mouth, tentacles, and velum. Like the stony corals, millepords rely on a commensal relationship with zooxanthellae and are thus restricted to the photic zone. Zancleida also includes well-known medusoid forms, formerly known as "chondrophorans," whose colonies may consist of gastrozooids, gonozooids, and dactylozooids, or as a solitary but highly specialized polypoid individual. Chondrophoran "zooids" are attached to a chitinous, multichambered, disclike float, that may or may not have an oblique sail (e.g., *Porpita*, *Velella*), their "gonozooids" bear medusiform gonophores that are released and shed gametes, and most are richly supplied with zooxanthellae The Corynida includes well known medusoid forms such as *Coryne*, *Dipurena*, *Polyorchis*, and *Sarsia*. The status of the Corynida

is presently unclear due to evidence that generic relationships may need revision.

SUBORDER APLANULATA Members of this taxon lack a clearly delineated planula stage, hence their name; the group is well supported by molecular phylogenetic analyses. This group includes *Corymorpha*, *Tubularia*, *Hydra*, and *Candelabrum*. *Hydra*, while often used to exemplify the Cnidaria, is actually quite unusual in life cycle and morphology.

SUBORDER FILIFERA This heterogeneous group of hydrozoans is currently divided into 4 major groups. The first group (Filifera I) is typified by the family Eudendriidae, which is distinguished from other filiferans by the absence of desmoneme nematocysts, the presence of a stylo id-shaped gonophore, and a trumpet-shaped hypostome. The second group (Filifera II) is less distinct but shares a solid ring canal and macrobasic eurytele cnidae, as well as reduction in hydranth tentacles. Many species in this group live on other invertebrates (e.g., *Hydrichthella* on octocorals; *Brinckmannia* within hexactinellid sponges; *Proboscidactyla* on sabellid polychaete tubes). Filifera III is typified by the families Hydractiniidae (e.g., *Clava*, *Hydractina*) and Stylasteridae (e.g., *Allopora*, *Stylaster*). Members of these families have polymorphic polyps and perisarc- or skeleton-covered stolons that can be colorful. The stylasterine skeleton is secreted within the epidermis and covered by a thick epidermal layer; a calcareous style often arises from base of polyp cup, hence the name "stylasterine"; polyps may have tentacles; free medusae are not produced, but sessile medusoid gonophores are retained in shallow chambers (ampullae) of the colony; several dactylozooids surround each gastrozooid, although polyp pits are joined. Filifera IV includes the families Bouganvilliidae (e.g., *Bouganvillia*, *Dicoryne*), Oceaniidae (e.g., *Cordylophora*), Pandeidae (e.g., *Pandea*) and Rathkeidae (e.g., *Rathkea*), which all bear gonophores on structures other than hydranths.

ORDER SIPHONOPHORA Siphonophores. Polymorphic swimming or floating colonies, with a number of distinct types of polyps and attached modified medusae; most have a gas filled flotation zooid. Siphonophores are major oceanic predators, some reaching tens of meters in length; a majority of the species is bioluminescent. Historically divided into three groups based on body structure, molecular phylogenetic research now suggests the existence of two major clades—Cystonecta and Codonophora.

SUBORDER CYSTONECTA Possessing an anterior gas filled float or pneumatophore, with a posterior, zooid-bearing siphosome (e.g., *Physalia*, *Rhizophysa*).

SUBORDER CODONOPHORA Structurally the more complex siphonophores, this suborder includes the monophyletic Calycophora and the paraphyletic Physonecta. The former possess an anterior nectosome, comprised of nectophores, swimming elements that propel the colony, and a posterior zooid-bearing siphosome but no pneumatophore (e.g., *Diphyes*, *Hippopodius*, *Sphaeronectes*). The Physonecta possess an anterior pneumatophore, a more posterior nectosome and a posterior siphosome (e.g., *Agalma*, *Apolemia*, *Bargmannia*, *Physophora*).

SUBPHYLUM MYXOZOA Intracellular parasites of poikilotherm vertebrates, annelids and bryozoans; possessing myxospores, cnida-like structures with two or more shell valves and polar capsules containing nematocyst like filaments. This taxon contains two clades (Myxosporea and Malacosporea), well supported by molecular phylogenetic analyses. About 2,200 described species.

CLASS MYXOSPOREA Marine and freshwater species, usually with hard valves; life cycles include a myxosporean phase in vertebrates and an actinosporean phase within polychaete and sipuncuan annelids. About 1,200 described species.

ORDER BIVALVULIDA Possessing two valves per myxospore; gut and tissue parasites (e.g., *Ceratomyxa*, *Henneguya*, *Myxidium*, *Myxobolus*, *Sphaerospora*; the genus *Myxidium* appears to be polyphyletic).

ORDER MULTIVALVULIDA Possessing more than two valves per myxospore (e.g., *Hexacapsula*, *Kudoa*, *Trilospora*).

CLASS MALACOSPOREA With a single order, Malacovalvulida, and a single family Saccosporidae. Freshwater species characterized by soft walled spores, bryozoans as invertebrate hosts, and spore formation within a sac-like body form (e.g., *Buddenbrockia*, *Tetracapsuloides*).

The Cnidarian Body Plan

Although showing marked advances over Porifera and Placozoa, cnidarians still appear to possess only two embryonic germ layers—the ectoderm and the endoderm—which become the adult epidermis and gastrodermis, respectively. The middle mesoglea or mesenchyme in adults is derived largely from ectoderm and never produces the complex organs seen in triploblastic Metazoa (i.e., the Bilateria).

Whether or not a true basement membrane (= basal lamina) exists in cnidarians is debatable. We define a **basement membrane** as a thin sheet of extracellular matrix upon which an epithelial layer may rest; it contains collagen and other proteins, and it helps hold the epithelial cells in place. By this definition, placozoans lack a basement membrane, cnidarians and ctenophores possess one by way of the mesenchyme, and

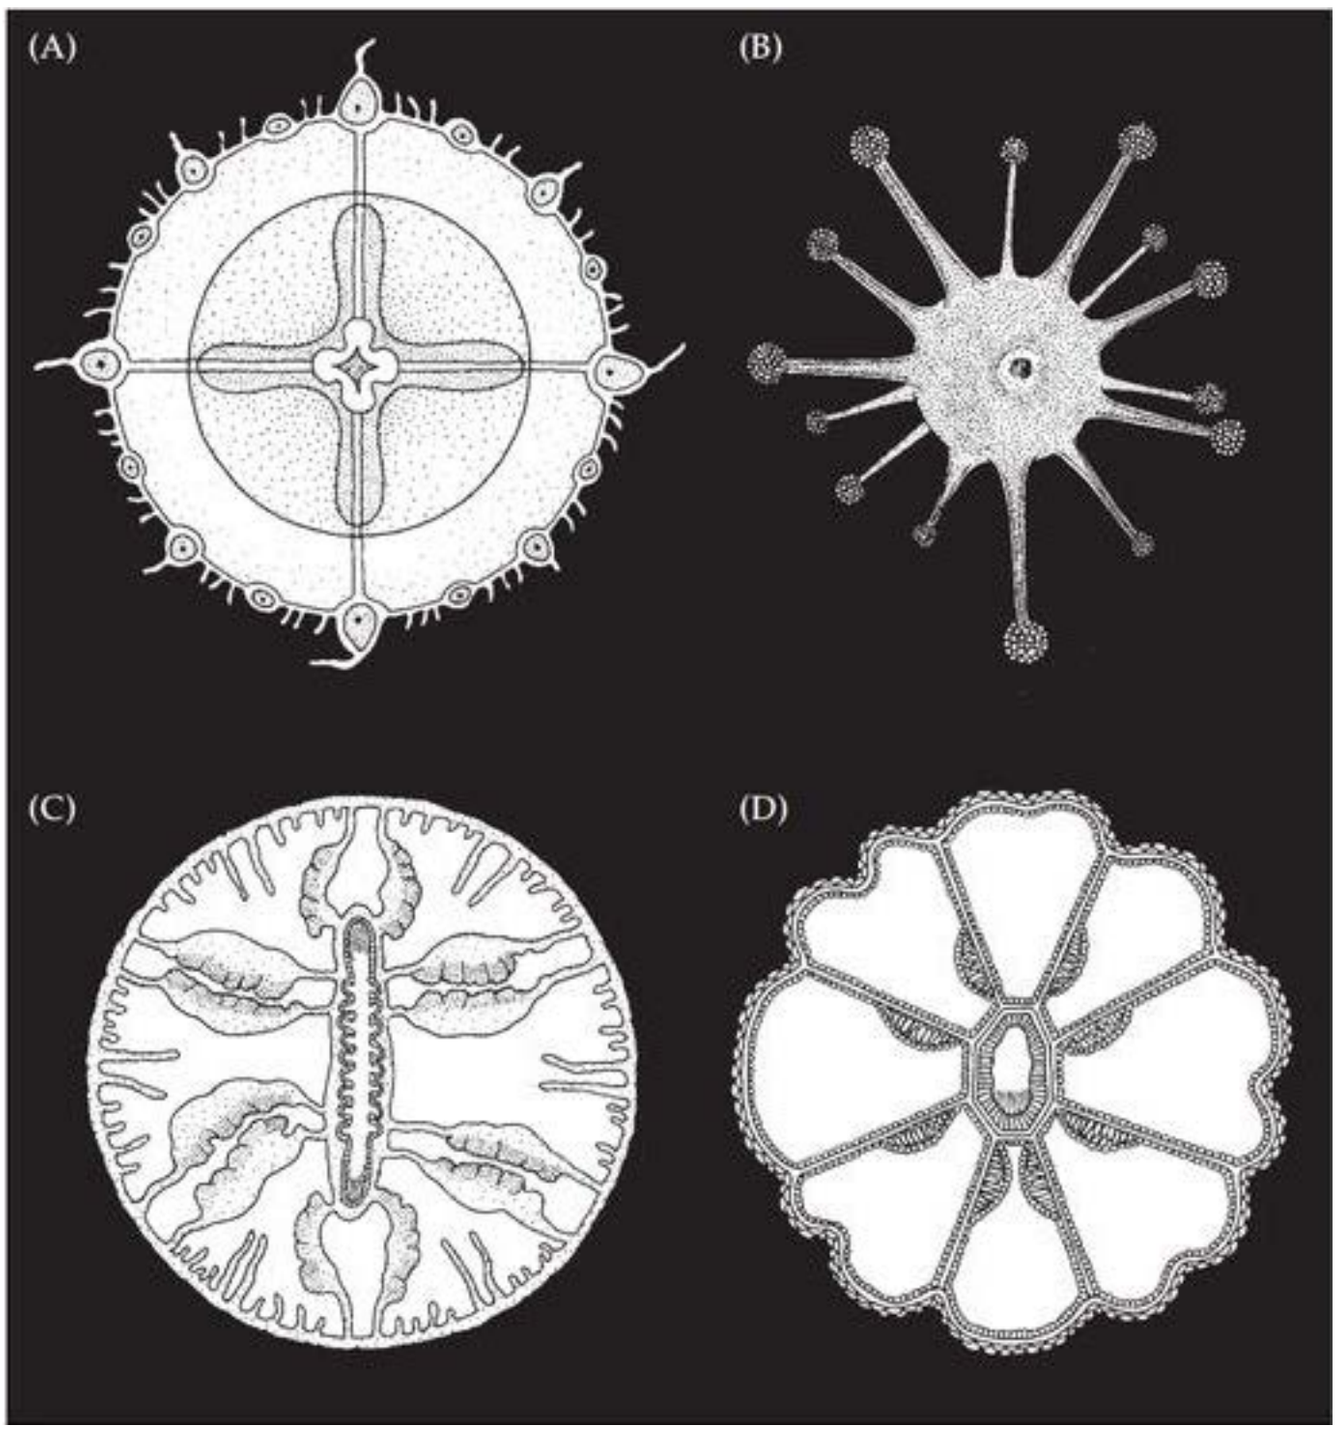

Figure 7.3 Cnidarian radial symmetries. (A) Quadriradial symmetry of a hydromedusa. (B) Radial symmetry of a hydrozoan polyp. (C) Biradial symmetry of an actinarian polyp (a sea anemone). (D) Biradial symmetry of an octocoral polyp (Anthozoa).

In spite of the limitations of a diploblastic, radially symmetrical body plan, cnidarians are a highly successful and diverse group. Much of their success has resulted from their possession of cnidae and the diversity of different dimorphic life histories. Although polyps and medusae are very different in appearance, they are really variations on the basic cnidarian body plan (Figure 7.2). And yet, the two stages are vastly different ecologically, and their presence in a single life history allows an individual species to exploit different environments and resources, leading a "double life."

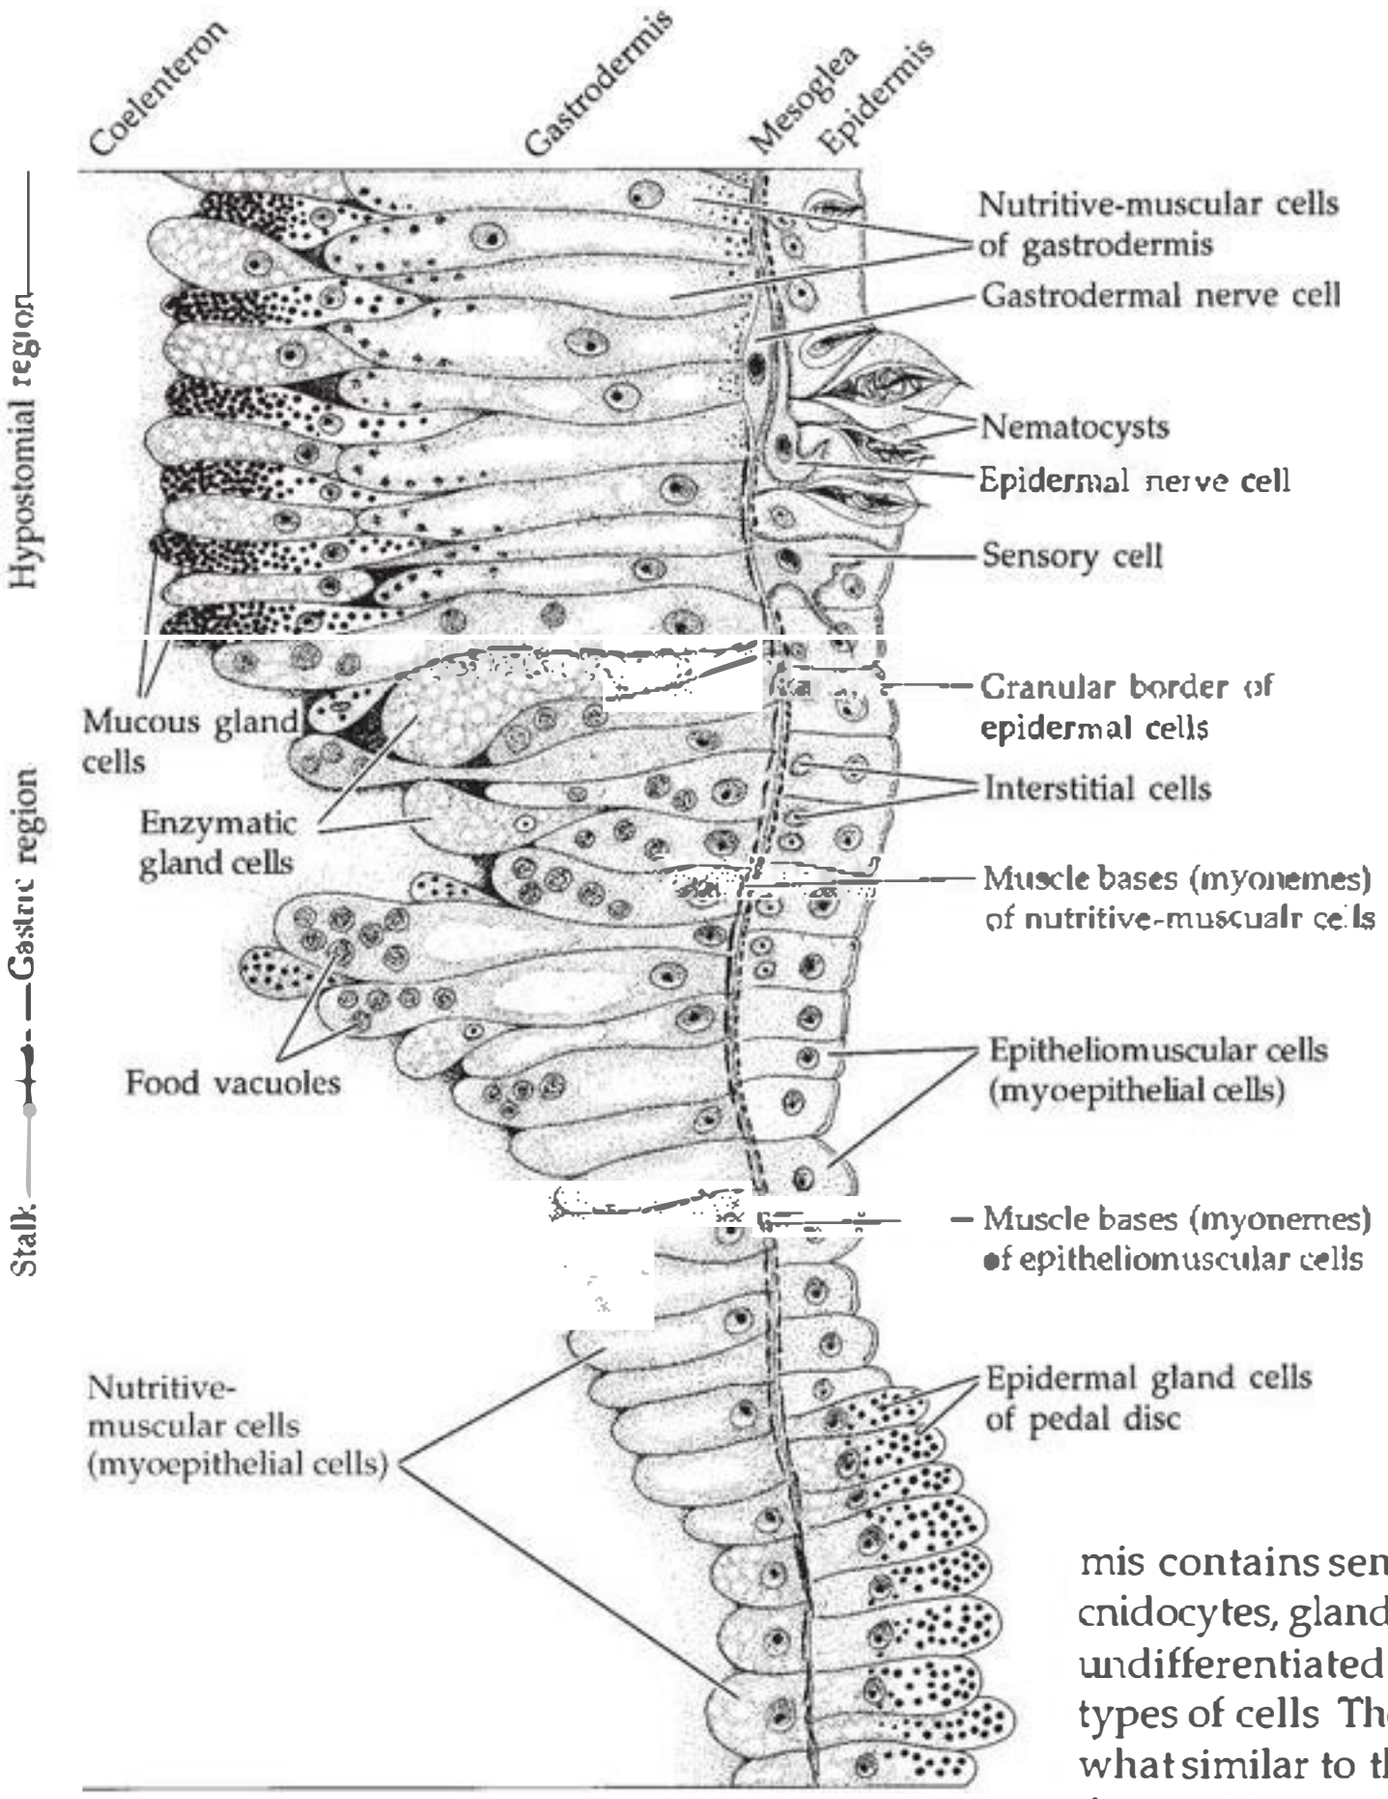
the Bilateria possess a well developed, highly proteinaceous basement membrane. And, as we've seen, basement membranes also occur in some sponges

The essence of the cnidarian body plan is radial symmetry (Figure 7.3). As discussed in Chapter 4, radial symmetry is associated with various architectural and strategic constraints. Cnidarians are either sessile, sedentary, or pelagic, and they do not engage in the active unidirectional movement seen in bilateral, cephalized creatures. Radial symmetry demands certain anatomical arrangements, particularly of those parts that interact directly with the environment, such as feeding structures and sensory receptors. Thus, we typically find a ring of tentacles encircling the body that can collect food from any direction, and a diffuse, noncentralized nerve net with radially distributed sense organs. These and other implications of radial symmetry are explored further throughout this chapter. Although polypoid and medusoid forms are often represented as inverted forms of one another (Figure 7.2A–C), studies of gene expression in cnidarians show that the oral tentacles of polyps and the marginal tentacles of medusae may not always be homologous structures (Figure 7.2D). As we will see, differences between polyps and medusae go well beyond how animals appear to be oriented along their oral-aboral axis.

The Body Wall

Cnidarian epithelia the outer epidermis and the inner gastrodermis include myoepithelial cells (Figures 7.4 and 7.19), which are primitive muscle cells. These columnar cells bear flattened, contractile, basal extensions called myonemes (Figure 7.19). In the epidermis, these cells are referred to as epitheliomuscular cells, and in the gastrodermis they are called nutritive-muscular cells. The myonemes rest against the middle mesoglea or mesenchyme, and the opposite ends of the cells form the outer body and gut surfaces. The myonemes run parallel to free surfaces and contain contractile myofibrils. Myonemes of neighboring cells are interconnected, often forming longitudinal and circular sheets capable of contracting like muscle layers of more advanced phyla. Primitive contractile cells similar to myoepithelial cells occur in poriferans the contractile myocytes Somewhat similar cells are even known among mammals, where they are found in association with certain secretory tissues.

Molecular studies of germ layer formation in anthozoans show that virtually all of the genes involved in endomesoderm formation in bilaterian embryos, including the core genes identified as components of an evolutionarily conserved endomesoderm ("kernel") gene regulatory network, are expressed in cnidarian



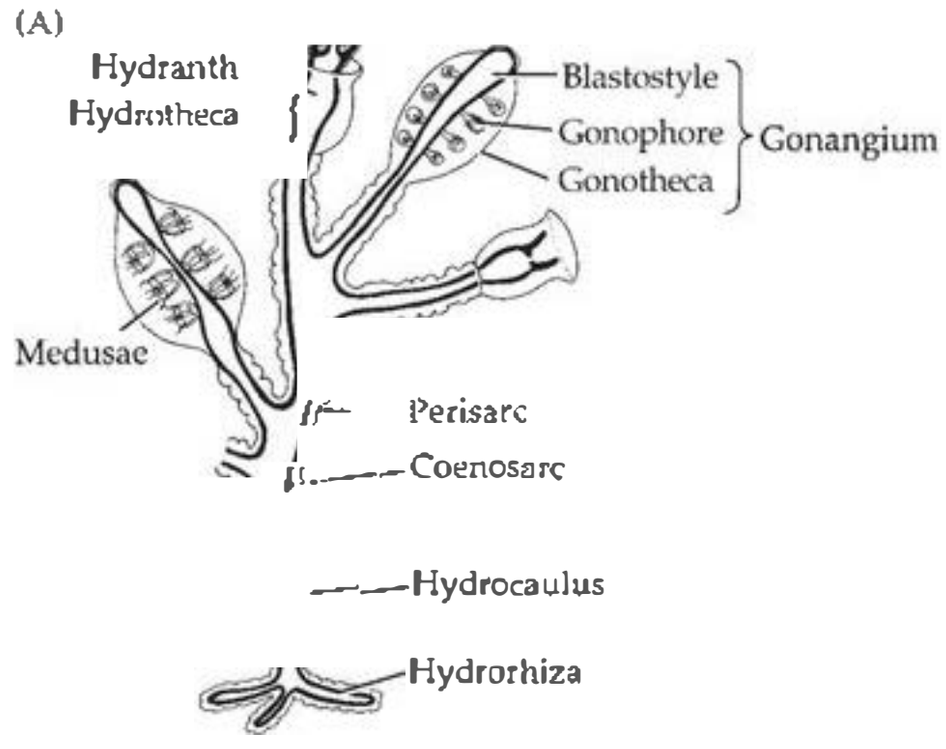


Figure 7.4 A hydrozoan polyp column wall (cross section) Iustrates the basic cnidarian cell and tissue types.

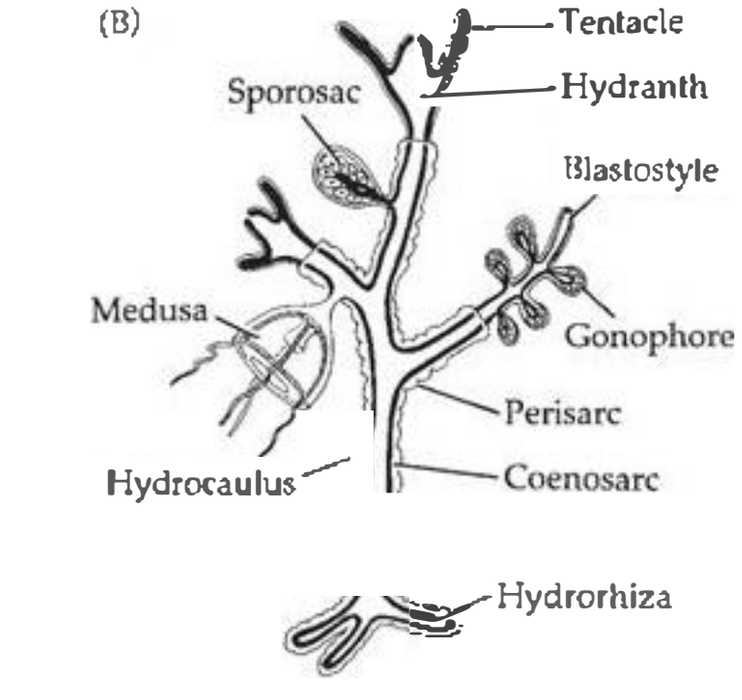
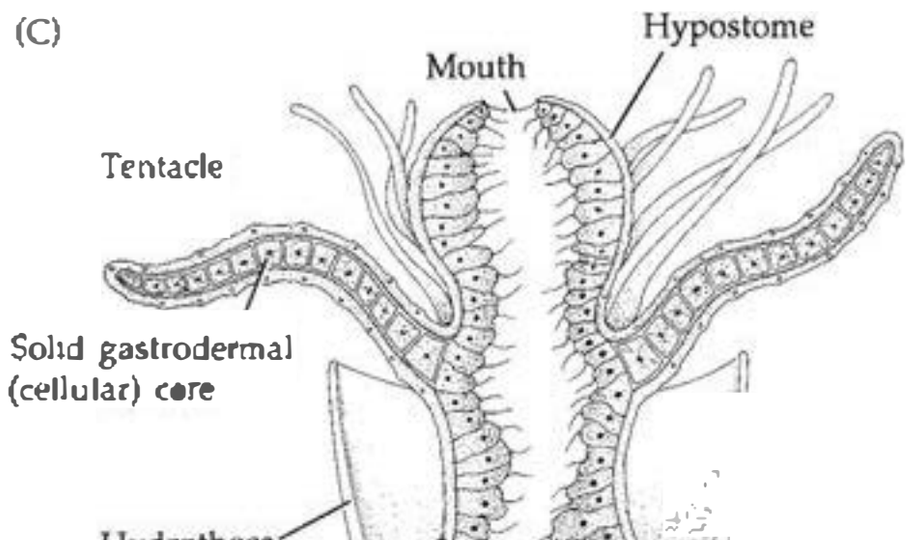
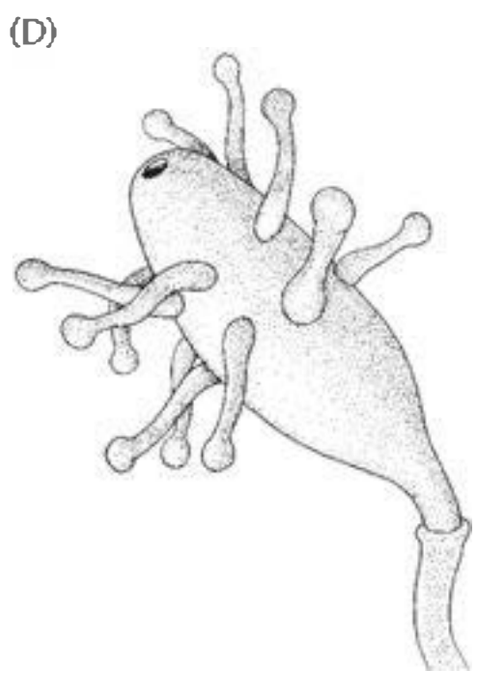


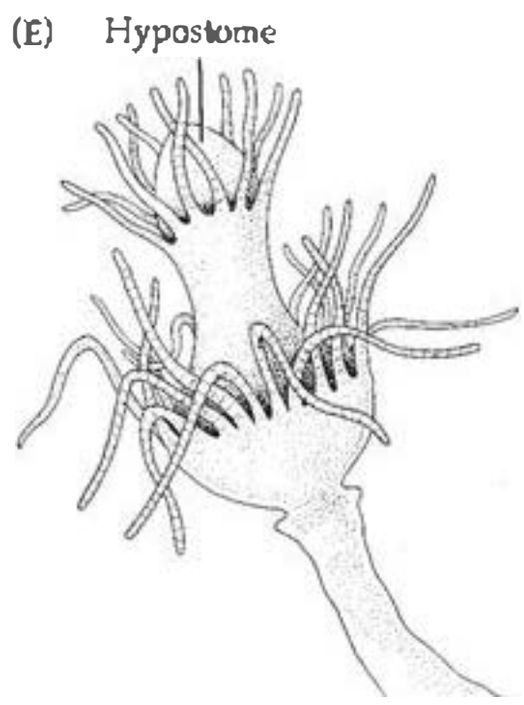
epithelial tissue that lines the gastric cavity or the phar ynx. This conservation in components of the endome sodermal gene regulatory network provides compel ling evidence that the endodermal and pharyngeal tissue of cnidarians (and probably ctenophores) is homologous with that of the gut and oral ectoderm of bilaterians, and that both endoderm and mesoderm of bilaterians evolved from an ancestral endomesodermal layer. Fate mapping experiments have shown that the definitive endoderm is generated from the oral pole/ animal hemisphere in both anthozoan cnidarians and ctenophore embryos. They also show that the single opening to the cnidarian and ctenophoran gut arises from the same region of embryo (the animal hemi sphere) that forms the mouth in all other bilaterians. This suggests that the oral pole of adult ctenophores and cnidarians is homologous to the anterior pole of bilaterians, and that the single opening is homologous to the mouth of other bilaterians. This relationship is also supported by molecular data. Thus, the mouths of all animals appear to be homologous, with the possible exception of the chordates. (The mouth of chordates does not express the same suite of genes as seen in other metazoans, and its position forms independently of a circumoral component of the nervous system shared by most other metazoans. If this interpretation is correct, it suggests that the single opening to the cnidarian and ctenophoran (and perhaps also acoel) gut preceded the evolution of the through gut, suggesting that the anus arose independently in protostomes and deuterostomes.



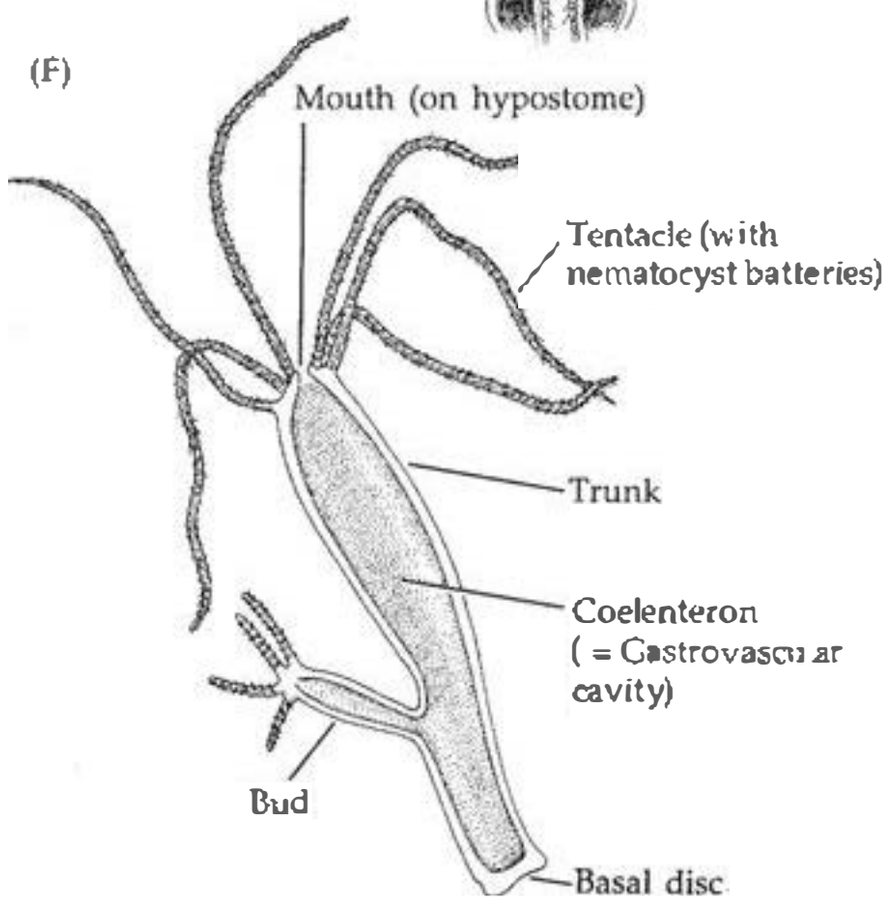
Some cnidarians also possess subepidermal mesenchymal muscles, apparently derived from the contractile elements of the myoepithelial cells. In anemones, for e x ample, cordlike sphincters are sunk below the epithelium and reside as distinct muscles wholly within the mesenchyme. In addition to epitheliomuscular cells, the epidermis contains sensory cells, cnidabearing cells called cnidocytes, gland cells, and interstitial cells. The last are undifferentiated and capable of developing into other types of cells The gastrodermis is histologically somewhat similar to the epidermis (Figure 7.4). Along with the nutritive muscular cells it also contains cnidocytes (except in the Hydrozoa) and gland cells.



In hydrozoans, the middle layer is a rather simple, gel-like, largely acellular mesoglea. Scyphomedusae have a very thick mesogleal layer with scattered cells. In stauromedusans, cubozoans, and hydrozoans, mesoglea is n on cellular. In anthozoans the middle layer is often a thick and richly cellular mesenchyme (see footnote 2, earlier in the chapter). Myxozoans are primarily small and cellular without clearly defined body walls, with a few exceptions. The actinosporan larva of many myxosporeans has rays comprised of single cells that are used to attach to the mucous membranes of vertebrate hosts. The worm-like *Buddenbrockia* has four blocks of longitudinal musculature that lie beneath the epidermis and surround a hollow, gut-free body cavity.



The polypoid form Polyps are much more diverse than are medusae, largely as a result of their capacities for asexual reproduction and colony formation (Figures 7.5–7 12). This diversity of form has led to an extensive lexicon of terms for the parts of polyps. This expansive



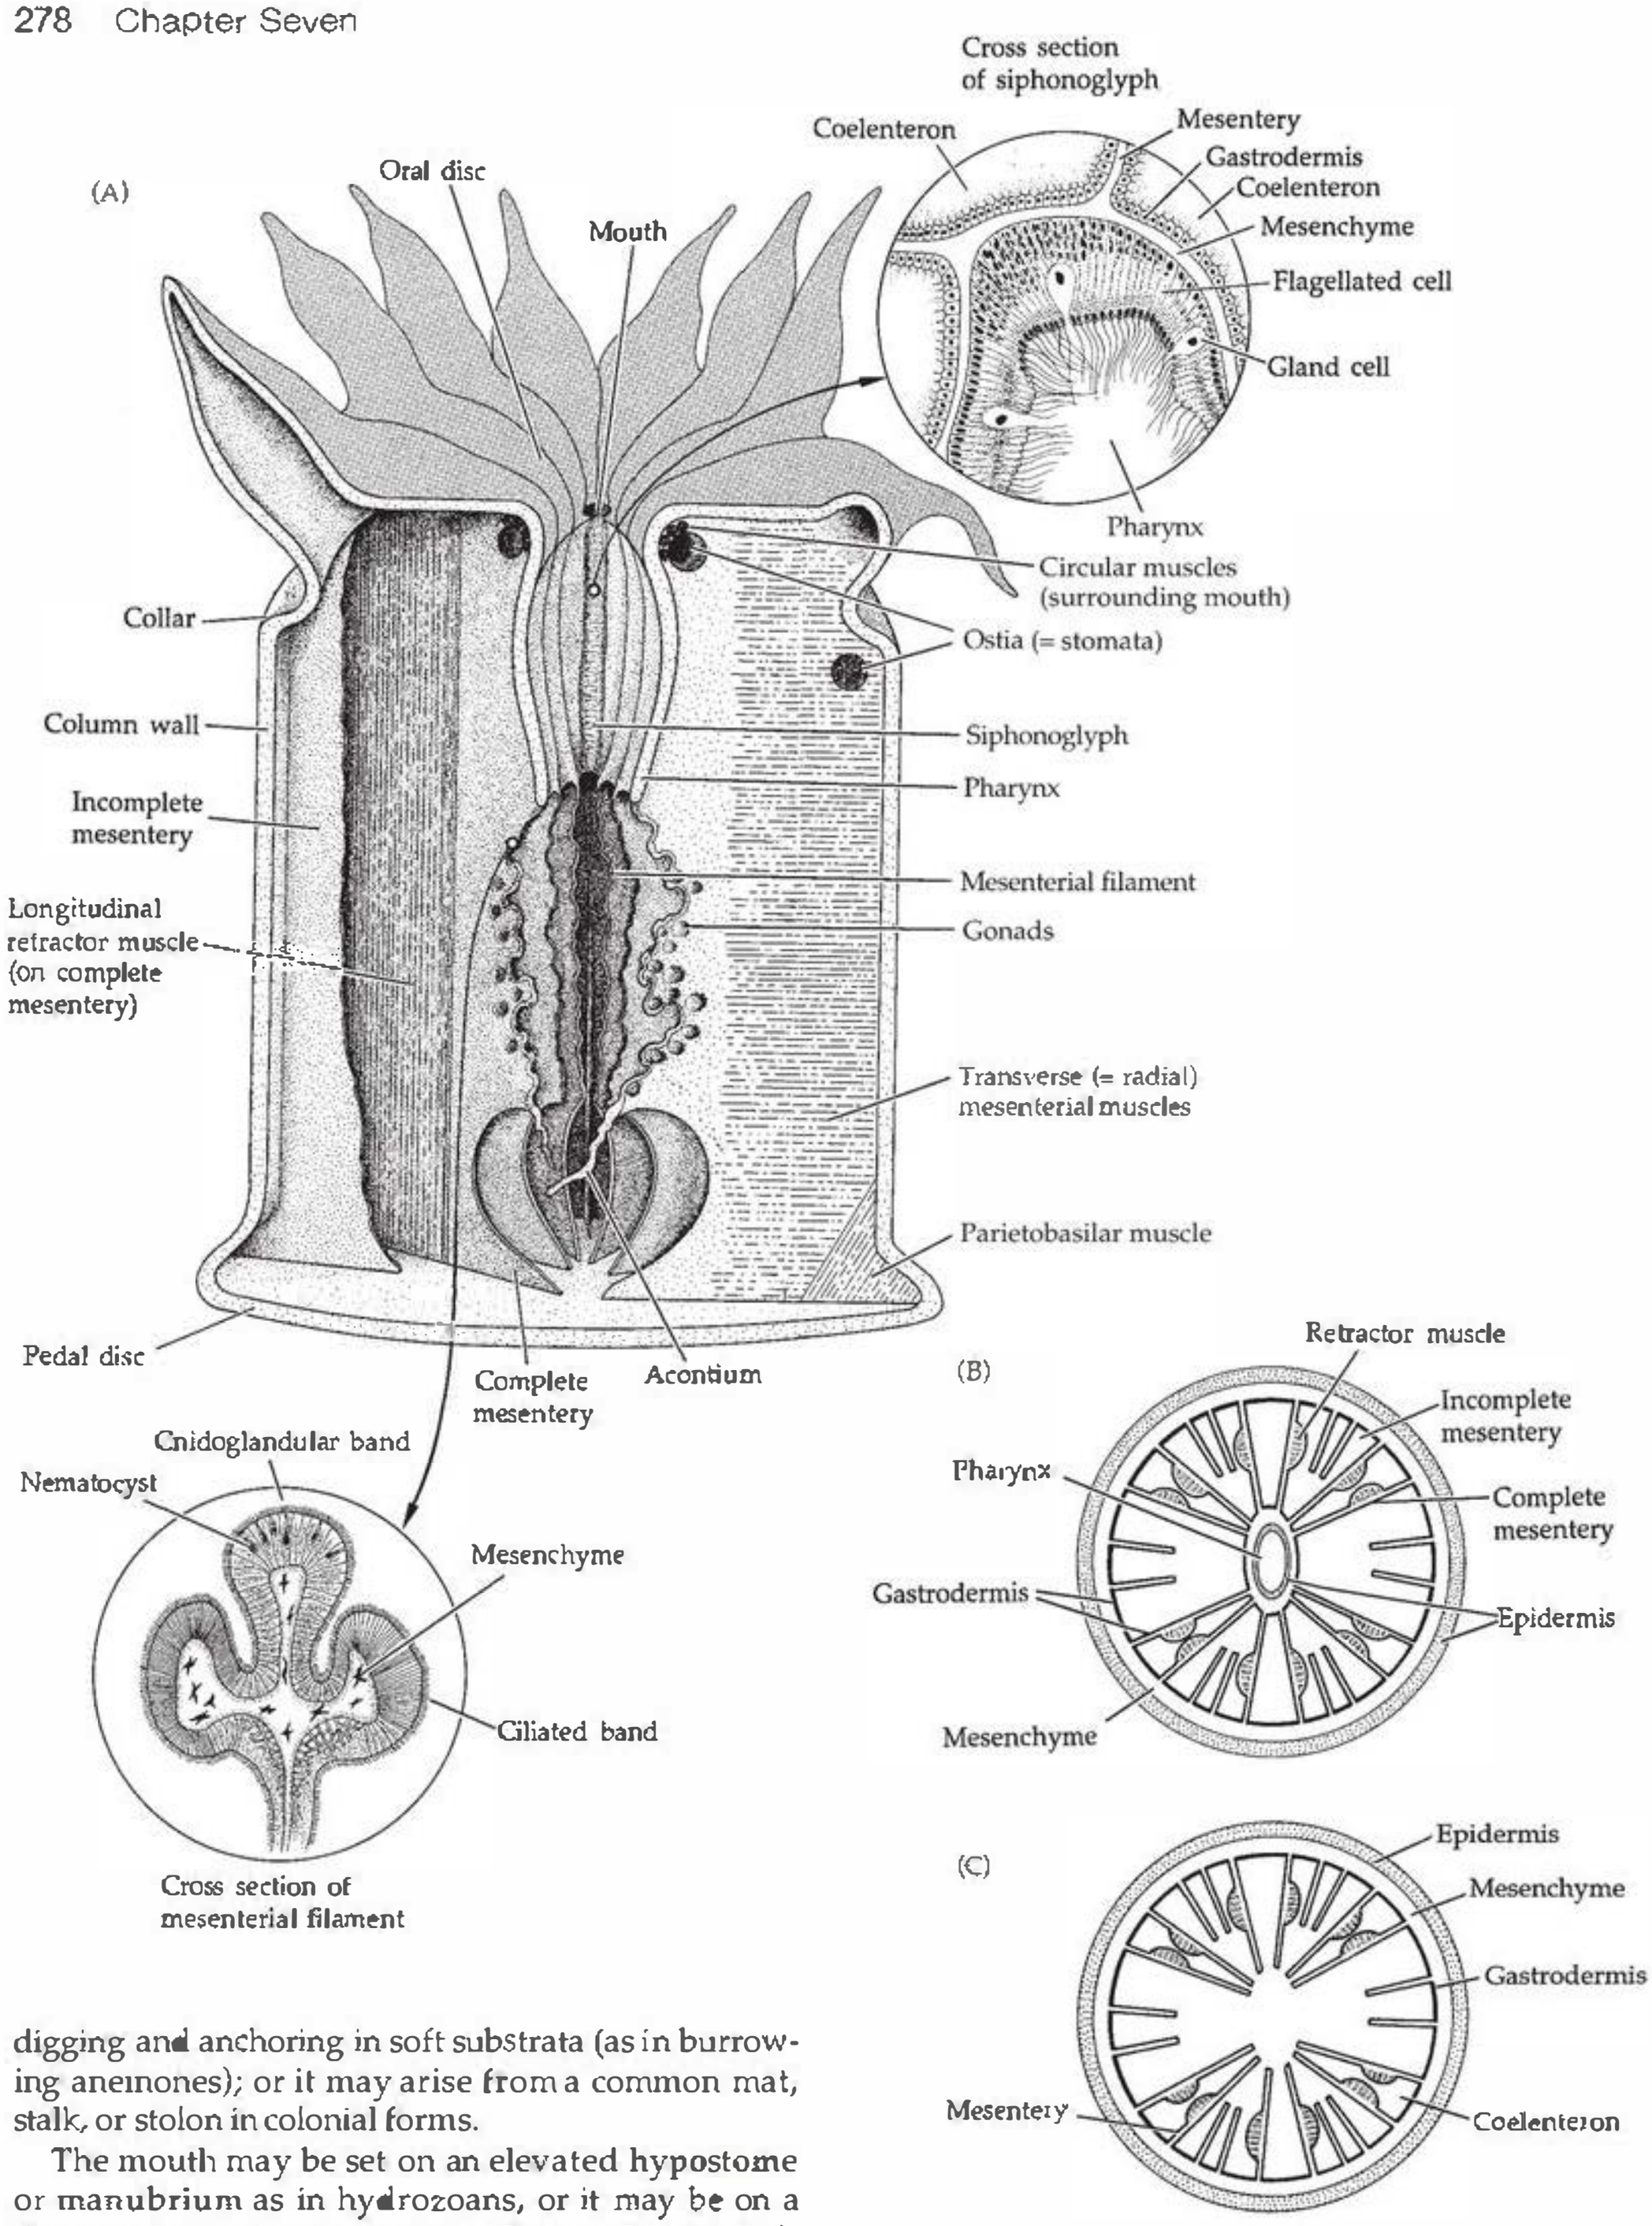


Figure 7.5 Hydrozoan polyps. (A) A thecate hydroid colony. The blastostyles produce either sporosacs or medusae. (B) An athecate hydroid colony, illustrating various types of reproductive structures. Note that A and B are composite diagrams; a given species produces either sporosacs or medusae, never both. (C) A thecate hydranth (= gastrozooid) (longitudinal section). (D) A hydranth with capitate tentacles. (E) A hydranth with two whorls of filiform tentacles (e.g., *Tubularia*). (F) The freshwater *Hydra* (body is shown in longitudinal section).

terminology may at first seem a bit overwhelming, but bear with us—we won't give you anything unnecessary here. The polypoid stage occurs in the subphyla Anthozoa and Medusozoa, although it is greatly modified in the Scyphozoa, Cubozoa, and Staurozoa. A clearly defined polypoid stage appears to be lacking in the subphylum Myxozoa. Polyps are tubular structures with an outer epidermis, an inner gut sac (coelenteron) lined with gastrodermis, and a layer of jelly-like mesoglea or mesenchyme in between. Most polyps are small, but the polyps of some species of sea anemones get quite large, the largest is the monstrous tropical Indo-Pacific *Stichodactyla mertensii*, which can exceed a meter in diameter, and the beautiful northeast Pacific *Metridium giganteum*, which can extend its column to a meter in height.

The fundamental polypoid symmetry is radial, although as a result of subtle modifications most species possess a biradial or quadriradial symmetry. The main body axis runs longitudinally through the mouth (oral end) to the base (aboral end) of the polyp. The aboral end may form a pedal disc for attaching to hard substrata (as in most common sea anemones); it may be a rounded structure—called a physa—adapted for

digging and anchoring in soft substrata (as in burrowing anemones); or it may arise from a common mat, stalk, or stolon in colonial forms.

The mouth may be set on an elevated **hypostome** or **manubrium** as in hydrozoans, or it may be on a flat **oral disc** as in anthozoans (Figures 7.5 and 7.6). In anthozoans the mouth is usually slitlike and leads to a muscular, ectodermally derived pharynx that extends into the coelenteron (the gut cavity of a polyp).

Figure 7.6 An anthozoan polyp. (A) A sea anemone (longitudinal section). (B) Cross section taken at the level of the pharynx. (C) Cross section taken below level of the pharynx.

The pharynx usually bears from one to several ciliated grooves called siphonoglyphs, which drive water into the coelenteron (Figure 7.6). It is in part the presence of siphonoglyphs that gives these polyps a secondary biradial or quadraradial symmetry. The side of an anthozoan polyp that bears a single siphonoglyph is called the sulcal side, and the opposite side is called the asulcal side.

The coelenteron, or gastrovascular cavity, serves for circulation as well as digestion and distribution of food. In hydrozoan polyps, the coelenteron is a single, uncompartmentalized tube. In scyphozoan (scyphistomae) and staurozoan polyps, it is partially subdivided by four longitudinal, ridgelike mesenteries, and in some staurozoans and cubozoans additionally by a transverse claustrum (a partition running parallel to the umbrellar margin and dividing each gastric pouch into inner and outer pockets); in anthozoan polyps, it is extensively compartmentalized by mesenteries. Anthozoan mesenteries are projections of the inner body wall and thus are lined with gastrodermis and filled with mesenchyme. They extend from the inner body wall toward the pharynx, some or all of them fusing with it as complete mesenteries. Those that do not connect to the pharynx are called incomplete mesenteries. In anthozoan polyps, the free inner edge of each mesentery below the pharynx has a thickened, cordlike margin armed with cnidae, cilia, and gland cells and is called the mesenterial filament (Figures 7.6 and 7.20). In some sea anemones these filaments give rise to long threads, called acontia, that hang free in the gastrovascular cavity. Acontia function in defense and feeding (see the section on Feeding and Digestion section below). In most colonial anthozoans the cellular mesenchyme unites individual zooids (Figure 7.12). In some, such as the soft corals, gastrovascular cavities are connected to one another by canals called solenia.

The tentacles that surround the mouth contain hollow extensions of the coelenteron in anthozoans, whereas they house a solid core of packed gastrodermal cells in most hydrozoans. Tentacles may taper to a point (filiform tentacles) or may terminate in a conspicuous knob of cnidae (capitate tentacles). In some polyps the tentacles are branched, often as pinnately arranged pinnules (e.g., in the octocorals).

Branched hydrozoan colonies grow in two patterns (Figure 7.7). In monopodial growth, the first polyp elongates continuously from a growth zone at the distal end of the simple or branched stem of the colony, the hydrocaulus. This primary (axial) polyp may even lose its hydranth and persist merely as a stalk. The primary hydrocaulus gives rise to secondary polyps by lateral budding. These secondary polyps grow and may give rise to lateral tertiary polyps in the same fashion. In hydrozoan colonies developing by sympodial growth,

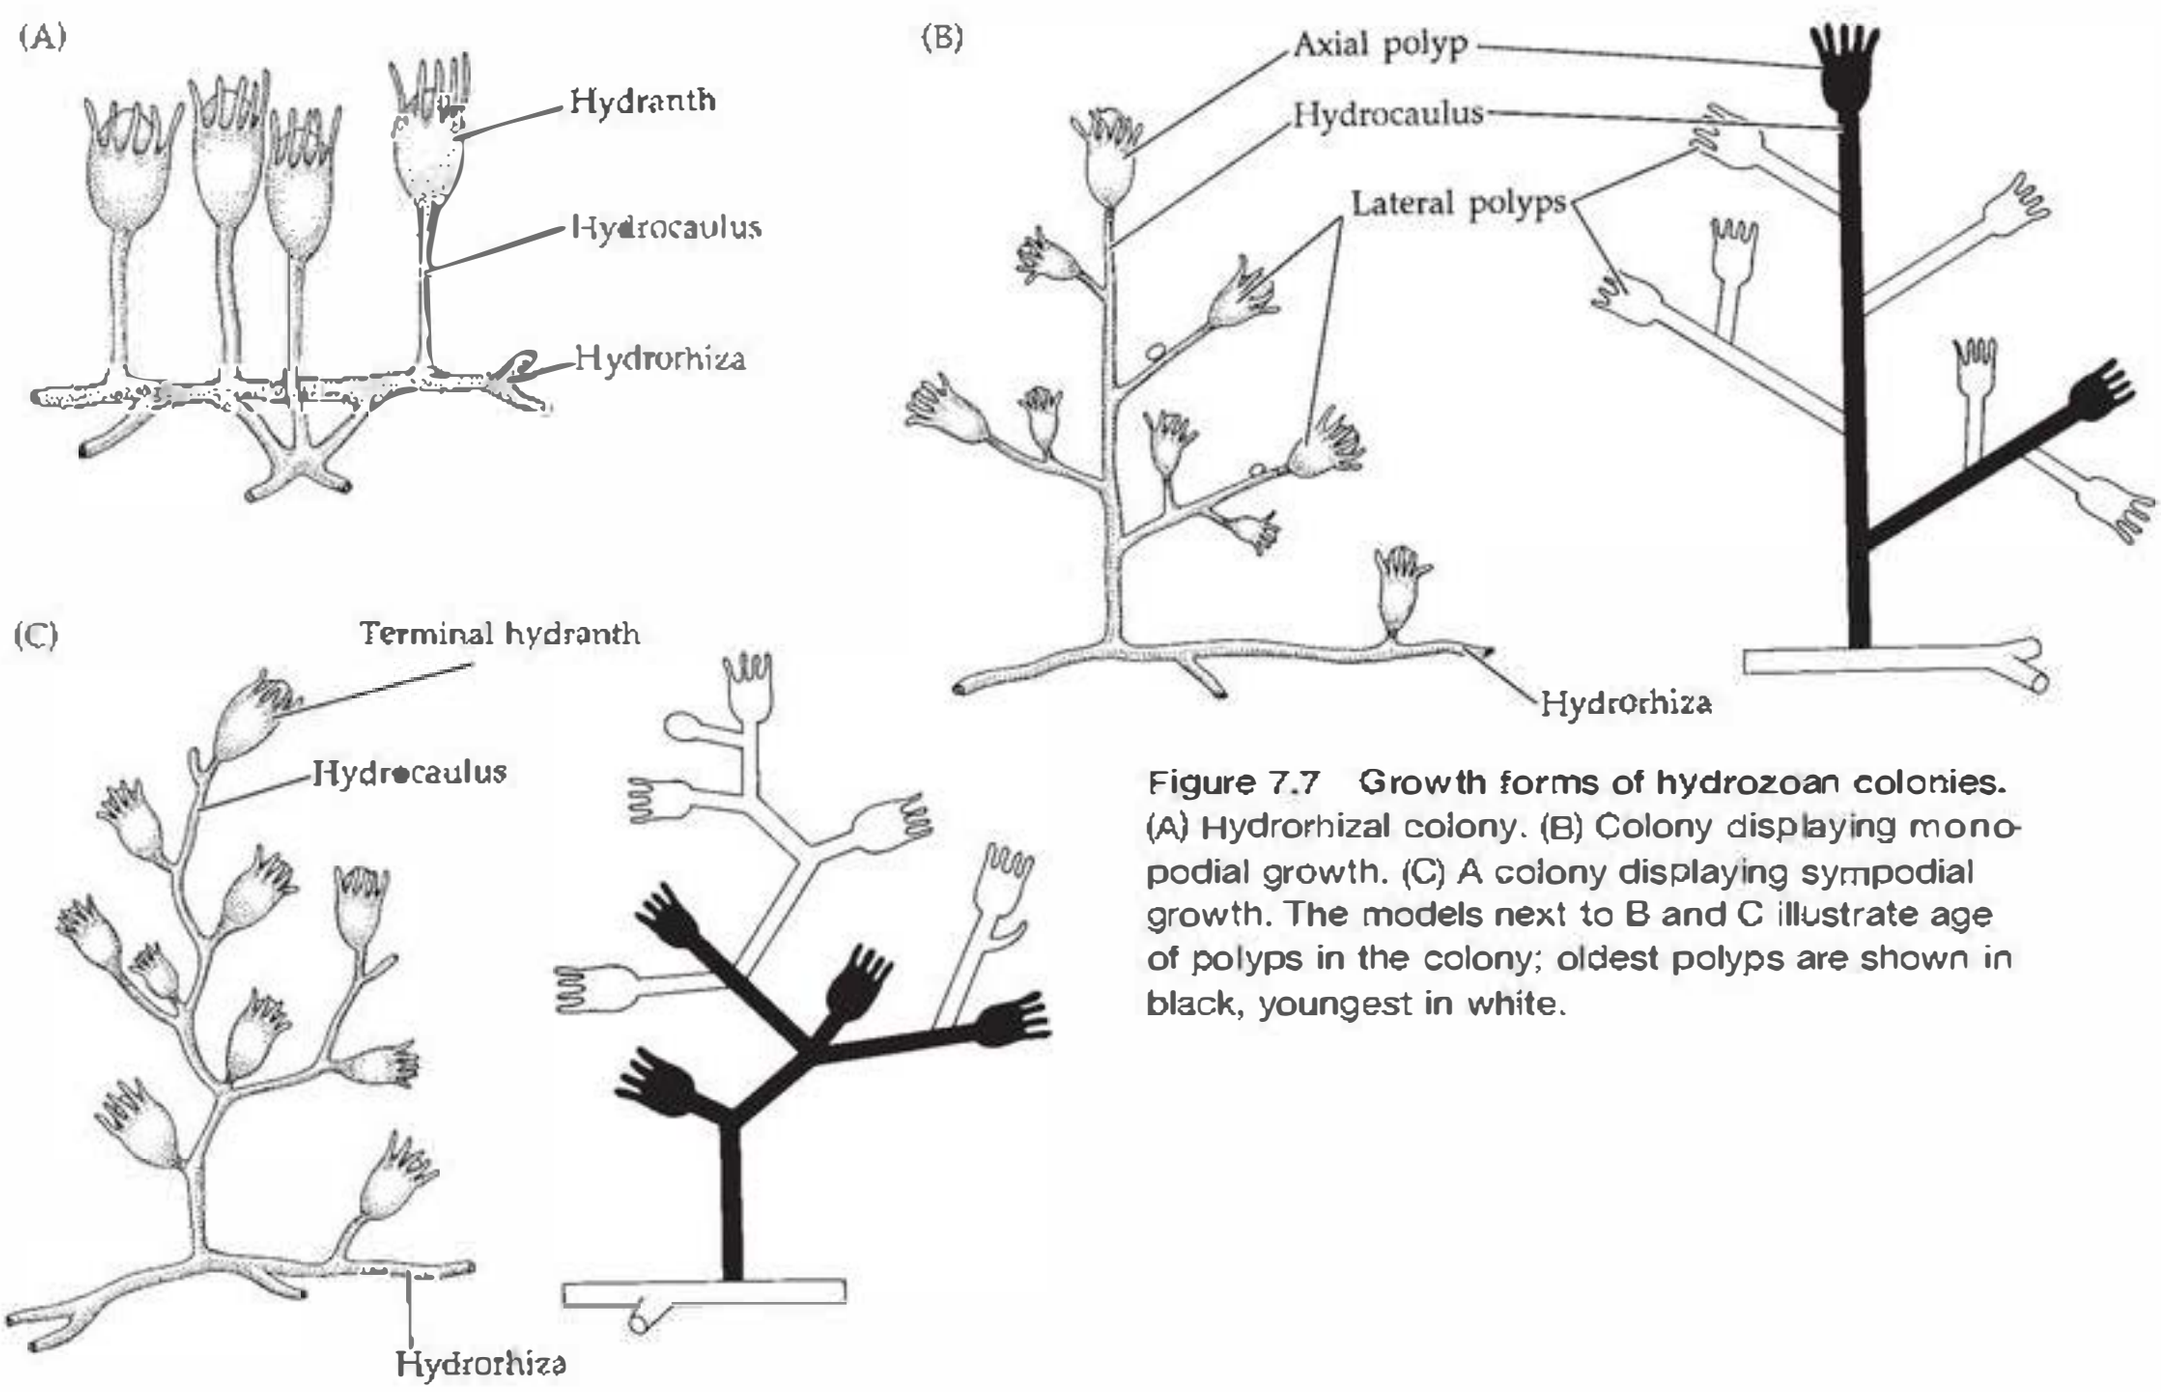

Figure 7.7 Growth forms of hydrozoan colonies. (A) Hydrorhizal colony. (B) Colony displaying monopodial growth. (C) A colony displaying sympodial growth. The models next to B and C illustrate age of polyps in the colony; oldest polyps are shown in black, youngest in white.

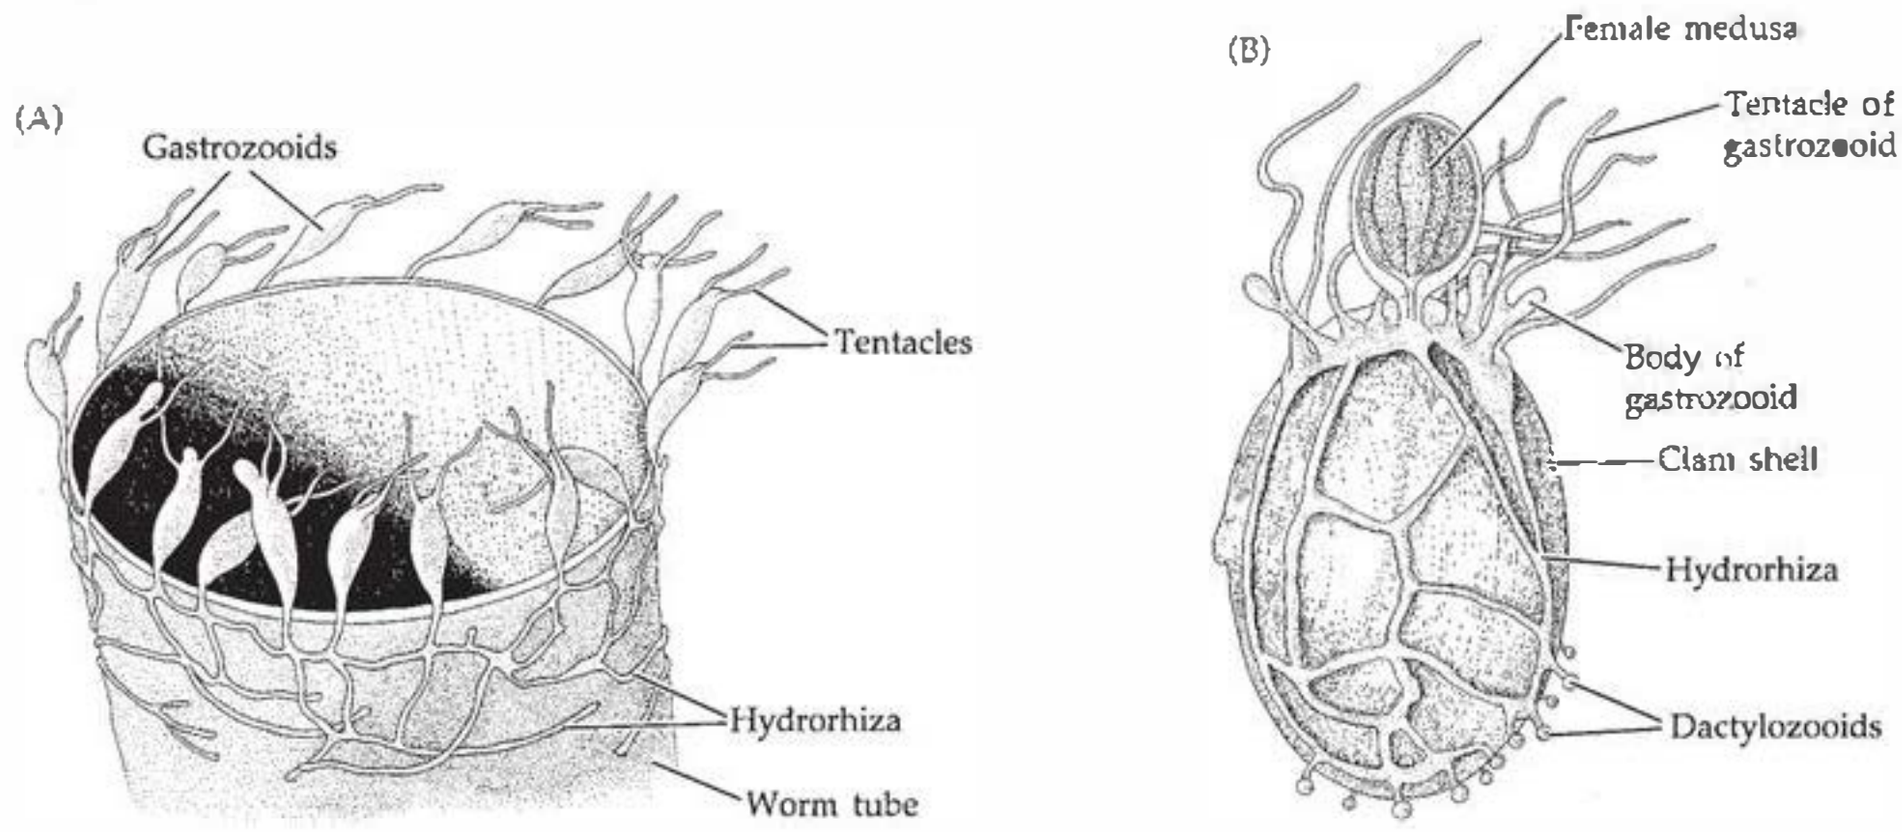

Figure 7.8 Diversity of form among the colonial Hydrozoa. (A) *Proboscidactyla*, a two-tentacled hydroid that lives around the open end of polychaete worm tubes. (B) *Monobrachium*, a one-tentacled hydroid that lives on clam shells. (C) *Hydractinia*, a colonial hydroid commensal on shells inhabited by hermit crabs. (D) The chondrophoran *Porpita* (aboral view). (E) A colony of the calcareous milleporid hydrocoral *Millepora* (fire corals). (F) A siphonophore, *Physalia* ("man-of-war"). (G) A colony of the calcareous stylasterine hydrocoral *Allopora*. (H) *Nectocarmen antonioi*, a colonial calycophoran siphonophore from California. (I) Another siphonophore.

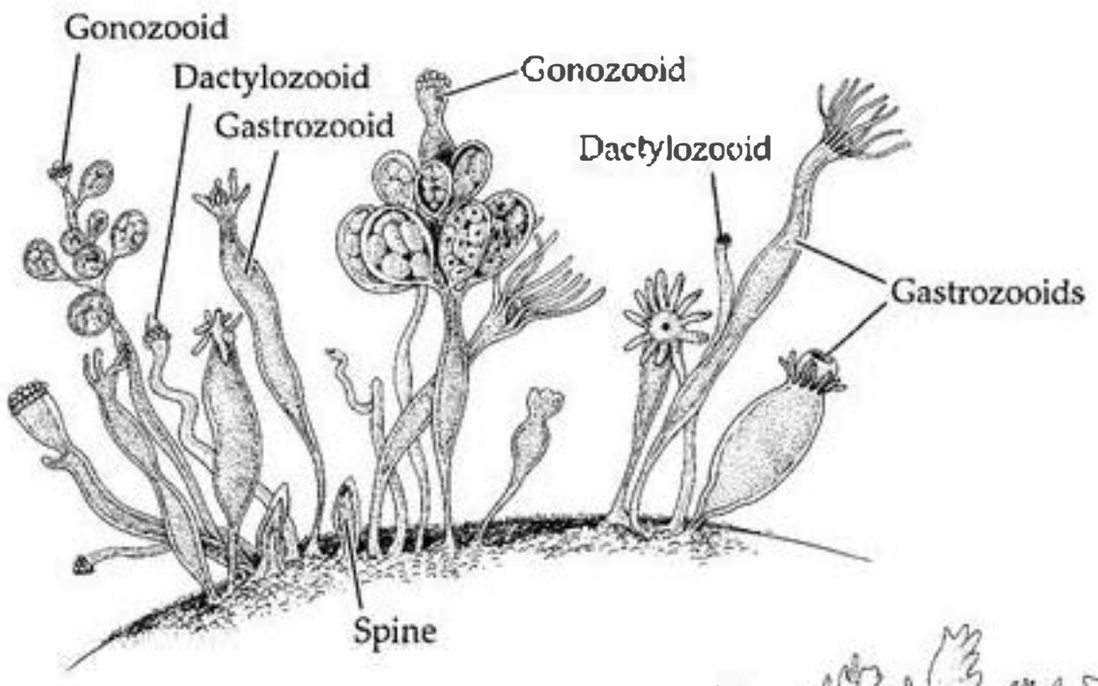
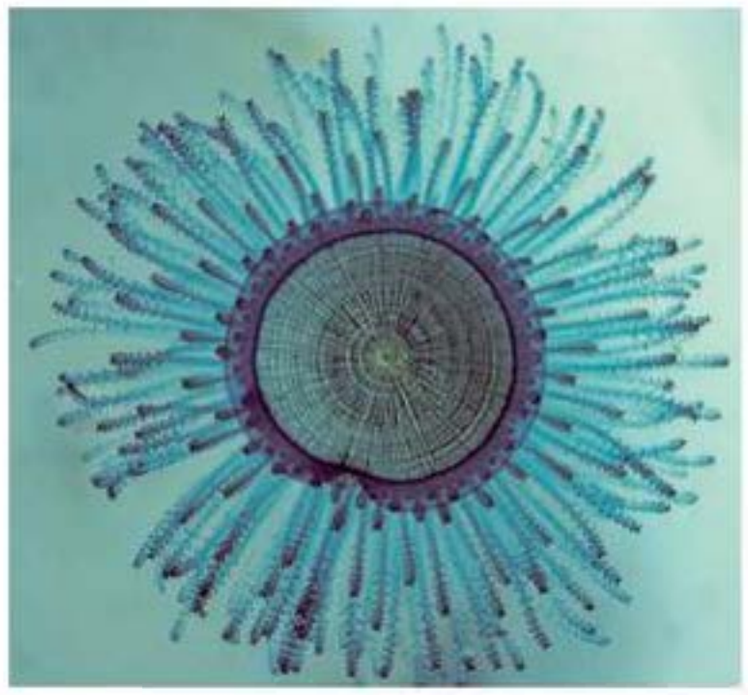
the primary polyp does not continue to elongate but produces one or more lateral polyps by budding and then stops growing. The new polyps extend the colony upward some distance then stop growing and give rise to more new polyps by budding. In these colonies the main stem or axis actually represents the combined hydrocauli of many polyps and the age of the polyps decreases from base to tip along each branch.

Most marine hydroids are surrounded, at least in part, by a nonliving protein–chitin exoskeleton secreted by the epidermis and called the perisarc (Figure 7.5). Interestingly, this outer covering is absent in freshwater hydroids. The living tissue inside the perisarc is termed the coenosarc. The perisarc may extend around each hydranth and gonozooid as a hydrotheca and gonotheca, respectively. When this occurs, the hydroids are said to be **thecate**; hydroids whose perisarcs do not extend around the zooids are **athecate**.



A complex terminology has been developed to describe hydrozoan polyps, or "hydroids" as they are commonly called (Figures 7.5 and 7.7). A big reason for this special nomenclature is that hydroid colonies are usually polymorphic, containing more than one kind of polyp, or zooid. The term hydranth or **gastrozooid** refers to feeding zooids, which typically bear tentacles and a mouth. Other commonly occurring polyp types include defensive polyps (dactylozooids) and reproductive polyps (**gonozooids** or **gonangia**). Each zooid typically arises from a stalk, called a **hydrocaulus** (pl. hydrocauli). In most colonial hydrozoans, the individual polyps are anchored in a rootlike stolon called a **hydrorhiza**, which grows over the substratum. From the hydrorhiza arise the hydrocauli, bearing polyps singly or in clusters.

Gastrozooids capture and ingest prey and provide energy and nutrients to the rest of the colony. Dactylozooids, which occur in a variety of sizes and shapes, are heavily armed with cnidae. Often several dactylozooids surround each gastrozooid and serve for both defense and food capture. Gonozooids produce medusa buds called gonophores that are either released or retained on the colony. Whether released as free medusae or retained as attached gonophores, they produce gametes for the sexual phase of the hydrozoan life cycle. The living tissue (coenosarc) of the gonozooid is called the **blastostyle**; the gonophores arise from this tissue. When a gonotheca surrounds the blastostyle, the zooid is called a **gonangium**.



The most dramatic examples of polymorphism among polyps are seen in the hydrozoan order Siphonophora and the anthozoan order Pennatulacea. Siphonophores (Figures 7.8F,H,I and 7.9) are hydrozoan colonies composed of both polypoid and medusoid individuals, with as many as a thousand zooids in a single colony. This large order includes a great variety of unusual and poorly understood species, including the famous Portuguese man-of-war, *Physalia* (Figure 7.8F). The gastrozooids of siphonophores are actually highly modified polyps with a large mouth and one long, hollow feeding tentacle that bears many cnidae (Figure 7.9). This feeding tentacle reaches lengths of 13 m in the Atlantic species *Physalia physalis*. The nonfeeding dactylozooids also bear one long (unbranched) tentacle. The gonozooids are usually branched; they produce sessile gonophores that are never released as free medusae.

Siphonophores use one or more swimming bells (**nectophores**) or a gas-filled float (a **pneumatophore**), or both, to help maintain their position in the water.

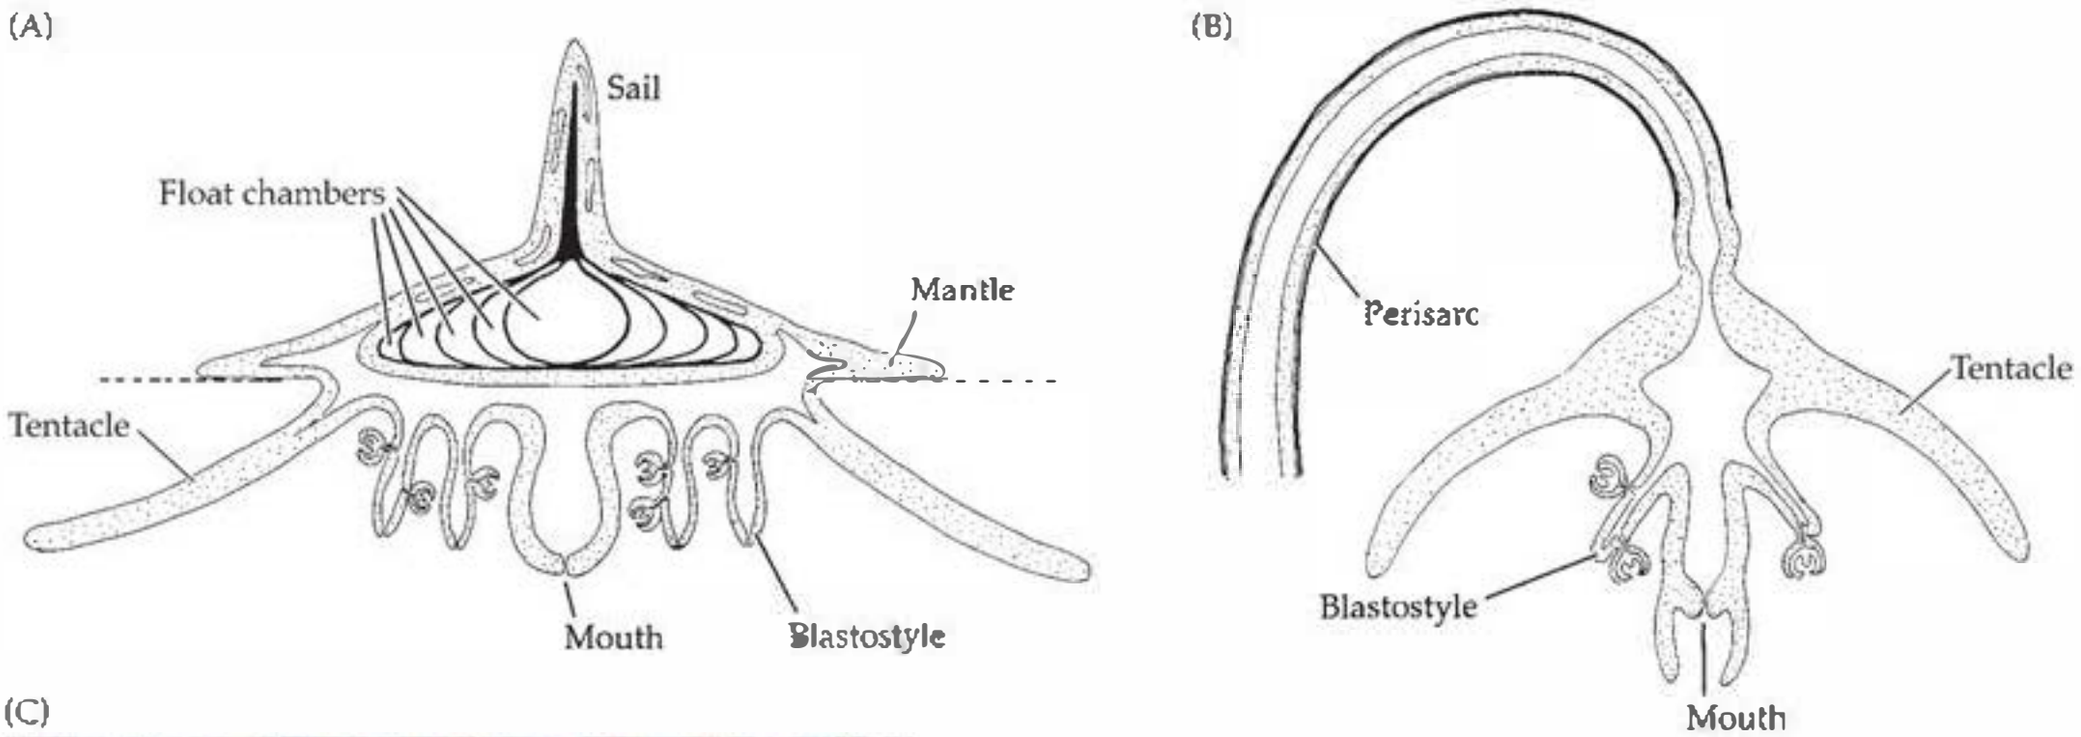
Nectophores are true medusoid individuals with many of the structures common to free-swimming medusae, although each nectophore has lost its mouth, tentacles, and sense organs. The pneumatophore, once also thought to be a modified medusa, is now known to be derived directly from the larval stage and probably represents a highly modified polyp. Pneumatophores are double-walled chambers lined with chitin. Each float houses a gas gland, which consists of a mitochondria-laden glandular epithelium lining a chamber. The gland secretes a gas usually similar to air in composition, although in *Physalia* it apparently includes a surprisingly high proportion of carbon monoxide. Many siphonophores have mechanisms by which they regulate gas in their floats to keep the colony at a particular depth, much like the swim bladders of fishes.

Siphonophores were formerly classified into three suborders on the basis of colony structure: the Calycophora included colonies with swimming bells but no float; Physonecta included those with a small float and a long train of swimming bells; and Cystonecta had a large float and no bell. However, recent molecular evidence suggests that the Cystonecta are basal to other siphonophores, with the monophyletic Calyphora and the paraphyletic Physonecta grouped for now within the suborder Codonophora. Calycophorans have a long tubular stem extending from the swimming bell, from which various types of zooids bud in groups called **cormidia** (Figure 7.8H). Each cormidium acts as a colony-within-a-colony, and is usually composed of a shieldlike bract, a gastrozooid, and one or more gonophores that may function as swimming bells. The cormidia commonly break loose from the parent colony to live an independent existence, at which time they are termed **eudoxids**. The physonectans have an apical float with a long stem bearing a series of nectophores followed by a long train of cormidia. The cystonectans, including *Physalia*, usually have a large pneumatophore with a prominent budding zone at its base, which produces the various polyps and medusoids (Figure 7.8F).

Within the hydrozoan suborder Capitata, a group formerly known as the "chondrophora" is composed of colorful oceanic organisms that drift about on the sea surface in enormous flotillas, occasionally washing ashore to coat the beach with their bluish-purple bodies (Figures 7.1D and 7.10). Although they superficially resemble some siphonophores, current opinion holds these animals to be large, solitary, athecate hydranth polyps, floating upside down instead of sitting on a stalk attached to the bottom. The aberrant medusae of chondrophorans are short-lived and do not possess a functional mouth or gut, probably relying instead on their symbiotic zooxanthellae for nutrition. The aboral sail in *Velella* (the "by-the-wind-sailor") has no counterpart in sessile hydroids. In its ability to sail at an angle to the wind, *Velella* resembles the siphonophore *Physalia*, a similarity attributed to convergent evolution. Figure 7.10 compares a chondrophoran and a sessile hydroid, such as *Tubularia* or *Corymorpha*.

The apparent polyps of *Polypodium hydriforme* (the only species in the bizarre class Polypoidozoa) exist intracellularly within the ova of their fish hosts as an



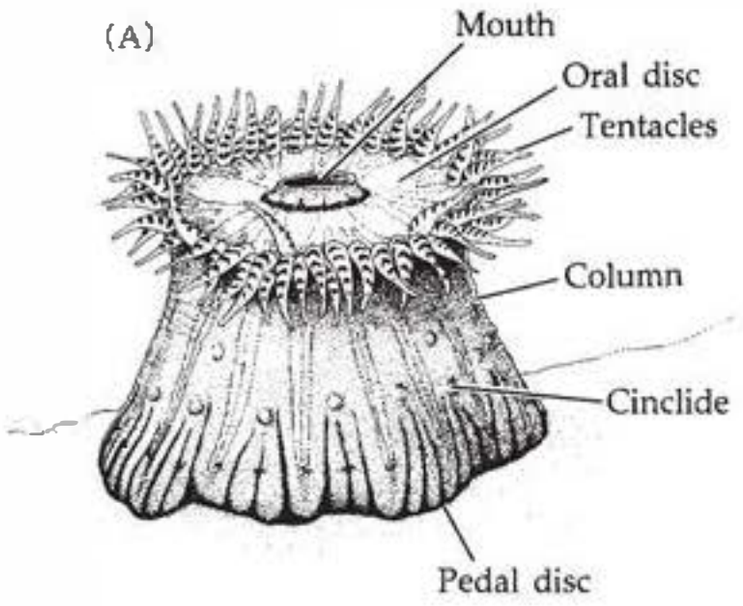


Figure 7.10 (A) A capitate hydrozoan such as Velella compared with (B) a sessile tubularian hydranth, in support of the view that "chondrophorans" are highly specialized, solitary tubularian zooids. (C) *Velella* skeletons in beach wrack, coast of Washington.

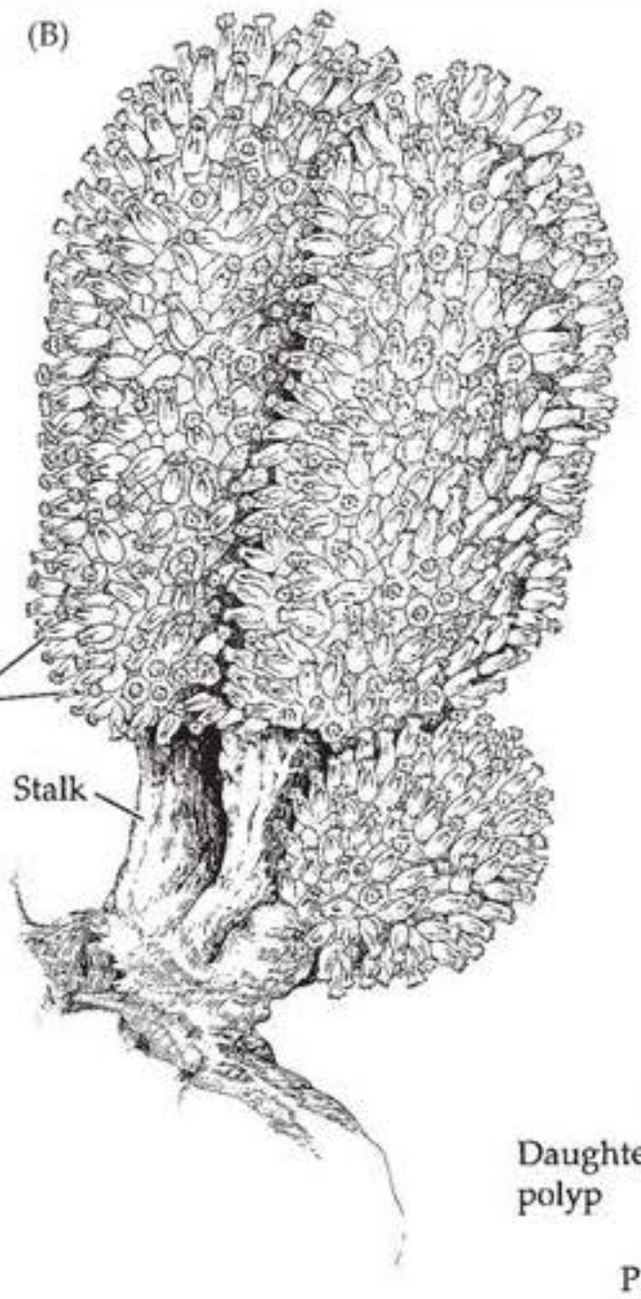
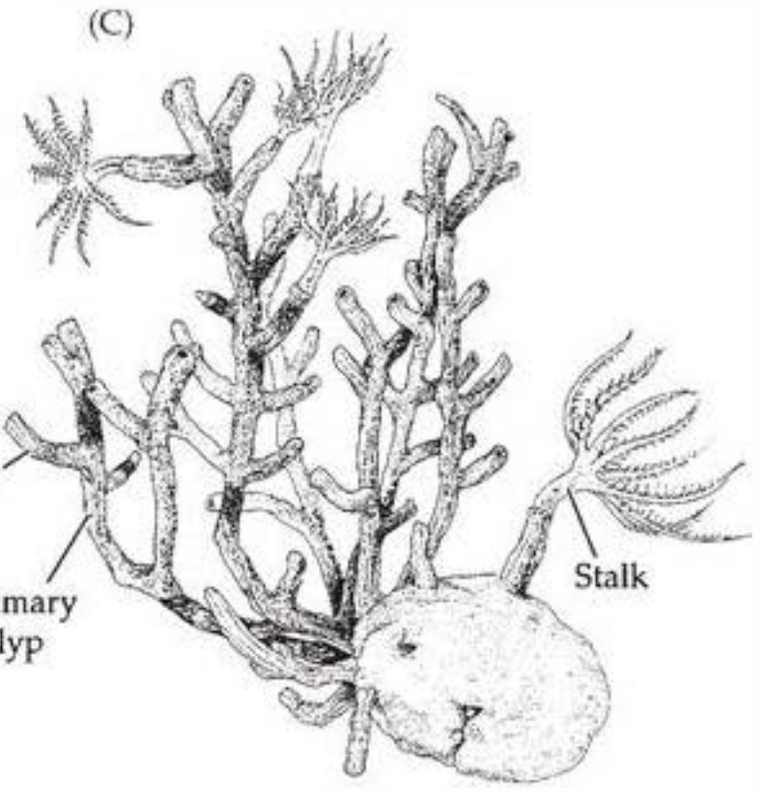
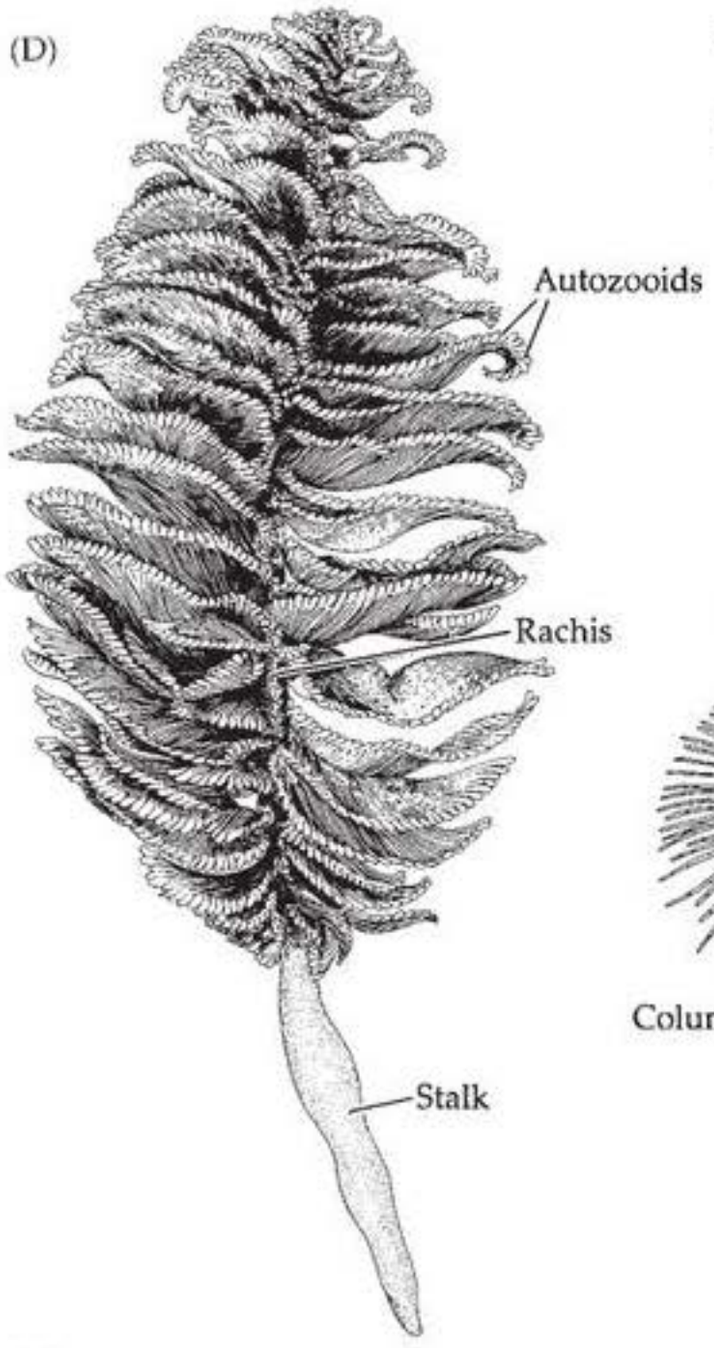


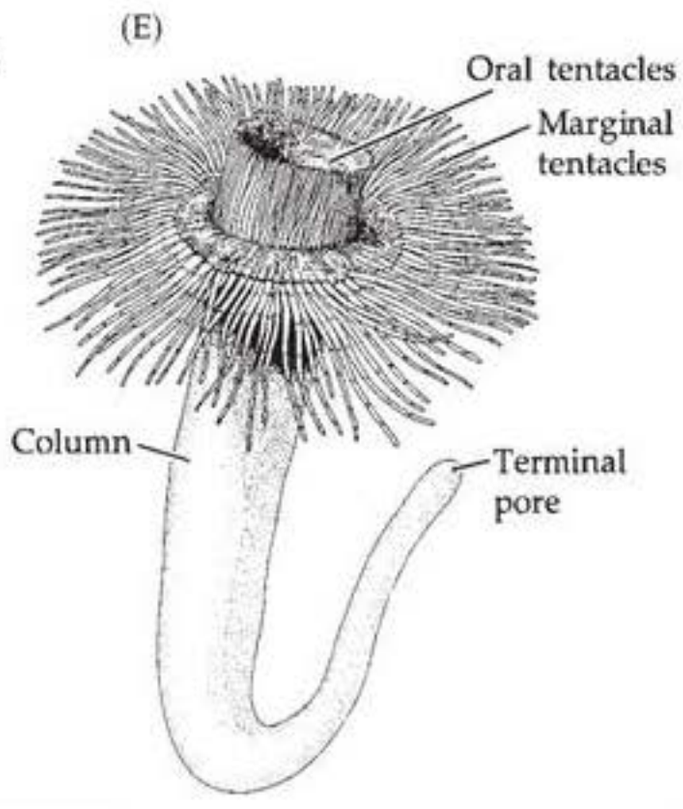
inverted stolon whose digestive surface faces outward. Prior to host spawning when ova are provisioned with yolk, *Polypodium* everts to assume normal cell layer position, filling its gastric cavity with host yolk and revealing tentacles distributed along the stolon's length.



The pennatulaceans are the sea pens and sea pansies, and these are the most complex and polymorphic members of the class Anthozoa (Figure 7.1C,E and 7.11D,F). The colony is built around a main supportive stem, which is actually the primary polyp and buds lateral polyps in a regular fashion. The base of the primary polyp (the peduncle) is anchored in sediment, but the upper, exposed portion (the rachis) produces polyps in whorls or rows, or sometimes united in crescent-shaped "leaves." Often these polyps are of two distinct types. Autozooids bear tentacles and function in feeding; siphonozooids are small, have reduced tentacles, and serve to create water currents through the colony. In sea pens the rachis is elongated and cylindrical; in sea pansies it is flattened and shaped like a large leaf (Figure 7.1E). In the odd deep-sea genus *Umbellula*, the secondary polyps radiate outward to give the colony the appearance of a pinwheel set on the end of a tall narrow stalk. The first deep benthic photos of *Umbellula* had biologists scratching their heads for years, wondering to which phylum this preposterous creature might belong.



Gorgonians are also colonial anthozoans (Figures 7.1D and 7.12). Some grow in bushy shapes, whereas others are planar; size and shape of the colony are often mediated by the hydrodynamics of prevailing surge and currents. Where prevailing currents are more or less in one plane (although they may move in two directions back and forth), the branches of the colony tend to grow largely in one plane also—perpendicular to the flow. In regions of mixed currents, the same species tends to grow in two planes.



The medusoid form Free medusae occur only in the subphylum Medusozoa. Although variation in form exists, medusae are far less diverse than polyps and it is much easier to generalize about their anatomy. (After reading about the amazing variation in polypoid colonies, you're probably happy to hear this!) The relative uniformity of medusae is largely a result of their usually similar lifestyles in open water, and of their inability to form colonies by asexual reproduction. They are participants in colonial life only insofar as some remain attached to hydrozoan colonies to function as sessile gonophores. Sessile benthic medusae exist, but are rare (Figure 7.1F). Despite their simplicity relative to polypoid forms, medusae do vary considerably in size, ranging from 2.0 mm diameter hydromedusae to 2.0 m scyphomedusae, and depending on their habitat can exhibit particular morphological specializations associated with movement in a fluid medium. In many medusae each radial canal opens near the ring canal onto the subumbrellar surface by a pore. These are thought to be "excretory pores" for the ejection of wastes and indigestible material that have been seen passing through them. While polyps often represent the vegetative stage of development among cnidarians, most medusae are sexual forms.

Even though the body walls of medusae and polyps are similar and both adhere to the general cnidarian body plan outlined earlier, their gross morphologies are adapted to their very different lifestyles. Medusae are bell-, dish-, or umbrella-shaped, and usually imbued with a thick, jellylike mesogleal layer (hence the name jellyfish, or simply "jellies"). The convex upper (aboral) surface is called the **exumbrella**; the concave lower (oral) surface is the **subumbrella**. The mouth is located in the center of the subumbrella, often suspended on a pendant, tubular extension called the **manubrium**, which is almost always present on hydromedusae (Figure 7.13), but usually reduced or absent in scyphomedusae (Figure 7.14).

The coelenteron or gastrovascular cavity occupies the central region of the umbrella and extends radially in the body via **radial canals**. In most hydromedusae (medusae of the class Hydrozoa), a marginal ring canal within the rim of the bell connects the ends of the radial canals. The presence of four radial canals and of tentacles in multiples of four (in hydromedusae) and the division of the stomach by mesenteries into four gastric pouches (in scyphomedusae) give most jellyfish a quadriradial (= tetramerous) symmetry (Figure 7.3A). Most hydromedusae have a thin circular flap of tissue, the **velum**, within the margin of the bell (Figure 7.13). Such medusae are termed **craspedote**. Those lacking a velum, such as scyphomedusae, are said to be **acraspedote** (Figures 7.14 and 7.15). The medusae of cubozoans possess an independently evolved structure, the **velarium**, which is structurally different but

functionally similar to the hydromedusan velum. As in polyps, the external surfaces of medusae are covered with epidermis, and the internal surfaces (coelenteron and canals) are lined with gastrodermis. The bulky, gelatinous middle layer is either a largely acellular mesoglea or a partly cellular mesenchyme.

Although morphologically similar, diversity within scyphozoan genera may be much greater than previously suspected. Molecular evidence suggests that *Aurelia aurita*, a cosmopolitan semaeostome species often used in invertebrate zoology laboratories to illustrate medusoid structure, may consist of 7 or more distinct species. While morphologically indistinguishable (so far), these genetically distinct populations may have diverged as early as the late Cretaceous (> 65 Ma).

Support

Cnidarians employ a wide range of support mechanisms. Polypoid forms rely substantially on the hydrostatic qualities of the water-filled coelenteron, which is constrained by circular and longitudinal muscles of the body wall. In addition, the mesenchyme may be stiffened with fibers, particularly in the anthozoans. Colonial anthozoans may incorporate bits of sediment and shell fragments onto the column wall for further support. Many colonial hydrozoans produce a flexible, horny perisarc, composed largely of chitin secreted by the epidermis. In medusae, the principal support mechanism is the middle layer, which ranges from a fairly thin and flexible mesoglea to an extremely thick and stiffened fibrous mesenchyme, which may be almost cartilaginous in consistency.

In addition to these soft or flexible support structures, there is an impressive array of hard skeletal structures of three fundamental types: horny or wood-like axial skeletal structures, calcareous sclerites, and massive calcareous frameworks. Horny axial skeletons occur in several groups of colonial anthozoans such as

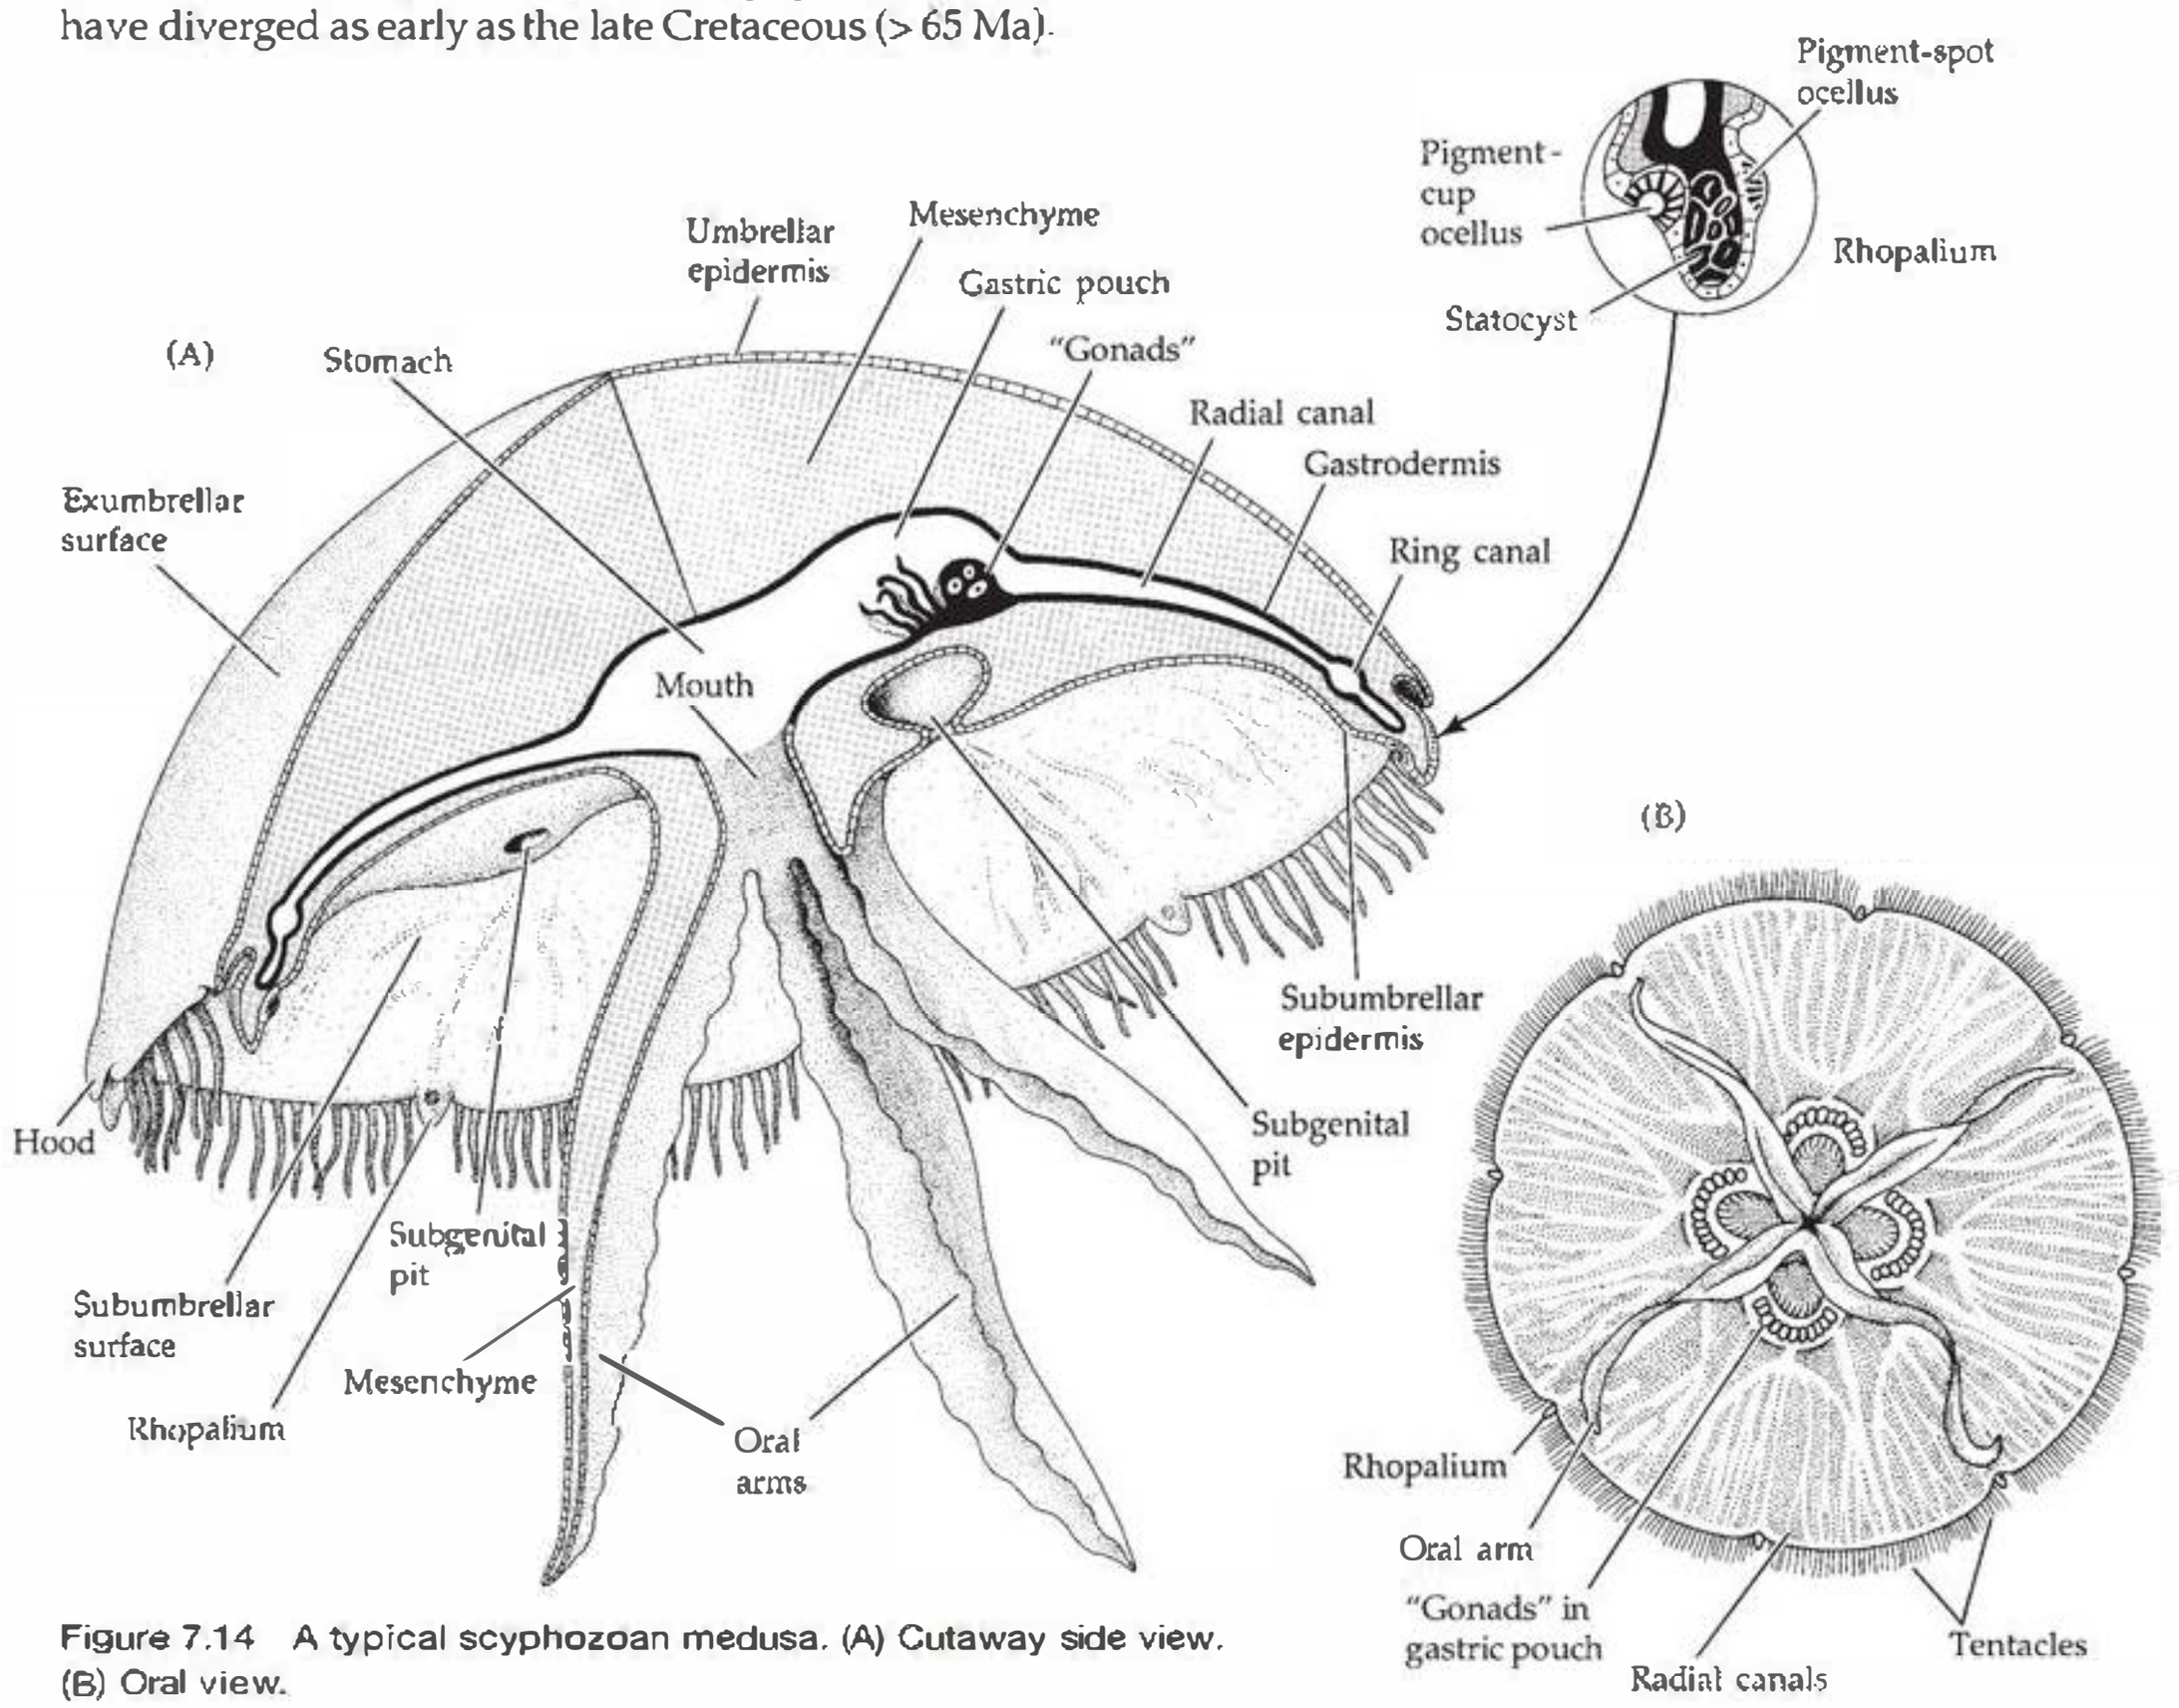

Figure 7.14 A typical scyphozoan medusa. (A) Cutaway side view. (B) Oral view.

gorgonians, sea pens, and antipatharian corals (Figures 7.11 and 7.12). Amebocytes in the coenenchyme secrete a flexible or stiff internal axial rod as a supportive base embedded in the coenenchymal mass. Axial rods are protein–mucopolysaccharide complexes (called **gorgonin** for "gorgonian" corals in the octocoral order Alcyonacea), but little is known of their chemistry. In the antipatharians (black corals), the axial skeleton is so hard and dense that it is ground and polished to make jewelry (leading to a serious over-harvesting of these animals around the world).

In most octocorals, mesenchymal cells called sclerobłasts secrete calcareous sclerites of various shapes and colors (Figure 7.16). It is usually these sclerites that give soft corals and gorgonians their characteristic color and texture. In many species, the sclerites become quite dense and may even fuse to form a more-or-less solid calcareous framework. The precious red coral *Corallium* is actually a gorgonian with fused red coenenchymal sclerites. In the stoloniferan organ-pipe corals (*Tubipora*), the sclerites of the body walls of the individual polyps are fused into rigid tubes. Invertebrate calcium carbonate skeletons do not usually have collagen incorporated into their framework, as occurs in vertebrates. However, in at least some gorgonians (e.g., *Leptogorgia*) the calcareous spicules do include a collagen component.

Massive calcareous skeletons are found in only certain groups of Anthozoa and Hydrozoa. The best known are the stony anthozoan corals (order Scleractinia), in which epidermal cells on the lower half of the column secrete a calcium carbonate skeleton (Figure 7.17). The skeleton is covered by the thin layer of living epidermis that secretes it, and thus it might technically be considered to be an internal skeleton. However, because the stony coral colony generally sits atop a large nonliving calcareous framework, most biologists speak of the skeleton as being external.

The entire skeleton of a scleractinian coral is termed the **corallum**, regardless of whether the animal is solitary or colonial; the skeleton of a single polyp, however, is called a **corallite**. The outer wall of the corallite is the theca; the floor is the basal plate (Figure 7.17). Rising from the center of the basal plate is often a supportive skeletal process called the **columella**. The basal plate and inner thecal walls give rise to numerous radially arranged calcareous partitions, the septa, which project inward and support the mesenteries of the polyp. Polyps occupy only the uppermost surface of the corallum. Skeletal thickness increases as polyps grow, and the bottoms of the corallites are sealed off by transverse calcareous partitions called tabulae, each of which becomes the basal support of a new polyp. The corallum can assume a great variety of shapes and sizes, from simple cup-shaped structures in solitary corals to large branching or encrusting forms in colonial species.

Members of the hydrozoan families Milleporidae (milleporids) and Stylasteridae (stylasterines) also produce calcareous exoskeletons, and they are often

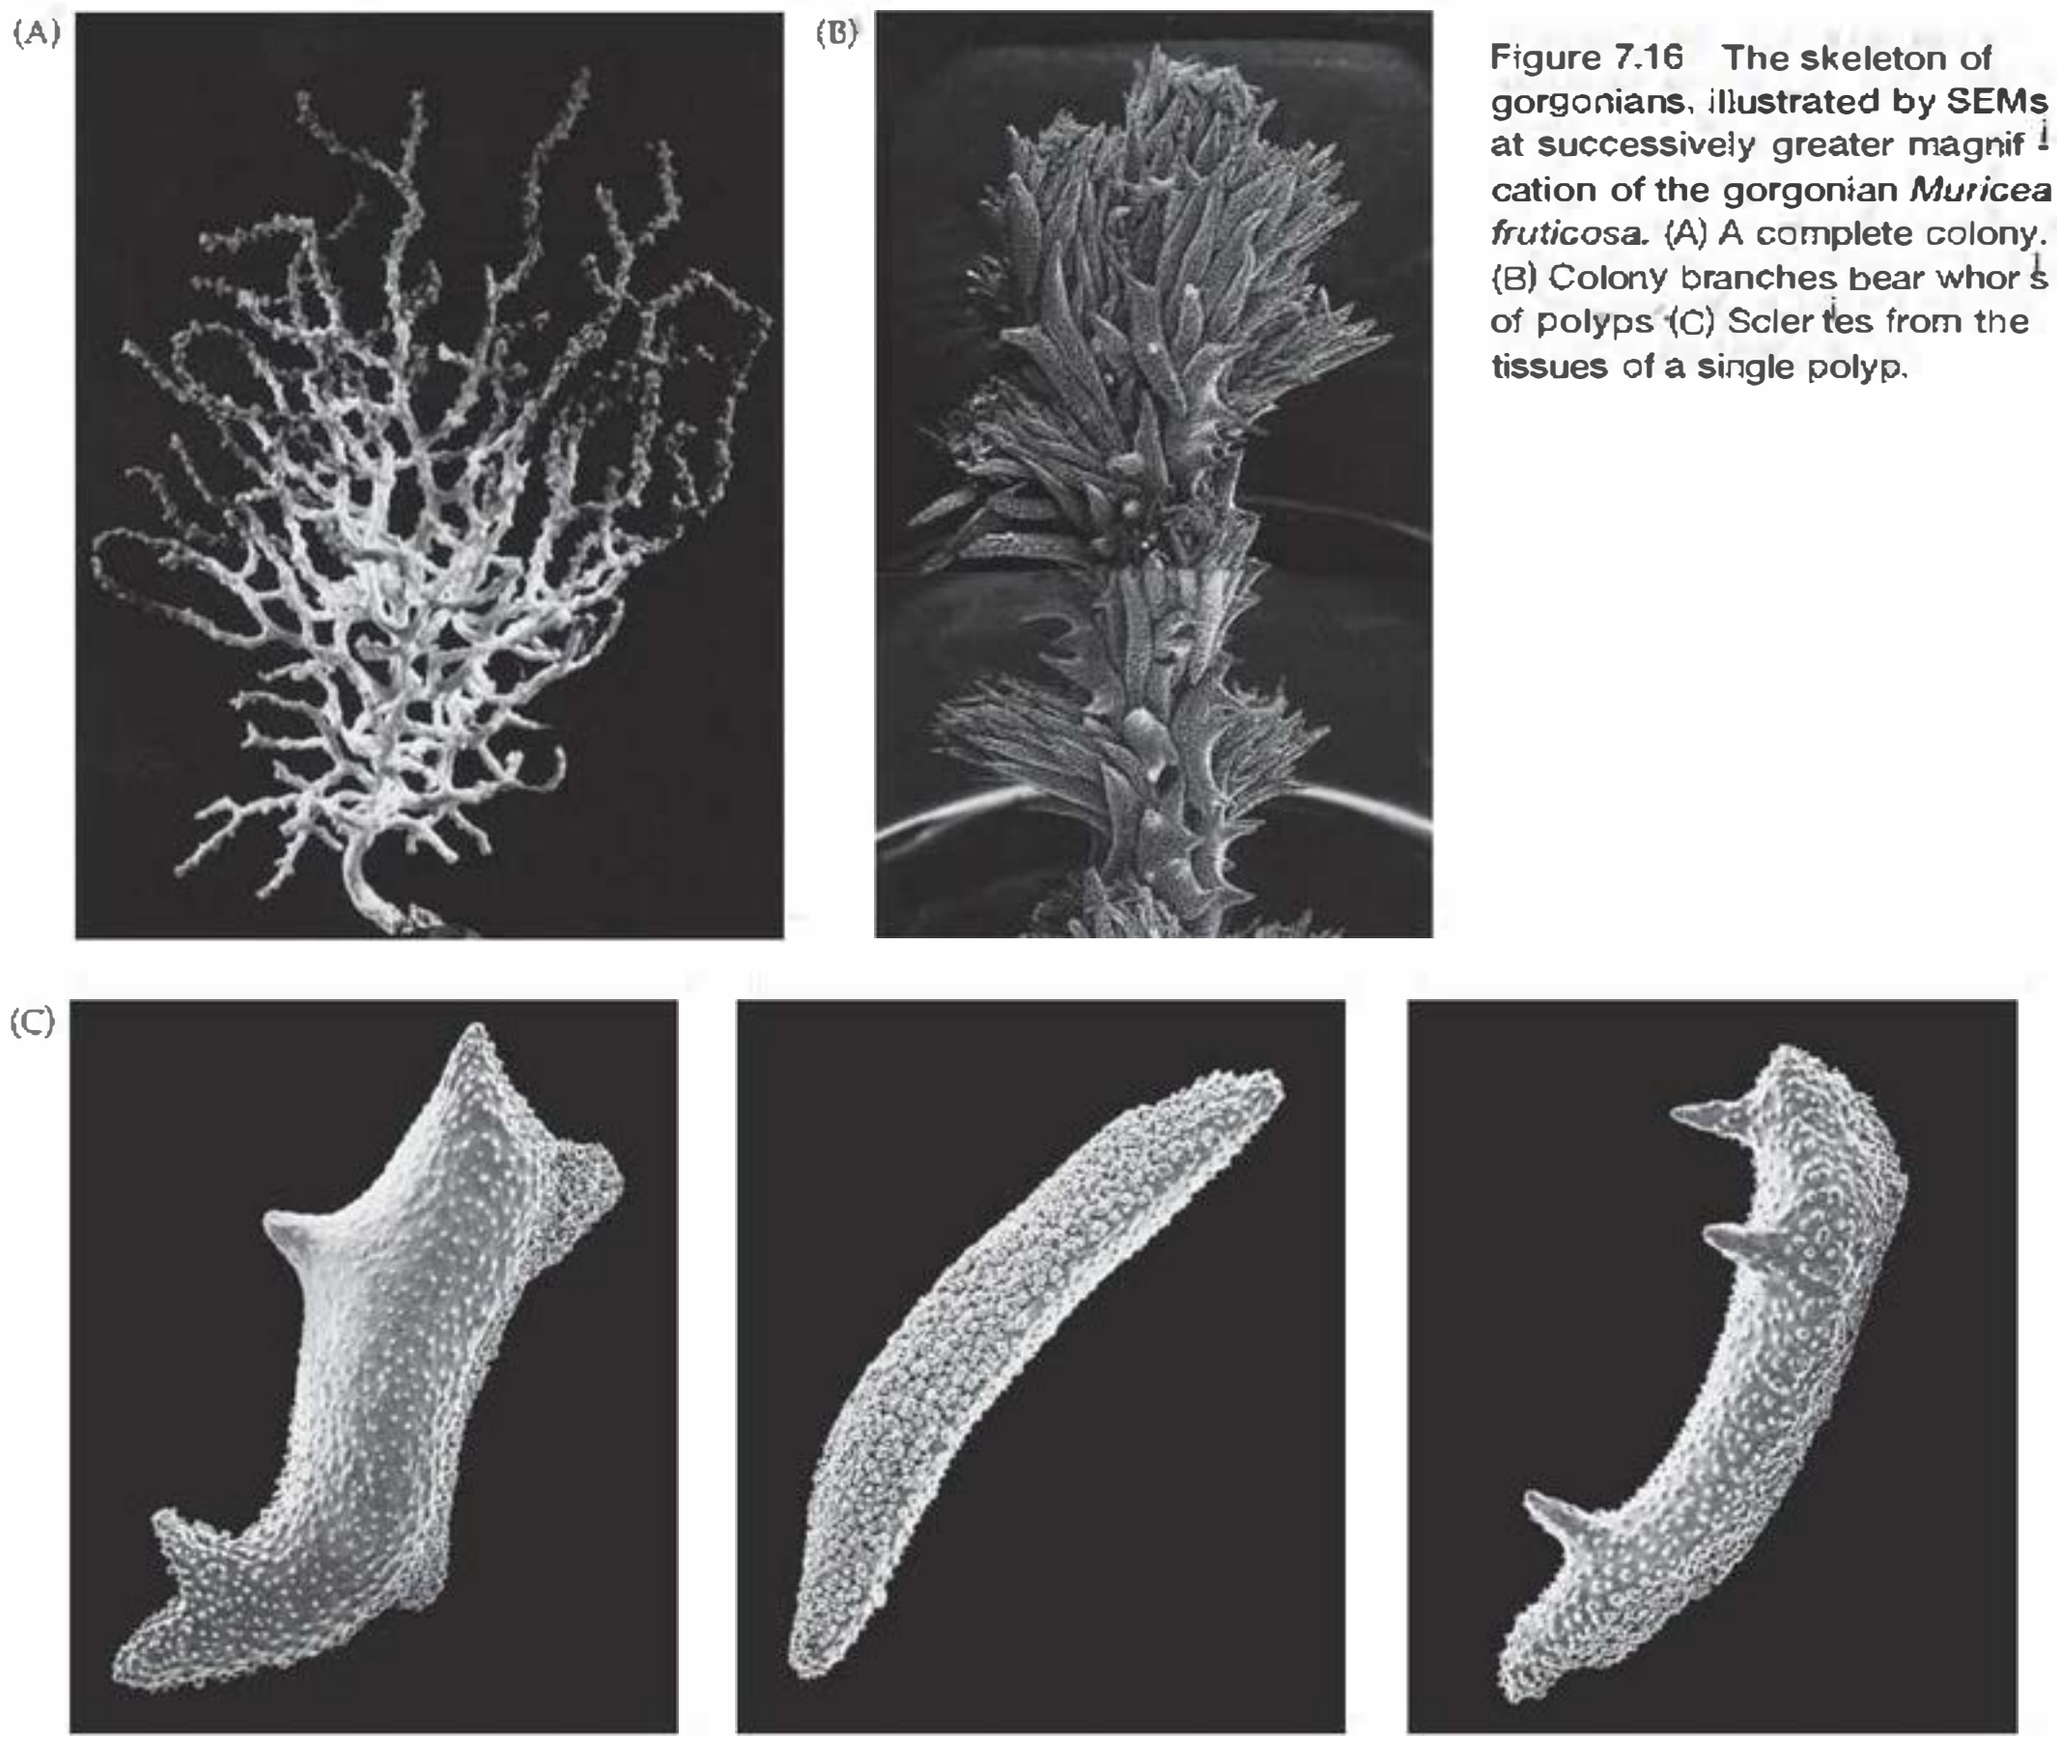

Figure 7.16 The skeleton of gorgonians, illustrated by SEMs at successively greater magnification of the gorgonian *Muricea fruticosa*. (A) A complete colony. (B) Colony branches bear whorls of polyps (C) Sclerites from the tissues of a single polyp.

referred to as the hydrocorals. Like stony corals (Scleractinia), milleporid colonies (fire corals) may assume a variety of shapes, from erect branching forms to encrustations. The milleporid exoskeleton, termed a coenosteum, is perforated by pores of two sizes that accommodate two kinds of polyps (Figure 7.18). The gastrozooids live in large holes, or gastropores, and are surrounded by a circle of smaller dactylopores, which house the dactylozooids. Canals lead downward from the pores into the coenosteum and are closed off below by transverse calcareous tabulae. As growth proceeds and the colony thickens, new tabulae are formed, keeping the polyp pores at a more or less fixed depth. Hydrocoral colonies thus differ from scleractinian colonies in having the skeleton penetrated by living tissue. The stylasterine skeleton is similar to the milleporid skeleton, but the margins of the gastropores often bear notches that serve as dactylopores, and the gastrozooids and dactylozooids are supported by calcareous, spine-like gastrostyles and low ridges called dactylostyles, respectively. Stylasterine gonophores arise in

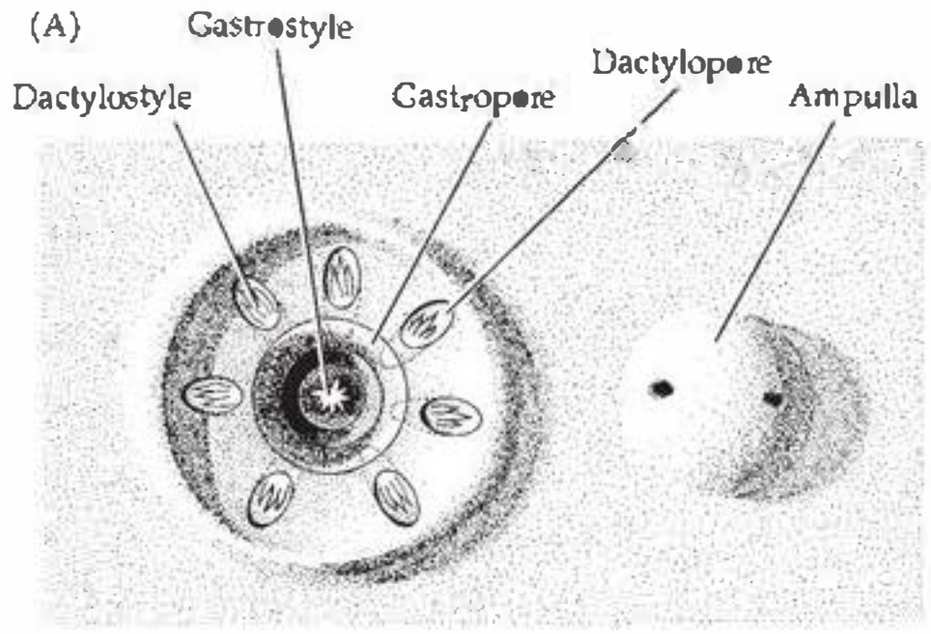

Figure 7.18 Hydrozoan skeletons. The stylasterine hydrocoral *Allopora* has a calcareous skeleton. Plane view, from above (A) and cross section through the skeleton (B).

chambers called **ampullae**, which connect to the feeding zooids through the coenosteum. In hydrocorals such as *Millepora*, ampullae open briefly to release large numbers of tiny medusae, which for each coralla (colony) contain either eggs or sperm, as milleporids are gonochoristic.

The calcium carbonate skeletons of cnidarians make them particularly vulnerable to a seldom appreciated outcome of continued carbon emissions and global warming—ocean acidification. Increased atmospheric carbon leads to more CO_2 dissolving into seawater (now estimated to occur at a rate of 1 million tons per hour), a reaction that accelerates with increasing temperature. More dissolved CO_2 reduces the pH of the ocean water, which tends to dissolve and thus destroy the primary building material of coral skeletons, calcium carbonate. Whereas calcification rates on the Great Barrier Reef increased 5.4% between 1900 and 1970, they dropped 14.2% between 1990 and 2005. The shells of echinoderms, molluscs, crustaceans, certain protists, and many other marine species are at similar and alarming risk.

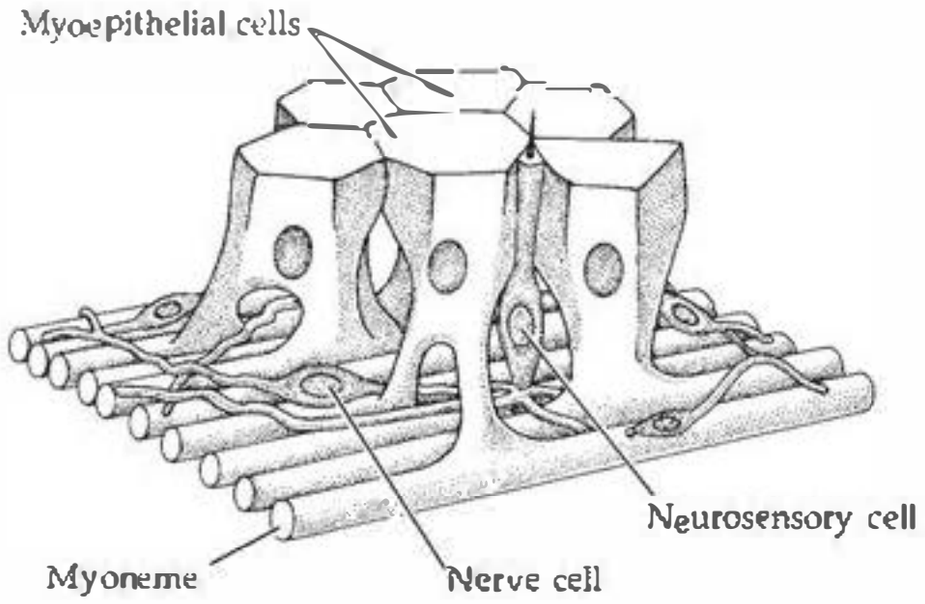

Figure 7.19 Myoepithelial cells and the nerve net of cnidarian epithelium.

Movement

The contractile elements of cnidarians are derived from their myoepithelial cells (Figure 7.19). In spite of the epithelial origin of these elements, for convenience we use the terms "muscles" and "musculature" for the sets of longitudinal and circular fibrils. In polyps, these two muscle systems work in conjunction with the gastrovascular cavity as an efficient hydrostatic skeleton, as well as providing a means of movement. However, unlike the fixed-volume hydrostatic skeletons of many animals (e.g., many worms), water can enter and leave the coelenteron of cnidarians, adding to its versatility as a support device. Polyp body musculature is most highly specialized and well developed in the anthozo-

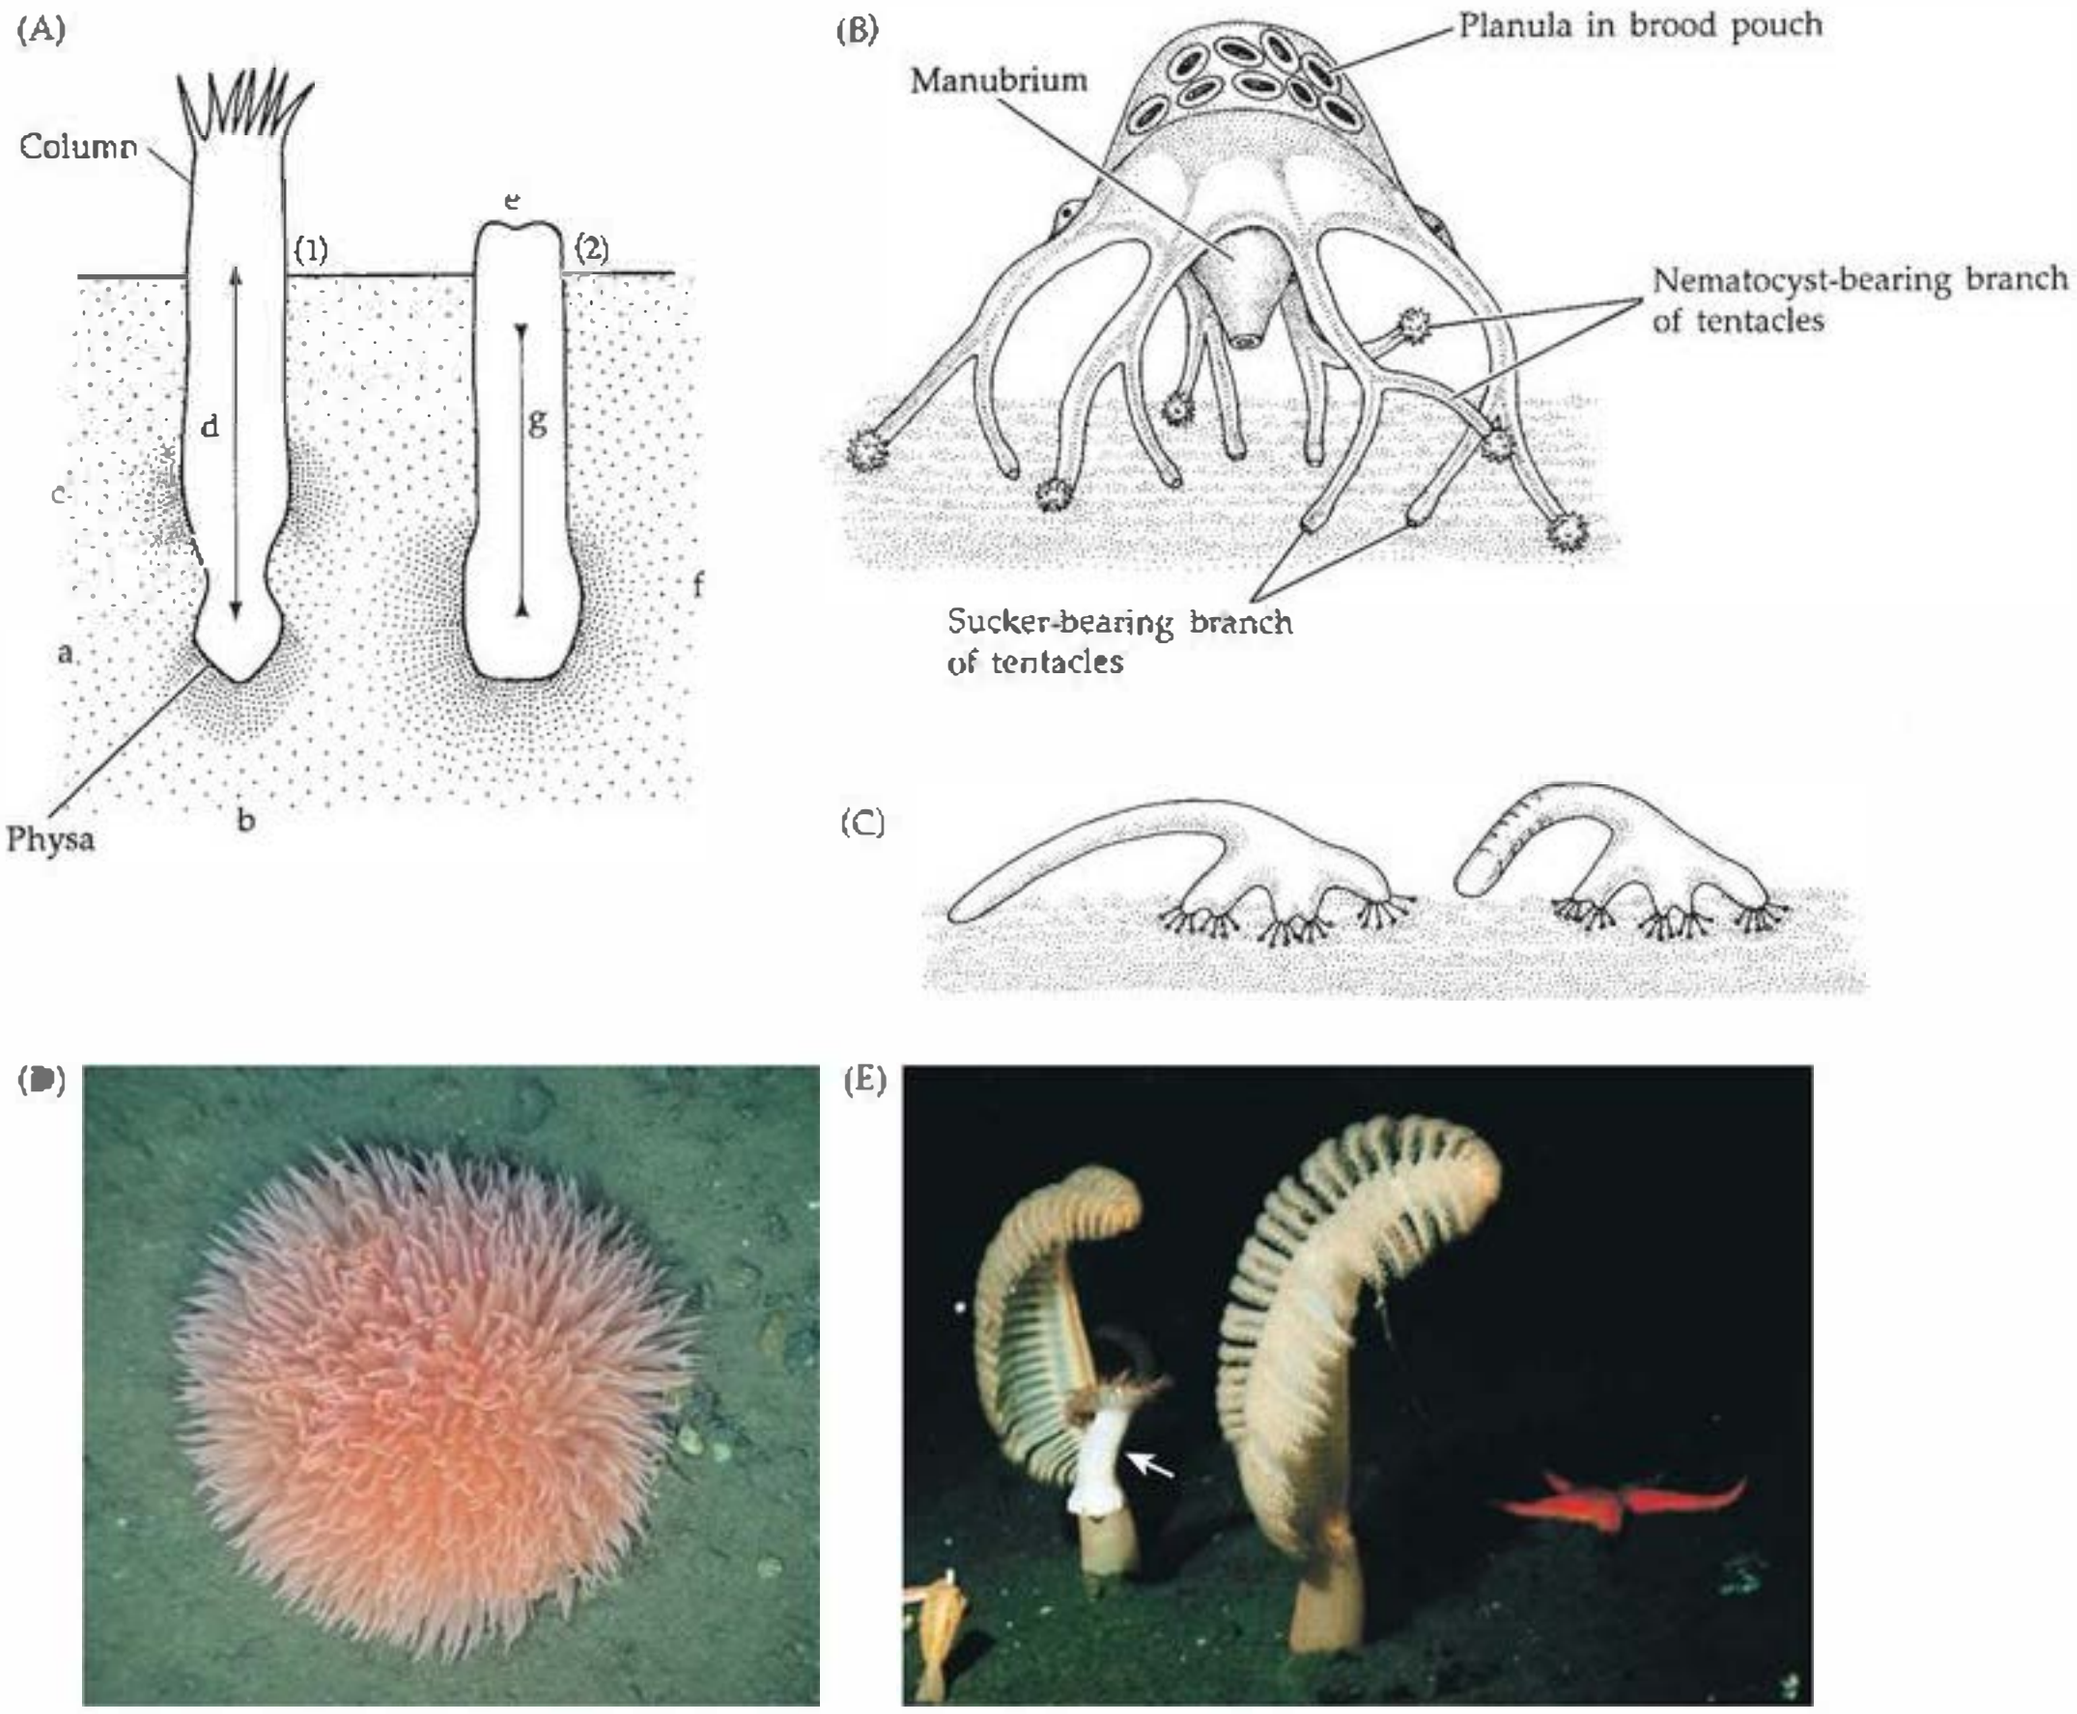

Figure 7.21 Benthic locomotion in some cnidarians. (A) A sea anemone burrowing: (1) eversion of the physa with displacement of sand (a) and further penetration (b) into substratum; the anemone is held by a column anchor (c) as extension (d) follows retraction in (2); with the tentacles folded inward (e), the physa is swollen to form an anchor (f), which allows retractor muscles (g) to pull the anemone into the sand. (B) The hydromedusan *Eleutheria*, which creeps about on its tentacles. (C) The staurozoan *Lucernaria*, which also creeps about on its tentacles. (D) *Liponema brevicornis*, a sea anemone that folds itself into a "ball" and rolls about on the sea floor with the bottom currents. (E) The sea anemone *Stomphia* (white arrow) swimming off the substratum by undulatory back-and-forth contractions of the column—an escape response to the predatory sea star *Gephyreaster swifti*, visible in this photo (Puget Sound, Washington).

ans, particularly the sea anemones, and many muscles lie in the mesenchyme. In anemones, the muscles of the column wall are largely gastrodermal, although epitheliomuscular cells occur in the tentacles and oral disc. Bundles of longitudinal fibers lie along the sides of the mesenteries and act as retractor muscles for shortening the column (Figure 7.20). Circular muscles derived from the gastrodermis of the column wall are also well developed. In most anemones, the circular muscles form a distinct sphincter at the junction of the column and the oral disc. Circular fibers also occur in the tentacles and the oral disc, and circular muscles surrounding the mouth can close it completely. When an anemone contracts, the upper rim of the column is pulled over to cover the oral disc. In many sea anemones, a circular fold—the collar, or parapet—occurs near the sphincter to further cover and protect the delicate oral surface upon contraction.

Most polyps are sedentary or sessile. Their movements consist mainly of food-capturing actions and the withdrawal of the upper portion of the polyp during body contractions. These activities are accomplished primarily by the epidermal muscles of the tentacles and oral disc, and by the strong gastrodermal muscles of the column. Circular muscles work in conjunction with the hydrostatic skeleton to distend the tentacles and body.

A variety of locomotor methods have evolved among polyps (Figure 7.21). Most can creep about slowly by using their pedal disc musculature. In some solitary hydrozoan polyps (e.g., *Hydra*), the column can bend far enough to allow the tentacles to contact and temporarily adhere to the substratum, whereupon

the pedal disc releases its hold and the animal somersaults or moves like an inchworm. Simple polyps like the hydrozoan *Hydra* transfer fluid within their gastrovascular cavity using contractions of the peduncle; these contractions are biochemically mediated by RFamides, chemicals that induce cardiac contraction in higher metazoans, suggesting that muscular contractions in these distantly related taxa might share neurological similarities. A few sea anemones can detach from the substratum and actually swim away by "rapid" flexing or bending of the column (e.g., *Actinostola, Stomphia*); others swim by thrashing the tentacles (e g , *Boloceroides*). These swimming activities are temporary behaviors, generally elicited by the a p proach or contact of a predator. In a few species of sea anemones, the basal disc may detach and secrete a gas bubble, permitting the polyp to float away to a new location.

Many species of small anthozoans can float hang ing upside down on the sea surface by using water surface-tension forces (e g., *Epiactis, Diadumene*). Sea anemones of one family (Minyadidae) are wholly pelagic and float upside down in the sea by means of a gas bubble enclosed within the folded pedal disc. *Hydra* also is known to float upside down by means of a mucus-coated gas bubble on the bottom of its pedal disc. One of the oddest forms of polyp locomotion is that of the sea anemone *Liponema brevicornis* of the Bermg Sea, which is capable of drawing itself into a tight ball that can be rolled around the sea floor by the bottom currents (Figure 7 21 D). Even colonial sea pansies (Pennatulacea) are motile, in that they can use their muscular peduncle to move to different depths on the sea floor.

Most cerianthid anemones are burrowing, tube-building organisms (Figure 7 11E). They differ from the sea anemones (Actiniaria) in several important ways. They have no sphincter muscle, and their weak lon gitudinal gastrodermal muscles d o not form distinct retractors in the mesenteries. As a result, cerianthids cannot retract the oral disc and tentacles as they with draw into their tubes. In contrast to other anemones, however, they possess a complete layer of longitudinal epidermal muscles in the column, which allows a very rapid withdrawal response. The mere shadow of a passing hand will cause a cerianthid to rapidly pull itself deep mto its long, buried tube.

In medusae, epidermal and subepidermal musculatures predominate, and the gastrodermal muscles that are so important in polyps are reduced or lacking The epidermal musculature is best developed around the bell margin and over the subumbrellar surface. Here the muscle fibers usually form circular sheets called coronal muscles that are partly embedded in the mesenchyme or mesoglea. Contractions of the coronal muscles produce rhythmic pulsations of the bell, driving water out from beneath the subumbrella and moving the animal by jet propulsion. The restriction of striated myofibrils to epithelial cells appears to constrain the force with which bell musculature may contract, favoring either small solitary or groups of prolate (streamlined) bells that move by jet propulsion (e.g., Anthoathecata, Trachymedusae, Siphonophora, Cubozoa) or larger, oblate (flattened) bells that move by more gentle contractions of the bell margin, called rowing (e.g., Leptothecata, Narcomedusae, scyphozo an medusae).

The stiffened cellular collenchyme of scyphomedusae and cubomedusae includes elastic fibers that provide the antagonistic force to restore the bell shape between contractions. Many medusae also possess radial muscles that aid in opening the bell between pulses. In craspedote forms, the velum serves to reduce the size of the subumbrellai aperture, thus increasing the force of the water jet (Figure 7.13). The velarium of the fast swimming cubomedusae has the same effect (Figure 7.15A), and the evolutionary forces that produced these two convergent features were probably similar.

Most medusae spend their time swimming upward in the water column, then sinking slowly down to capture prey by chance encounter, thereafter to pulsate upward once again. Some medusae have the ability to change direction as they swim, however, and many are strongly attracted to light (especially those harboring symbiotic zooxanthellae). Medusoid form also appears to correlate with feeding mode. Jet propulsion is associated with ambush foraging by medusa who lie motion less, waiting for motile prey to swim into their tentacles before rapidly consuming the ensnared prey, whereas rowing propulsion is associated with cruising foraging by medusa which swim continuously with tentacles extended to capture slow moving or floating prey At least some medusae house their zooxanthellae in small pockets that remain contracted at night but expand during the day, exposing the algae to light

Medusae can be abundant in certain localities. Some, such as the moon jelly *Aurelia* (Figure 7 22), are known to aggregate at temperature or salinity discon tinuity layers in the sea where they feed on small zooplankters, which also concentrate at these boundaries. Large flotillas of scyphomedusae are sometimes seen at sea (e.g., *Phacellophora* in the eastern Pacific). A few unusual groups of medusae are benthic. Some hydro medusae (e g., *Eleutheria, Gonionemus*) crawl about on algae or sea grasses by adhesive discs on their tentacles (Figure 7.21B). Members of the Class Staurozoa (e.g, *Haliclystus*) develop directly from the stauropolyp stage and affix to algae and other substrata by an aboral adhesive disc (Figure 7.1F). Aggregations are common in scypho and cubomedusae, possibly to enhance feeding or defense. Almost all cubomedusae are tropical to subtropical in their range, but a large temperate

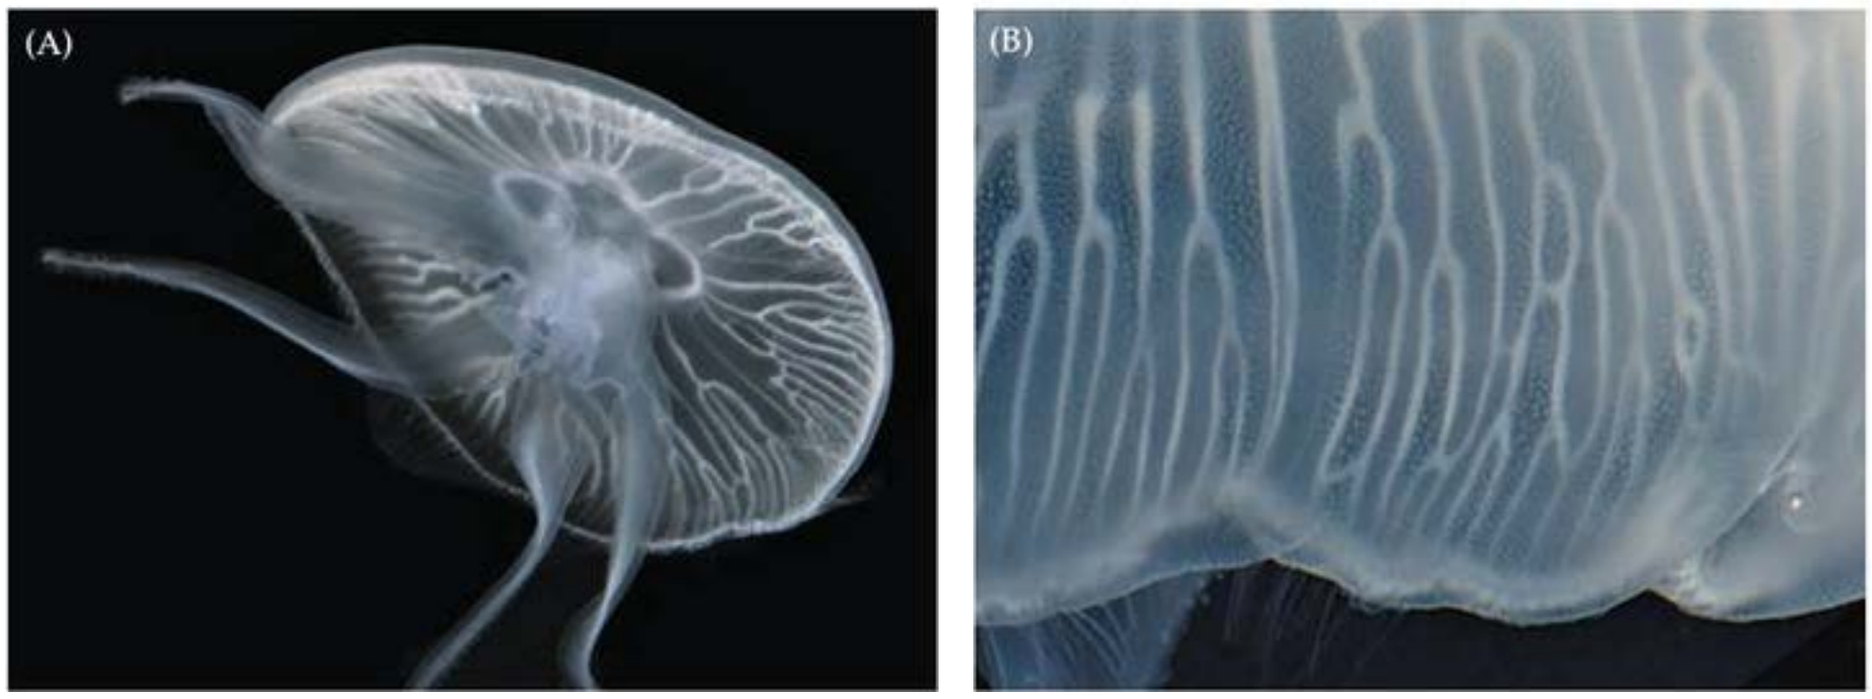

Figure 7.22 The semaeostoman medusa *Aurelia* (moon jellies) often form large swarms. (A) *Aurelia aurita*; notice elongated oral arms. (B) *Aurelia* radial canals and rhopalium.

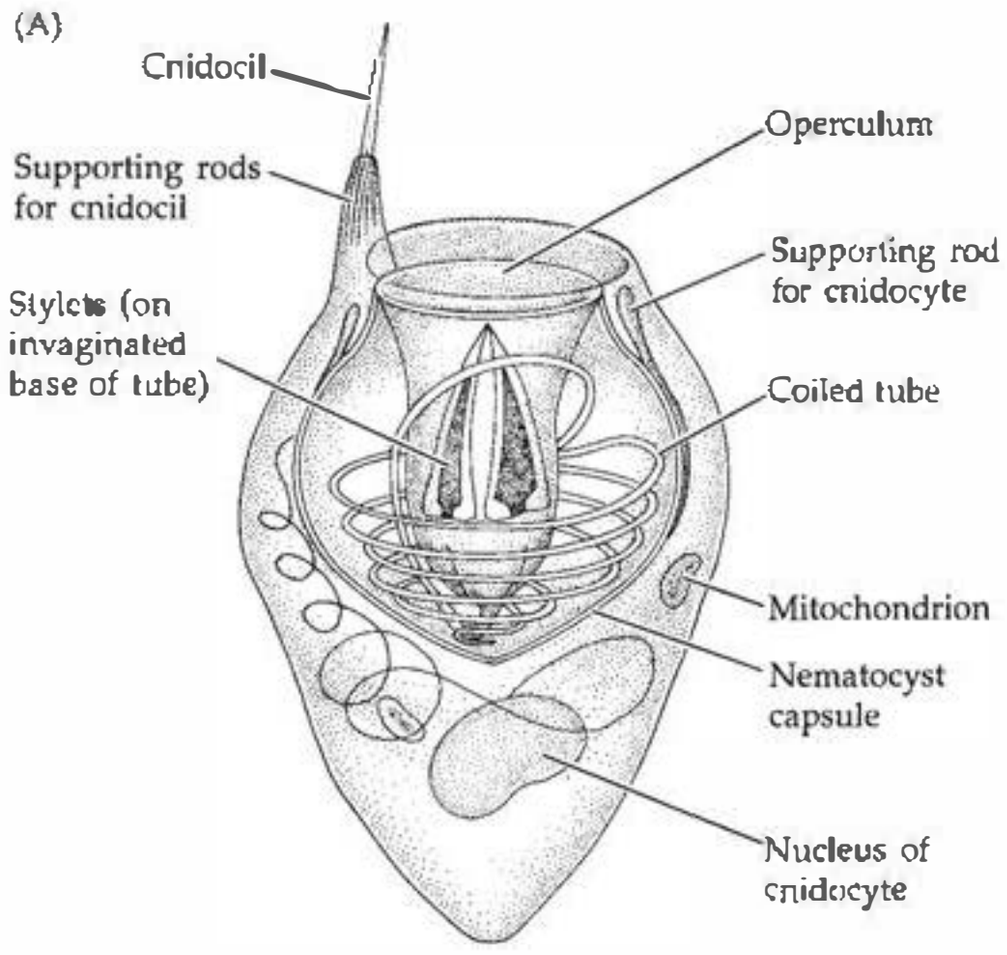
species (*Carybdea branchi*) occurs on the Skeleton Coast of southwestern Africa where it can occur in dense "clouds" of an acre or more across.



Cnidae

Before considering feeding and other aspects of cnidarian biology, it is necessary to present some information on the structure and function of cnidae. Cnidae (sing. cnida), often referred to collectively as "nematocysts" in older works, are unique to the phylum Cnidaria. They have a variety of functions, including prey capture, defense, locomotion, and attachment. They are produced inside cells called **cnidoblasts**, which develop from interstitial cells in the epidermis and, in many groups, also in the gastrodermis. Once the cnida is fully formed, the cell is properly called a cnidocyte. During formation of a cnida, the cnidoblast produces a large internal vacuole in which a complex but poorly understood intracellular reorganization takes place. Cnidae may be complex secretory products of the Golgi apparatus of the cnidoblast. There is also some evidence that cnidae might have originated symbiogenetically from some ancient protist(s), and cnidalike structures have been reported from such diverse groups as dinoflagellates, "sporozoans," and microsporans.

Cnidae are among the largest and most complex intracellular structures known. When fully formed, they are cigar- or flaskshaped capsules, 5–100 μm or more long, with thin walls composed of a collagen-like protein. One end of the capsule is turned inward as a long, hollow, coiled, eversible tubule (Figure 7.23). The outer capsule wall consists of globular proteins of unknown function. The inner wall is composed of bundles of collagen-like fibrils having a spacing of 50–100 nm, with cross striations every 32 nm (in the nematocysts of *Hydra*). The distinct pattern of mini collagen fibers provides the tensile strength necessary to withstand the high pressure in the capsule. The entire structure is anchored to adjacent epithelial cells (supporting cells) or to the underlying mesenchyme.

When sufficiently stimulated, the tube everts from the cell. In members of the classes Hydrozoa, Scyphozoa, and perhaps Cubozoa, the capsule is covered by a hinged lid, or operculum, which is thrown open when the cnida discharges. In members of these three classes, each cnida bears a long cilium-like bristle called a **cnidocil**, a mechanoreceptor that elicits discharge when stimulated. The cnidocil responds to specific water-borne vibration frequencies. Anthozoan cnidae lack a cnidocil and have a tripartite apical flap instead of an operculum (anthozoan cnidae are only spirocysts and ptychocysts). Cnidocytes are most abundant in the epidermis of the oral region and the tentacles, where they often occur in clusters of wartlike structures called **nematocyst batteries**.

About 30 kinds of cnidae have been described (Figures 7.24 and 7.25). Combinations of cnida types, called **cnidomes**, occur in recognizable taxonomic patterns within Cnidaria, and these have had limited usefulness in analyzing phylogenetic patterns in the phylum. However, cnidae more or less sort out as three basic types. True nematocysts have double-walled capsules containing a toxic mixture of phenols and proteins. The tubule of most types is armed with spines or barbs that aid in penetration of and anchorage in the victim's flesh. The toxin is injected into the victim through a terminal pore in the thread or is carried into the wound on the tubule surface. Spirocysts have single-walled capsules containing mucoprotein or glycoprotein. Their adhesive tubules wrap around and stick to the victim rather than penetrating it. The capsule tubules of spirocysts never have an apical pore. Nematocysts occur in members of all cnidarian classes except within the Myxozoa (although polar capsules appear to be homologous structures, see following paragraph); spirocysts occur only in the Hexacorallia.

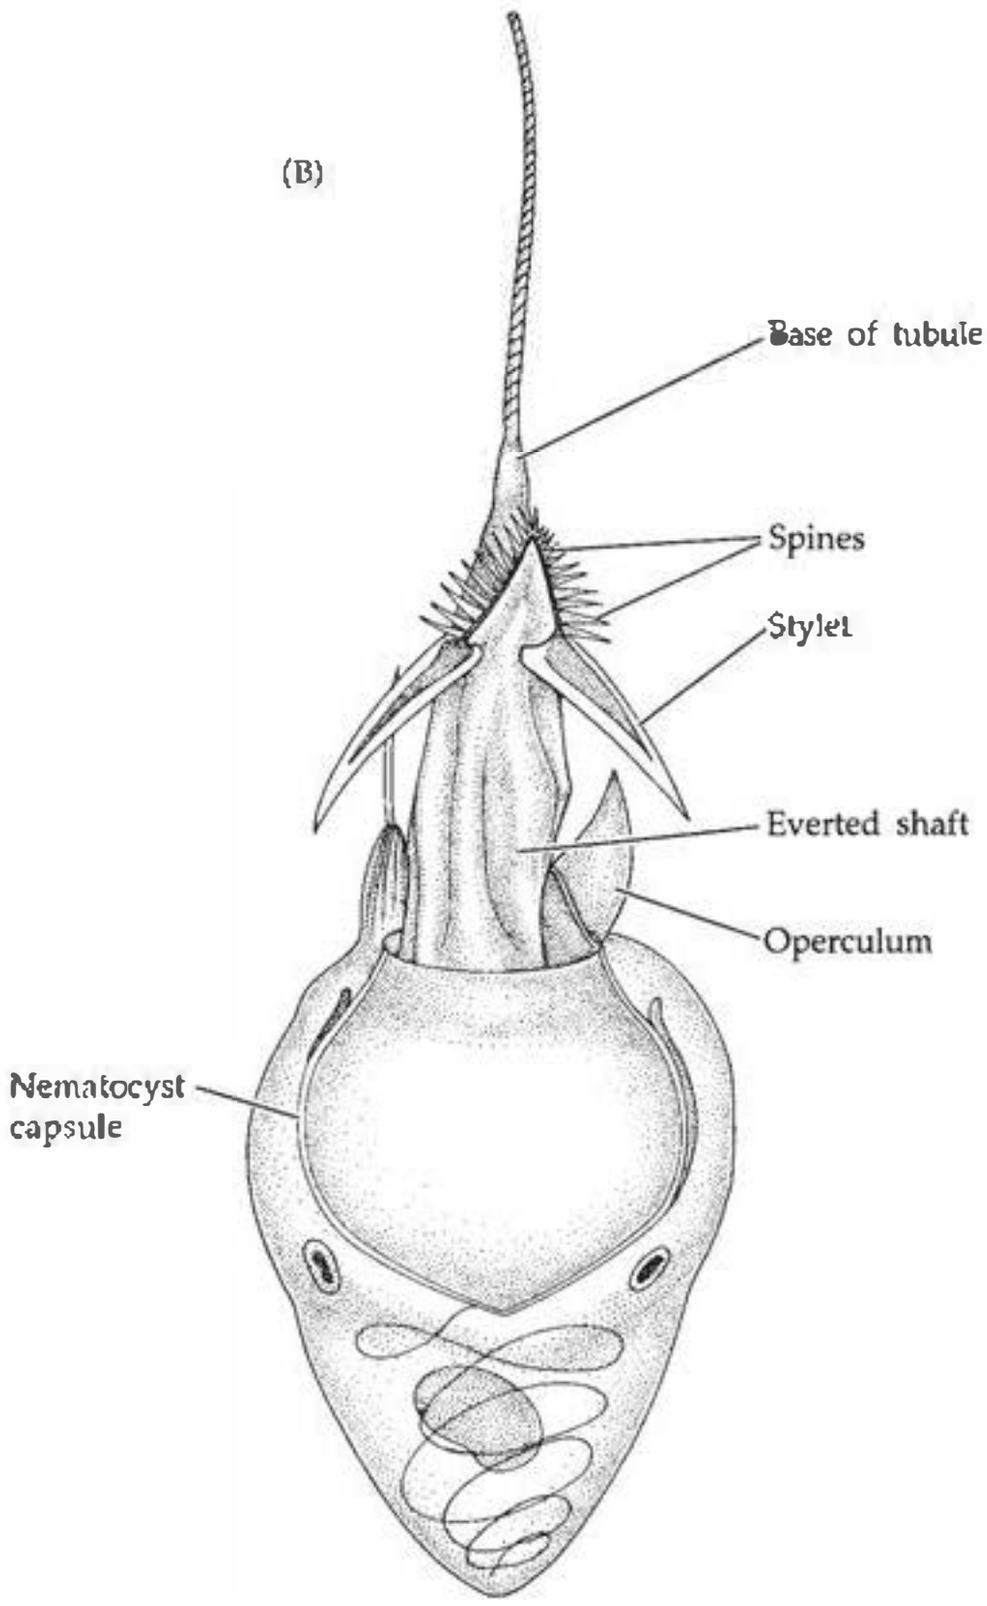


Figure 7.23 Nematocyst. (A) Before discharge. (B) After discharge.

The third kind of cnidae, the **ptychocyst**, differs morphologically and functionally from both nematocysts and spirocysts. The capsule tubule of a ptychocyst lacks spines and an apical pore and is strictly adhesive in nature. In addition, the tubule is folded into pleats rather than coiled within the capsule. Ptychocysts occur only in the cerianthids and function in forming the unique tube in which these animals reside.

The polar capsules of myxozoans are now widely viewed as homologous to other cnidarian cnidae, although they are simpler in form. Polar capsules are found in both myxosporean and actinosporean life stages of myxozoans. The capsules consist of a thick capsular wall; an eversible hollow filament that is spiraled along its length, may vary in length (up to 10× the length of the capsule) and is contiguous with the capsule; and a stopper-like structure that covers the inverted filament at its base. A variety of substances have been explored as possible inducers of polar filament extrusion and, like cnidae, polar capsules appear to be sensitive to pressure, extreme pH and K^+ concentrations. However, no consistent physical or chemical cue responsible for extrusion appears to exist across most taxa.

Cnidae have usually been viewed as independent effectors, and, indeed, they often discharge upon direct stimulation. However, experimental evidence suggests that the animals do have at least some control of the action of their cnidae. For example, starved anemones seem to have a lower firing threshold than satiated animals. It has also been demonstrated that stimulating discharge of cnidae in one area of the body results in discharge in surrounding areas. Still, either chemical and/or mechanical stimuli, initially perceived by the cnidocil or a similar structure, cause most cnidae to fire. Cnidarians are known to discharge their cnidae in the presence of various sugars and low-molecular-weight amino compounds.

The rapid protrusion of the tubule from a cnida is called exocytosis, and an individual cnida can be fired only once. Three hypotheses have been proposed to explain the mechanism of firing: (1) the discharge is the result of increased hydrostatic pressure caused by a rapid influx of water (the osmotic hypothesis); (2) intrinsic tension forces generated during cnidogenesis are released at discharge (the tension hypothesis); and (3) contractile units enveloping the cnida cause the discharge by "squeezing" the capsule (the contractile hypothesis). Because of the small size of cnidae and the extreme speed of the exocytosis process, these hypotheses have been difficult to test. Recent work using ultra high-speed microcinematography suggests that both the osmotic and tension models may be at work, and that capsules have very high internal pressures. The coiled capsular tubule is forcibly everted and thrown out of the bursting cell to penetrate or wrap around a portion of the unwary victim. It takes only a few milliseconds for the cnida to fire, and the everting tubule may reach a velocity of 2 m/sec—an acceleration force of about 40,000 g—making it one of the fastest cellular processes in nature. The firing mechanism of hydrozoan cnidae is thwarted by

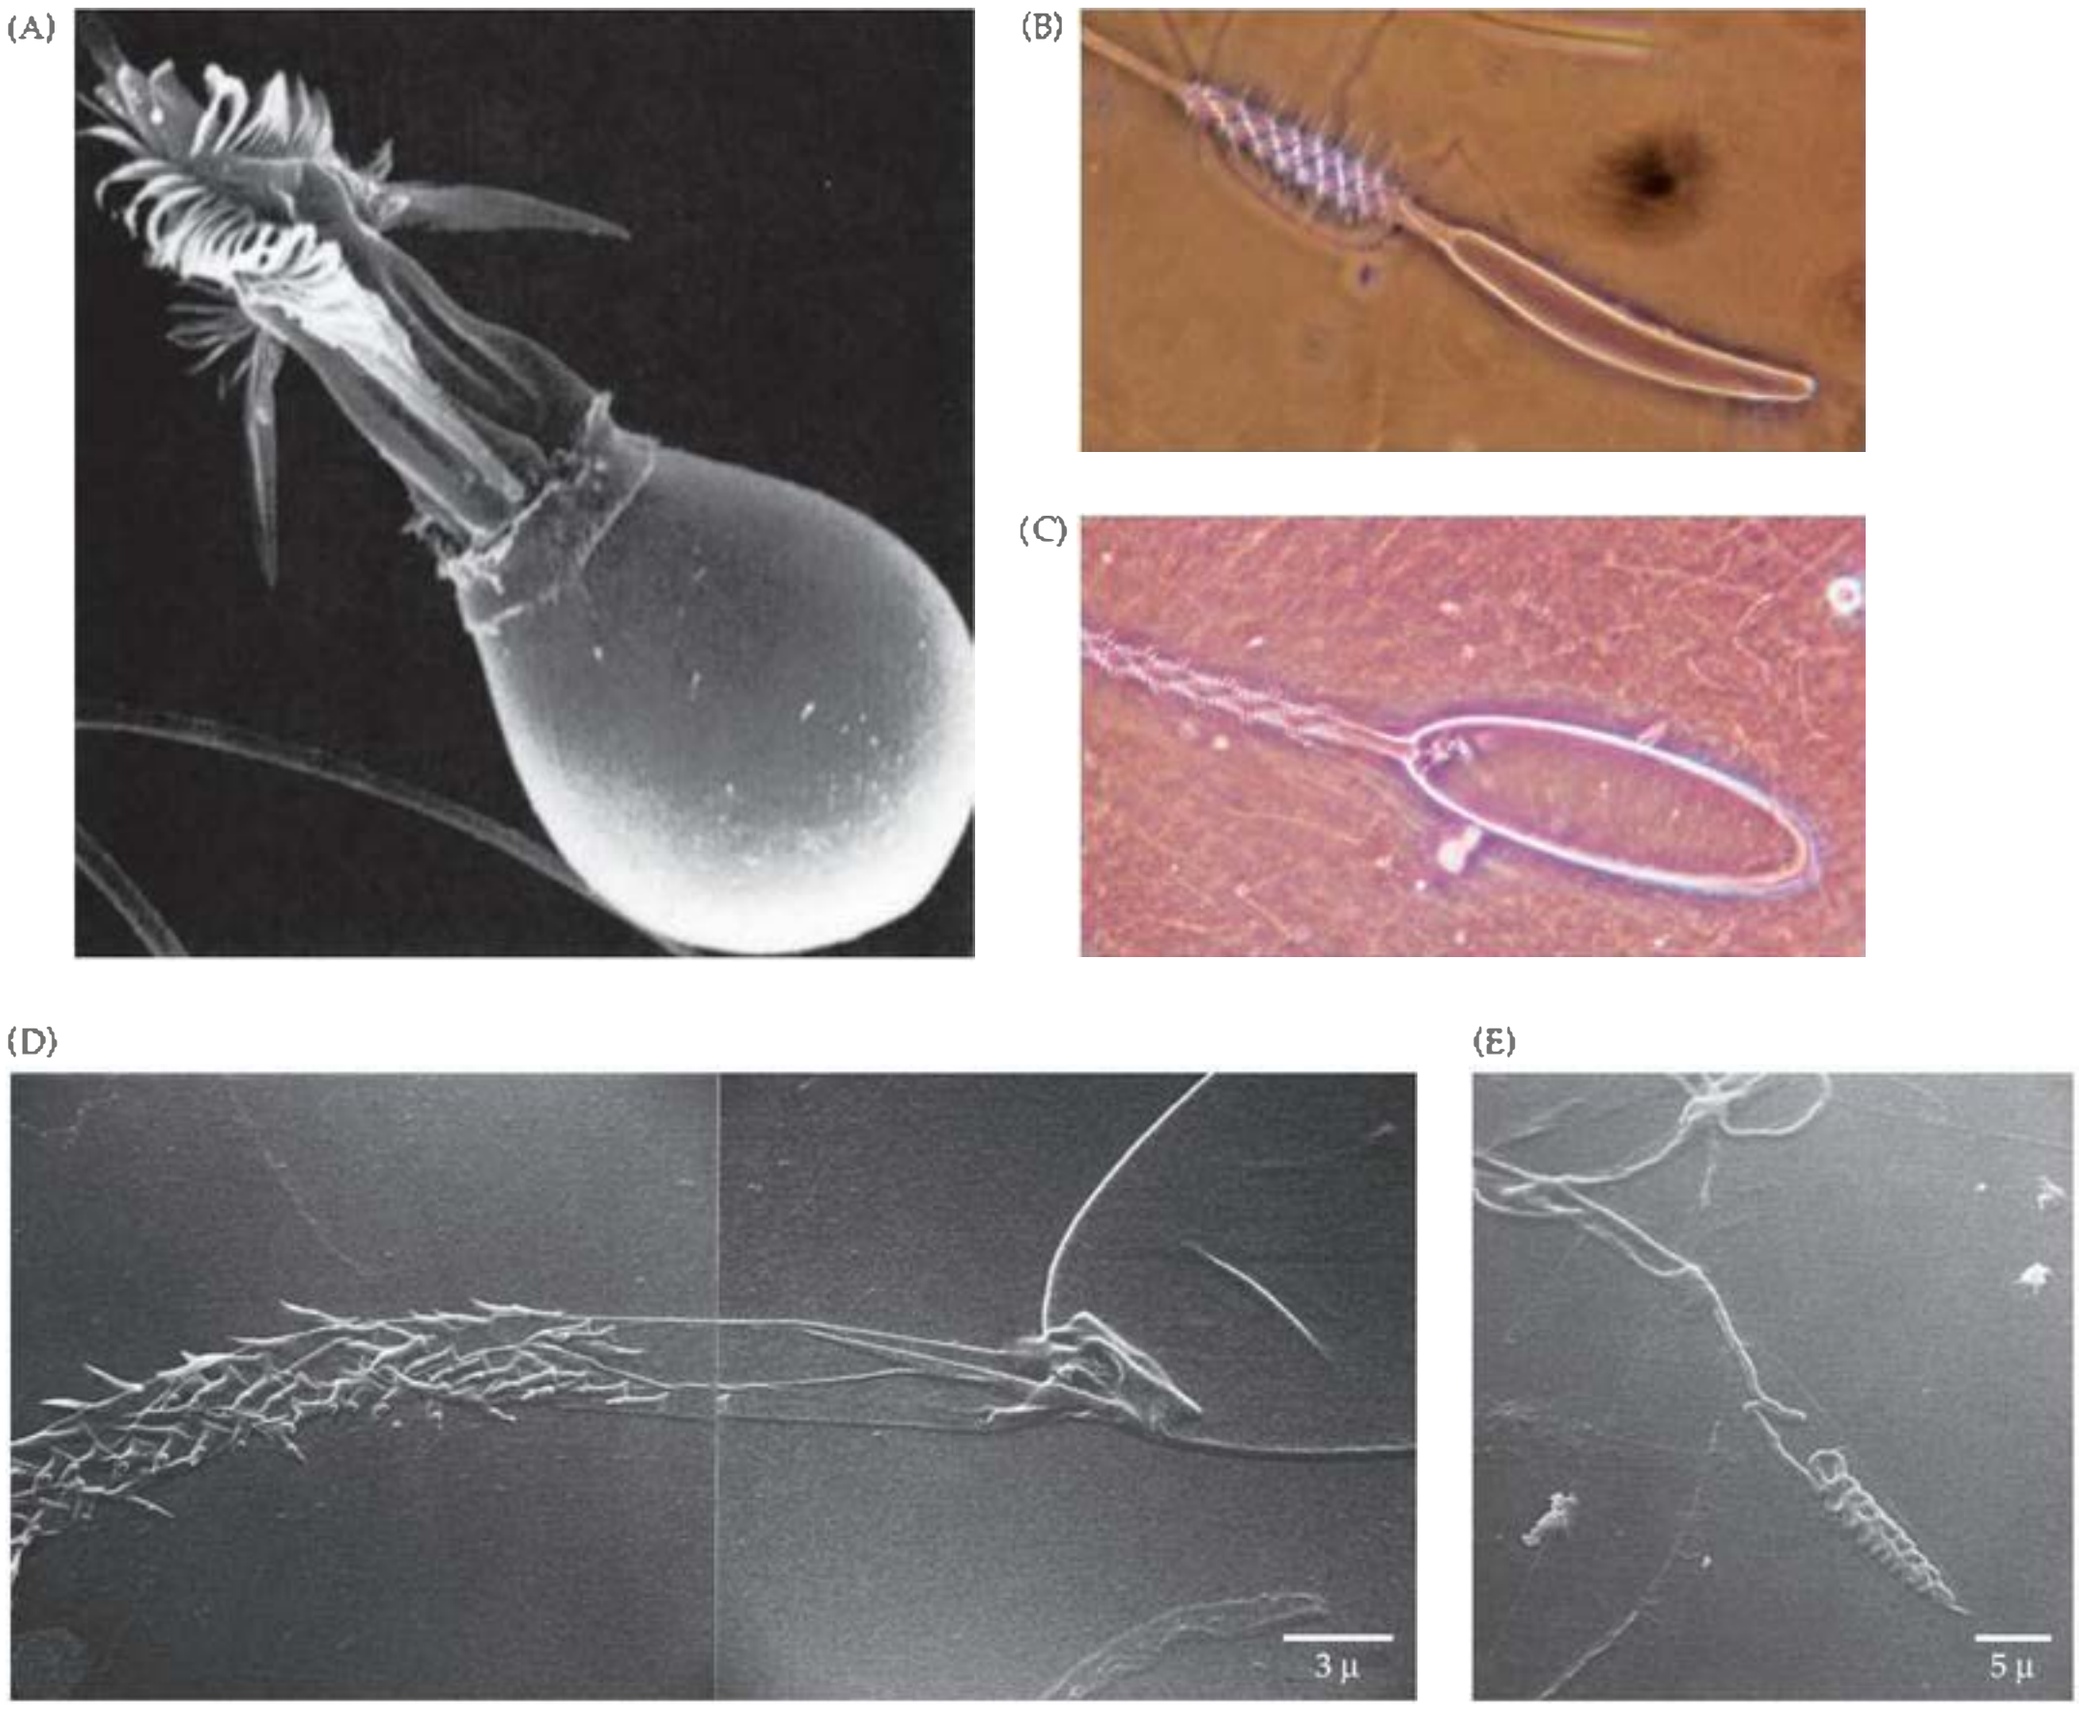

Figure 7.24 Discharged nematocysts. (A) The base of a discharged nematocyst from the hydrozoan *Hydra* (SEM). (B) A nematocyst of the anthozoan *Corynactis californica* (Corallimorpharia). The nematocyst has been "stopped" when partially averted; the averting tubule can be seen passing up tubule the a ready external region (light micrograph). (C) A fully everted nematocyst of *C. californica* (light micrograph). (D) A fully everted nematocyst of *C. californica* (SEM of the base of the everted thread and the tip of the capsule). (E) Everting nematocyst of the anthozoan coral *Balanophyllia elegans*.

certain nudibranch gastropods that, in order to feed upon and capture intact cnidae from their prey, release copious amounts of mucus to entangle and envelop hydroid tentacles containing still intact cnidae.

Most nematocysts contain several different toxins that vary in activity and strength, but as a class of chemicals they are all potent biological poisons capable of subduing large, active prey, including fish. Most appear to be neurotoxins. The toxins of some cnidarians are powerful enough to affect humans (e.g., those of cubozoans; some jellyfish; certain colonial hydroids, such as *Lytocarpus*; many hydrocorals, such as *Millepora*; and many siphonophores, such as *Physalia*). The toxins of most scyphozoans are not strong enough to create problems for most people, unless they have an allergic reaction; even the effects of *Physalia* stings disappear within a few hours. However, toxins of most cubomedusans (box jellies) are another story altogether, and are estimated to be more potent than cobra venom. In tropical Australia, twice as many people die annually from box jellies as from sharks. Stings by *Chironex* (the "sea wasp") usually result in severe pain at least, and fatal respiratory or cardiac failure at worst. Both acidic and alkaline environments suppress nematocyst firing. Thus, if you come out of the surf with a jellyfish tentacle stuck to you, dousing it with urine (acidic) or baking soda (alkaline) may reduce the impact. Meat tenderizer or vinegar works somewhat, perhaps by denaturing the toxins or desensitizing the nematocysts, and in our experience following this with hot compresses seem to alleviate the pain. This is consistent with experiments showing that the lethality

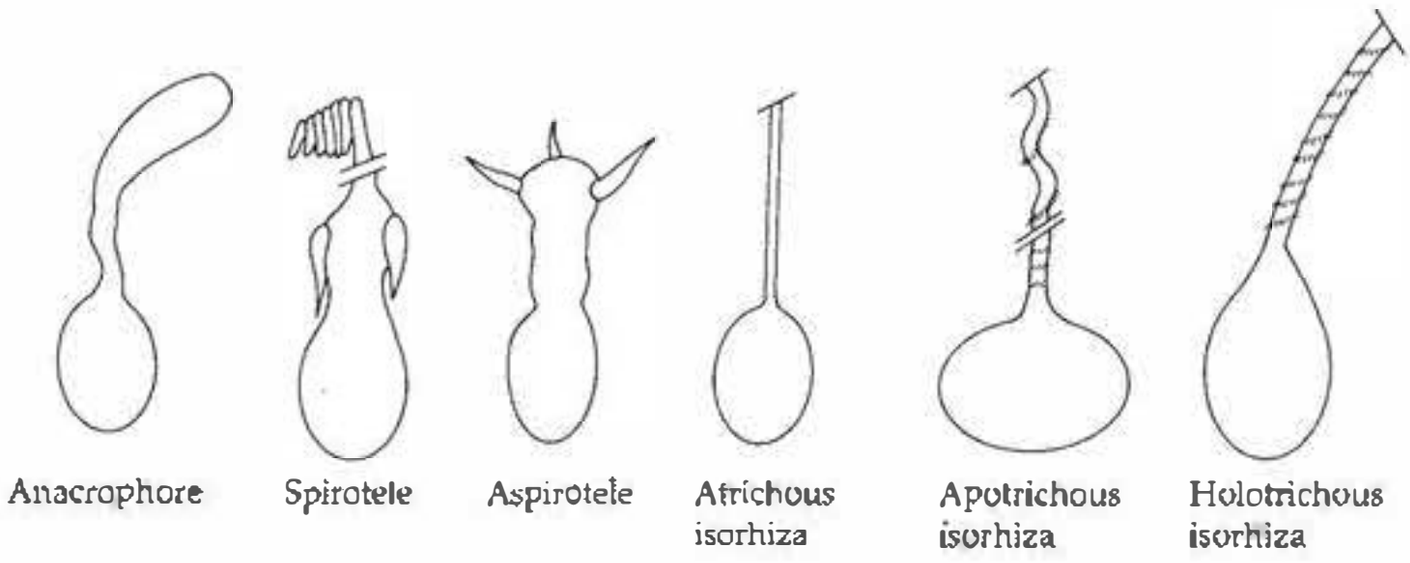

Figure 7.25 Some types of cnidae and their specialized nomenclature.

of box jellyfish (*Chironex*) venom to crayfish cardiac muscle was eliminated at temperatures approaching 60° C. If you want to swim in an area known to be frequented by dangerous jellies, you can always do what lifeguards in northern Australia do—don a pair of pantyhose (not fishnet!), which seem to offer some protection.

Feeding and Digestion

All cnidarians are carnivores (or parasites). Typically, nematocyst-laden feeding tentacles capture animal prey and carry it to the mouth region where it is ingested whole (Figure 7.26). Digestion is initially extracellular in the coelenteron. The gastrodermis is abundantly supplied with enzyme-producing cells that facilitate digestion (Figure 7.4). In many groups, gastrodermal cilia (or flagella) aid in mixing of the gut contents. In the absence of a true circulatory system, the gastrovascular cavity distributes the partially digested material. The larger the cnidarian, the more extensively branched or partitioned is its coelenteron. The product of this preliminary breakdown is a soupy broth, from which polypeptides, fats, and carbohydrates are taken into the nutritive-muscular cells by phagocytosis and pinocytosis. Digestion is completed intracellularly within food vacuoles. Undigested wastes in the coelenteron are expelled through the mouth. In cubozoans, and at least some hydrozoans, ciliary movement of material in the coelenteron is enhanced by peristaltic movements.

In anthozoans, the free edges of most of the gastrovascular mesenteries are thickened to form three-lobed mesenterial filaments (Figures 7.6 and 7.20). The lateral lobes are ciliated and aid in circulating the digestive juices in the coelenteron. The middle lobe, called the cnidoglandular band, bears cnidae and gland cells. In some sea anemones (e.g., *Aiptasia, Anthothoe, Calliactis, Diadumene, Metridium, Sagartia*), the cnidoglandular band continues beyond the base of the pharynx as a free thread called an acontium, which floats about in the coelenteron. The cnida-bearing acontia not only subdue live prey within the coelenteron, but they may be shot out through the mouth or through pores in the body wall (called cinclides) when the animal contracts violently; when this occurs, the acontia presumably play a defensive role.

Prey type appears to influence medusoid form. Most oblate medusae feed on small ciliated or soft-bodied prey, following their quarry by continuous rowing (using their large flat bell), and then using nematocysts on the tentacles, the oral arms, or both to capture their victims. *Pelagia noctiluca*, an open-sea diurnal migrator, follows the other migrating macrozooplankton upon which it feeds. *Pelagia* uses its marginal tentacles to paralyze and capture moving prey, then transports it to the oral arms dangling from the center of the subumbrella. The oral arms transport the prey to the mouth. Motionless prey may also be captured by the oral arms directly through chance contact. Most prolate medusa feed on actively swimming prey. These species often retract their tentacles while swimming to reduce drag. Cubomedusae such as *Chironex* spp. feed actively on fish, and can swim in bursts of up to five feet per second. Because of their higher metabolic demands, unlike other Medusozoa, they move semidigested food from their central gastrovascular cavity to canals lining the interior walls of each tentacle for absorption. Some cubomedusae catch and ingest fish and prawns matching their own diameter, and a large *Chironex* can eat fish 20-50 cm in length! Some cubomedusae are less active hunter-predators and feed primarily by passive hunting (e.g., *Tripedalia cystophora*, and perhaps also *Chironex fleckeri* and *Carybdea rastonii*), and in these cases the eyes are probably used to position themselves in the right food-rich habitat.

Several groups of cnidarians have adopted feeding methods other than the direct use of nematocyst-laden tentacles. One group of large tropical anemones in the order Corallimorpharia (e.g., *Amplexidiscus*) lacks nematocysts on the external surfaces of most tentacles.

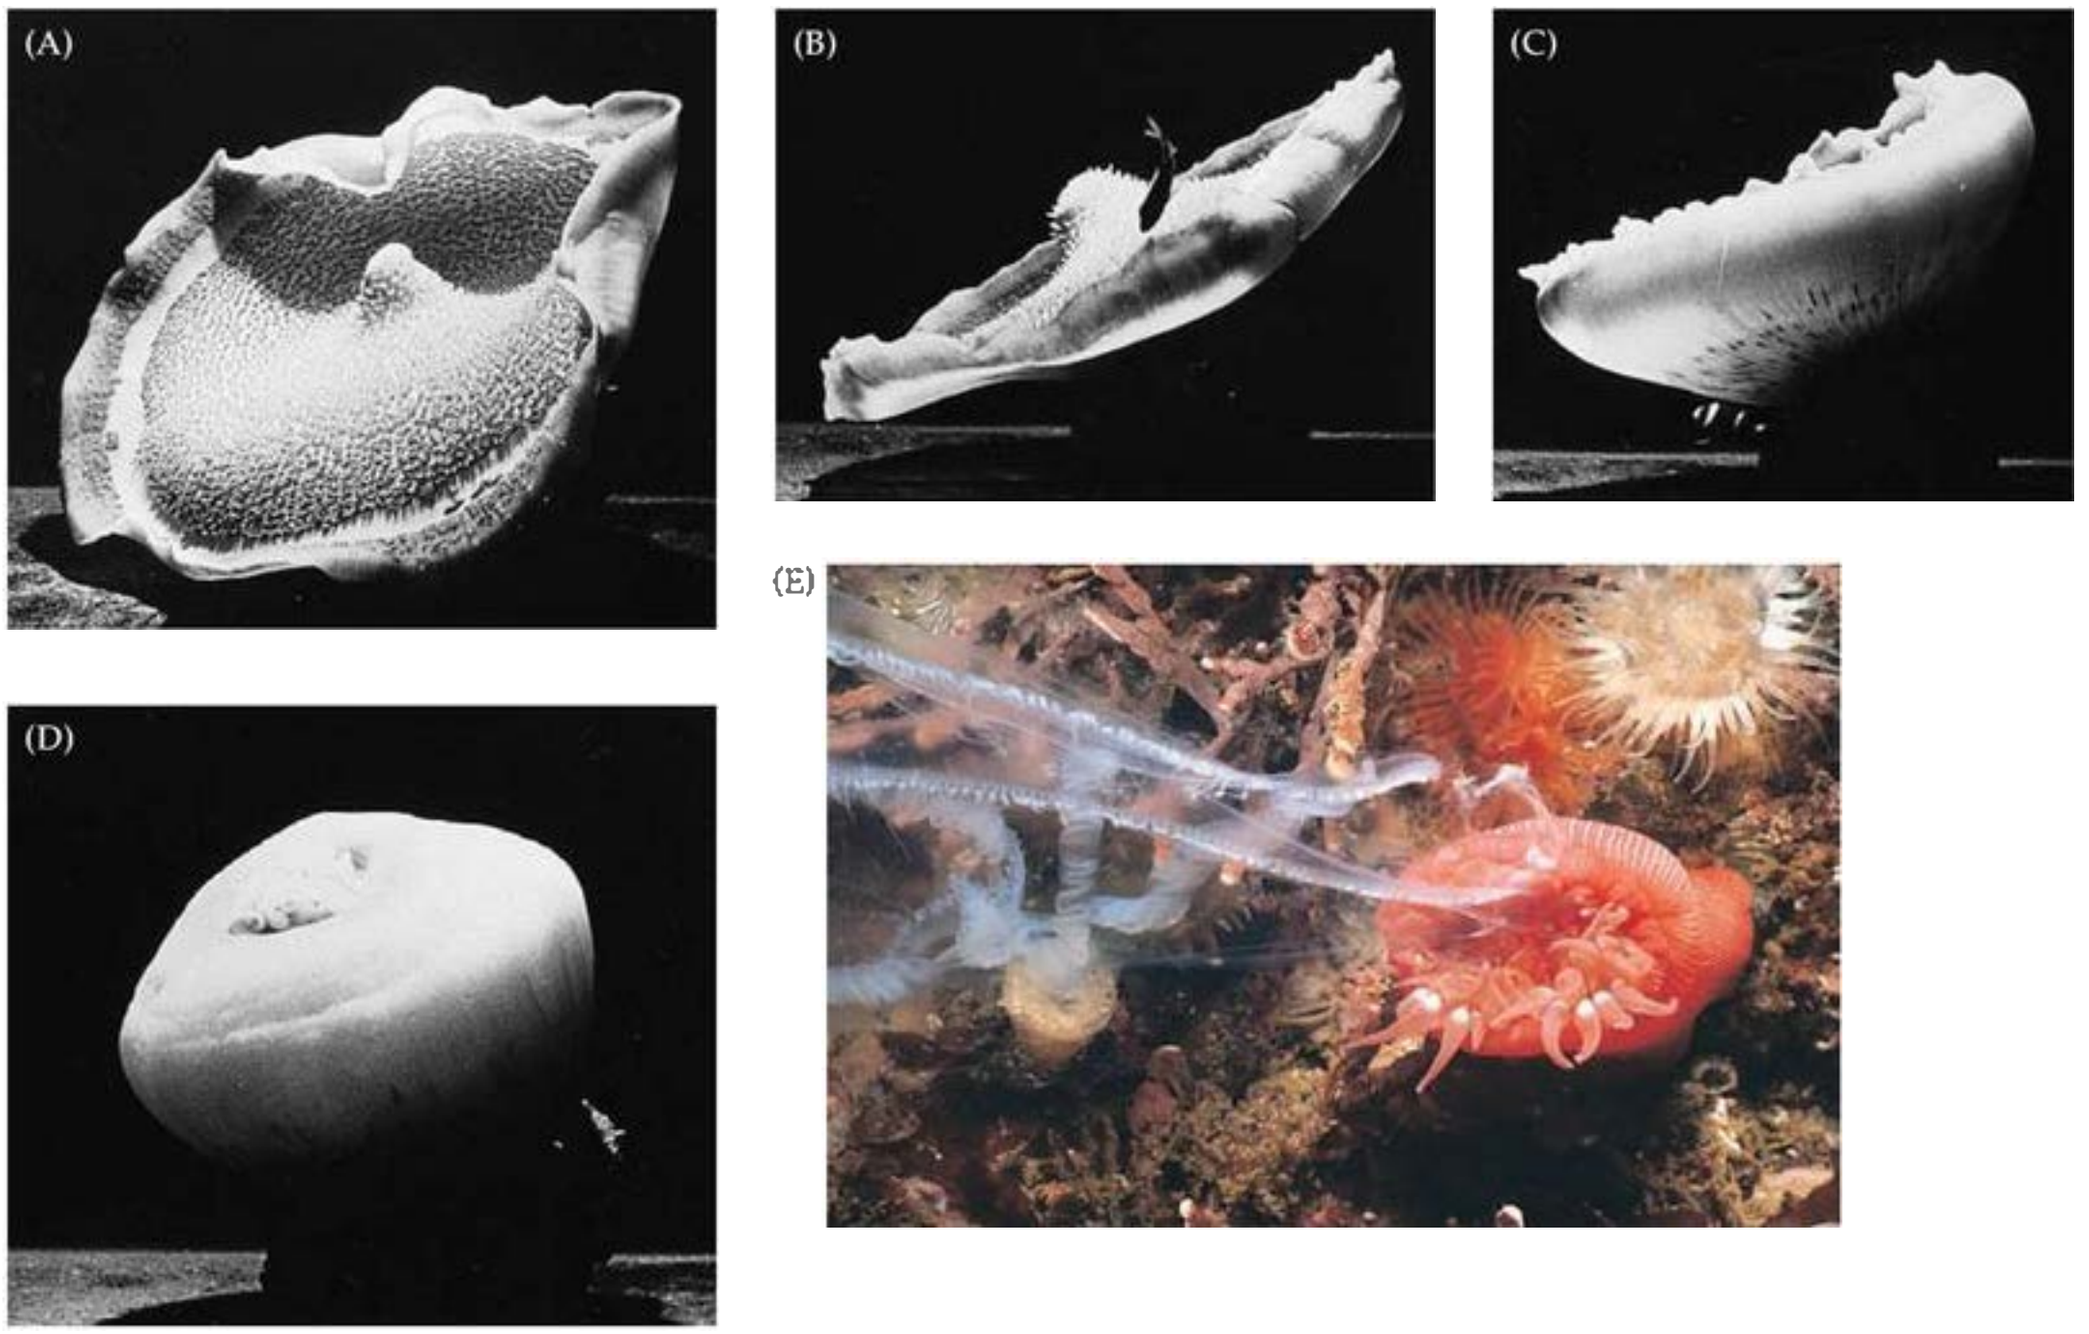

Figure 7.26 (A–D) Feeding sequence in the tropical sea anemone *Amplexidiscus senestrafer* (A) An expanded oral disc has a tentacle free area near the periphery, and an oral cone. (B) An expanded disc (side view). (C) Closure one-third complete, 1 second after stimulation of the oral disc. (D) Complete closure, 3 seconds after stimulation. (E) The temperate sea anemone *Epiactis prolifera* capturing a jellyfish (*Aequorea*?).

These remarkable anemones capture prey directly with the oral disc, which can envelop crustaceans and small fishes, rather like a fisherman's cast net (Figures 7.26A–D).

In addition to tentacular feeding on small plankters, many corals are capable of mucous net suspension feeding, which is accomplished by spreading thin mucous strands or sheets over the colony surface and collecting organic particulate matter that rains down from the water. The food-laden mucus is driven by cilia to the mouth. In a few corals (e.g., members of the family Agariciidae), the tentacles are greatly reduced or absent, and all direct feeding is by the mucous-net suspension method. The amount of mucus produced by corals is so great that it is an important food source for certain fishes and other reef organisms, which feed directly off the coral or recover mucus sloughed into the surrounding sea water. Coral mucus released into the sea contains a variable mixture of macromolecular components (glycoproteins, lipids, and mucopolysaccharides) or a mucous lipoglycoprotein of specific character for a given species. These loose mucous webs, or flocs, are usually enriched by bacterial colonies and entrapped detrital materials, further enhancing their nutritional value.

The role of cnidarians as potentially significant members of food webs depends largely on location and circumstance. Stony corals obviously hold critical trophic positions in tropical reef environments, as do zoanthids and octocorals in many tropical and subtropical habitats. In many warm and temperate areas sea pens and sea pansies dominate benthic sandy habitats. Large scyphomedusae (e.g., *Aurelia*, *Cyanea*, *Pelagia*, *Phacellophora*) often occur in great swarms and may consume high numbers of larvae of commercially important fishes, as well as competing with other fishes for food. Swarms of jellyfish may be so dense that they clog and damage fishing nets and power plant intake systems. We once witnessed a swarm of *Phacellophora* in the Gulf of California that ran like a broad river from Loreto to La Paz, a distance of about 200 kilometers. Certain scyphozoans (*Chrysaora*) have undergone population blooms in their native habitats, perhaps due to climate shifts, while other species (*Phyllorhiza*) have become invasive after transport by ships or in shifting currents. In large numbers jellies significantly influence local fish and plankton populations.

Hydromedusae too are major components of temperate pelagic food webs. Members of several hydrozoan genera also occur in huge congregations in tropical seas, where they are important carnivores in the

neustonic food web. Best known among these are the chondrophorans *Porpita* (which actively feeds on motile crustaceans, such as copepods) and *Velella* (which feeds on relatively passive prey, such as fish eggs and crustacean larvae), and the siphonophore *Physalia* (which actively catches and consumes fish). Other siphonophores inhabiting deep sea environments (e.g., *Erenna* sp.) possess bioluminescent and red-fluorescent lures that may be important for capturing fish sensitive to long wavelength light. Like scyphomedusae, hydromedusae and siphonophores can reach high densities in surface waters and have significant effects on zooplankton and human populations. The Chinese freshwater limnomedusa, *Craspedacusta sowerbyi*, is now established throughout the United States and Europe where it can undergo "blooms" and impact fisheries. The Portuguese man-of-war, *Physalia* sp., is a known menace for swimmers during summer months in coastal areas throughout the world.

Defense, Interactions, and Symbiosis

There are so many interesting aspects of cnidarian biology that do not fall neatly into our usual coverage of each group that we present this special section. The following discussion also points out the surprising level of sophistication possible at the relatively simple diploblastic, radiate grade of complexity.

In most cnidarians, defense and feeding are intimately related. The tentacles of most anemones and jellyfish usually serve both purposes, and the defense polyps (dactylozooids) of hydroid colonies often aid in feeding. In some cases, however, the two functions are performed by distinctly separate structures (as in many siphonophores).

Some species of acontiate sea anemones (e.g., *Metridium*) bear separate and distinct feeding tentacles and defense tentacles. Whereas the former usually move in concert to capture and handle prey, the defense tentacles move singly, in a so-called searching behavior, in which they extend to three or four times their resting length, gently touch the substratum, retract, and extend once more. Defense tentacles are used in aggressive interactions with other sea anemones, either those of a different species or nonclonemates of the same species. The aggressive behavior consists of an initial contact with the opponent followed by autonomous separation of the defense tentacle tip, leaving the tip behind attached to the other sea anemone Severe necrosis develops at the site of the attached tentacle tip, occasionally leading to death Defense tentacles develop from feeding tentacles and tend to increase under crowded conditions. The development involves loss of typical feeding tentacle cnidae (largely spirocysts) and acquisition of true nematocysts and gland cells, which dominate in defense tentacles. Similarly, elongated "sweeper tentacles" in many species of corals are used for defense and competition for space, by direct contact or release of toxic exudates.

The acrorhagi (= marginal tubercles or bumps) that ring the collar of some sea anemones (e.g., *Anthopleura*) also have a defensive function. These normally inconspicuous vesicles at the base of the tentacles bear nematocysts and usually spirocysts. In *A. elegantissima*, contact of an acrorhagi-bearing sea anemone with nonclonemates or other species causes the acrorhagi in the area of contact to swell and elongate. The expanded acrorhagi are placed on the victim and withdrawn, and the application may be repeated. Pieces of acrorhagial epidermis break off and remain on the victim, resulting in localized necrosis. Interclonal strips of bare rock are maintained by this aggressive behavior, and may help prevent overcrowding (Figure 7 27A). In addition to this behavior, the acrorhagi are exposed as a ring of nematocyst batteries around the top of the constricted column whenever an acrorhagi bearing sea anemone contracts in response to violent stimulation. Other competitive interactions are known among stony corals (Figure 7 27C).

Octocorals, which lack toxic stinging nematocysts, have been shown to be a rich source of biologically active and structurally unusual compounds that appear to provide protection against predators and may allow them to colonize new habitats by causing tissue necrosis in potential competitors. These compounds include prostaglandins, diterpenoids, and nausea-inducing furanocembranolides including the descriptively named 11β, 12β epoxypukalide. In contrast to many coastal and coral reef dwelling species, octocorals are remarkably free from predation except by the few species that are specialized to use them as food. While sclerites have also been proposed to provide antipredatory benefits, there is little clear evidence that sclerites decrease the nutritional value of octocorals sufficiently to deter predation. Thus, like sponges, octocorals appear to use secondary metabolic compounds as their primary anti-predator defense. Chemical defenses may have evolved to compensate for poor regenerative abilities in these slow growing cnidarians, or because their sessile habit makes them especially conspicuous to visual predators.

There are many examples of associations between cnidarians and other organisms, some of which are truly symbiotic, others of which are less intimate. With the exception of myxozoans, few groups of cnidarians are truly parasitic, although several species of hydroids infest marine fishes. The polyps of some of these hydroids lack feeding tentacles and occasionally even lack cnidae. The basal portion of the polyp erodes the fish's epidermis and underlying tissues, and nutrients are absorbed directly from the host. One species invades the ovaries of Russian sturgeons (a caviar feeder!).

Figure 7.27 (A) Defensive acrorhagi (white-tipped tentacles) on two sea anemones (*Anthopleura elegantissima*), engaging in territorial chemical combat. (B) Close-up showing acrorhagi of *Anthopleura elegantissima*. (C) Competition between true corals (Scleractinia) in the Virgin Islands. The coral *Isophyllia sinuosa* is seen extruding its mesenterial filaments and externally digesting the edge of a colony of *Porites astereoides*

However, the Myxozoa, by any standard, are indeed parasitic. This group consists of about 1,200 species of tiny parasites, previously classified among the protists as the phylum Myxozoa. Morphological data, DNA sequence data, and the presence of metazoan Hox genes, all provide evidence that these strange creatures are allied with the cnidarians, possibly as a sister group to the Medusozoa (Figure 7.46). The coiled polar filaments housed within polar capsules of myxozoans are now viewed as modified nematocysts (Figure 7.28).

Myxozoan cnidarians infect annelids and various poikilothermic vertebrates, especially fishes (Figure 7.29). The life cycle begins when actinospore larvae (which may vary in form) are released from spores, contact the mucous membranes of an appropriate vertebrate host (either by ingestion or contact; Figure 7.29, part 1), and extrude their polar filaments to release sporoplasm into the host cells. Presporogonic development occurs within these cells, producing infective cell-doublets, which rupture host cells and disperse to infect other cells (Figure 7.29, part 2). Infection can spread to other tissues, particularly neural tissue, and can cause disruption of host tissue structure (e.g., a blackened tail in infected trout) or behavior (see below). Sporulation often occurs in particular tissues (e.g., cartilage in *M. cerebralis*), where a multinucleated plasmodium develops and produces sporoblasts with variable numbers of internal spores depending on the species (Figure 7.29, part 3).

Within plasmodia, valvogenic cells produce spore valves, which enclose capsulogenic cells that become polar capsules as well as sporoplasm. When complete, this process generates myxospores that are released by the vertebrate host and are infective to annelids (Figure

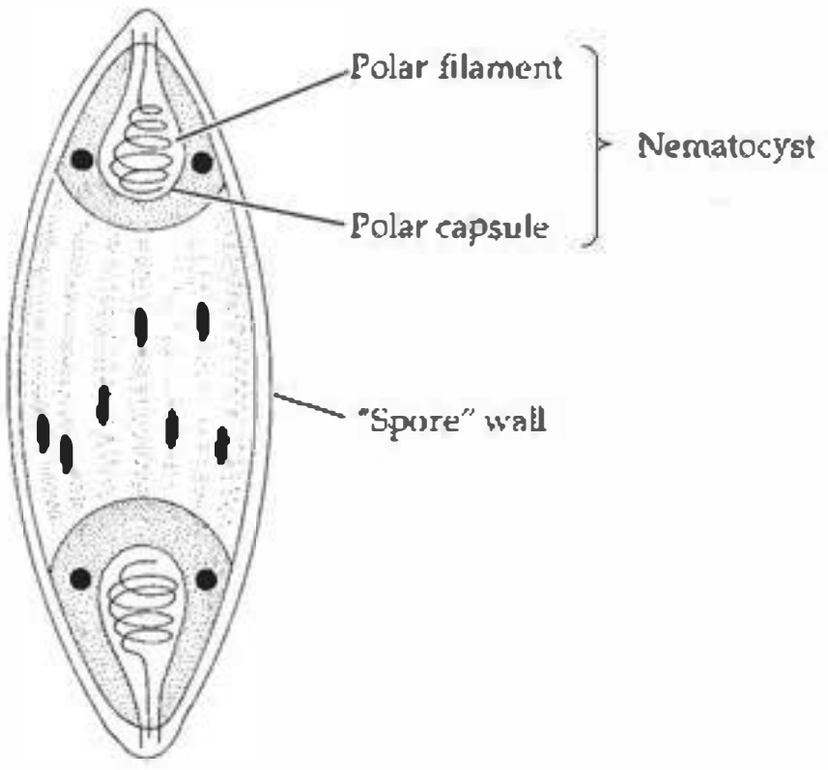

Figure 7.28 Previously considered to be protists, myxozoans are now viewed as highly specialized, parasitic cnidarians.

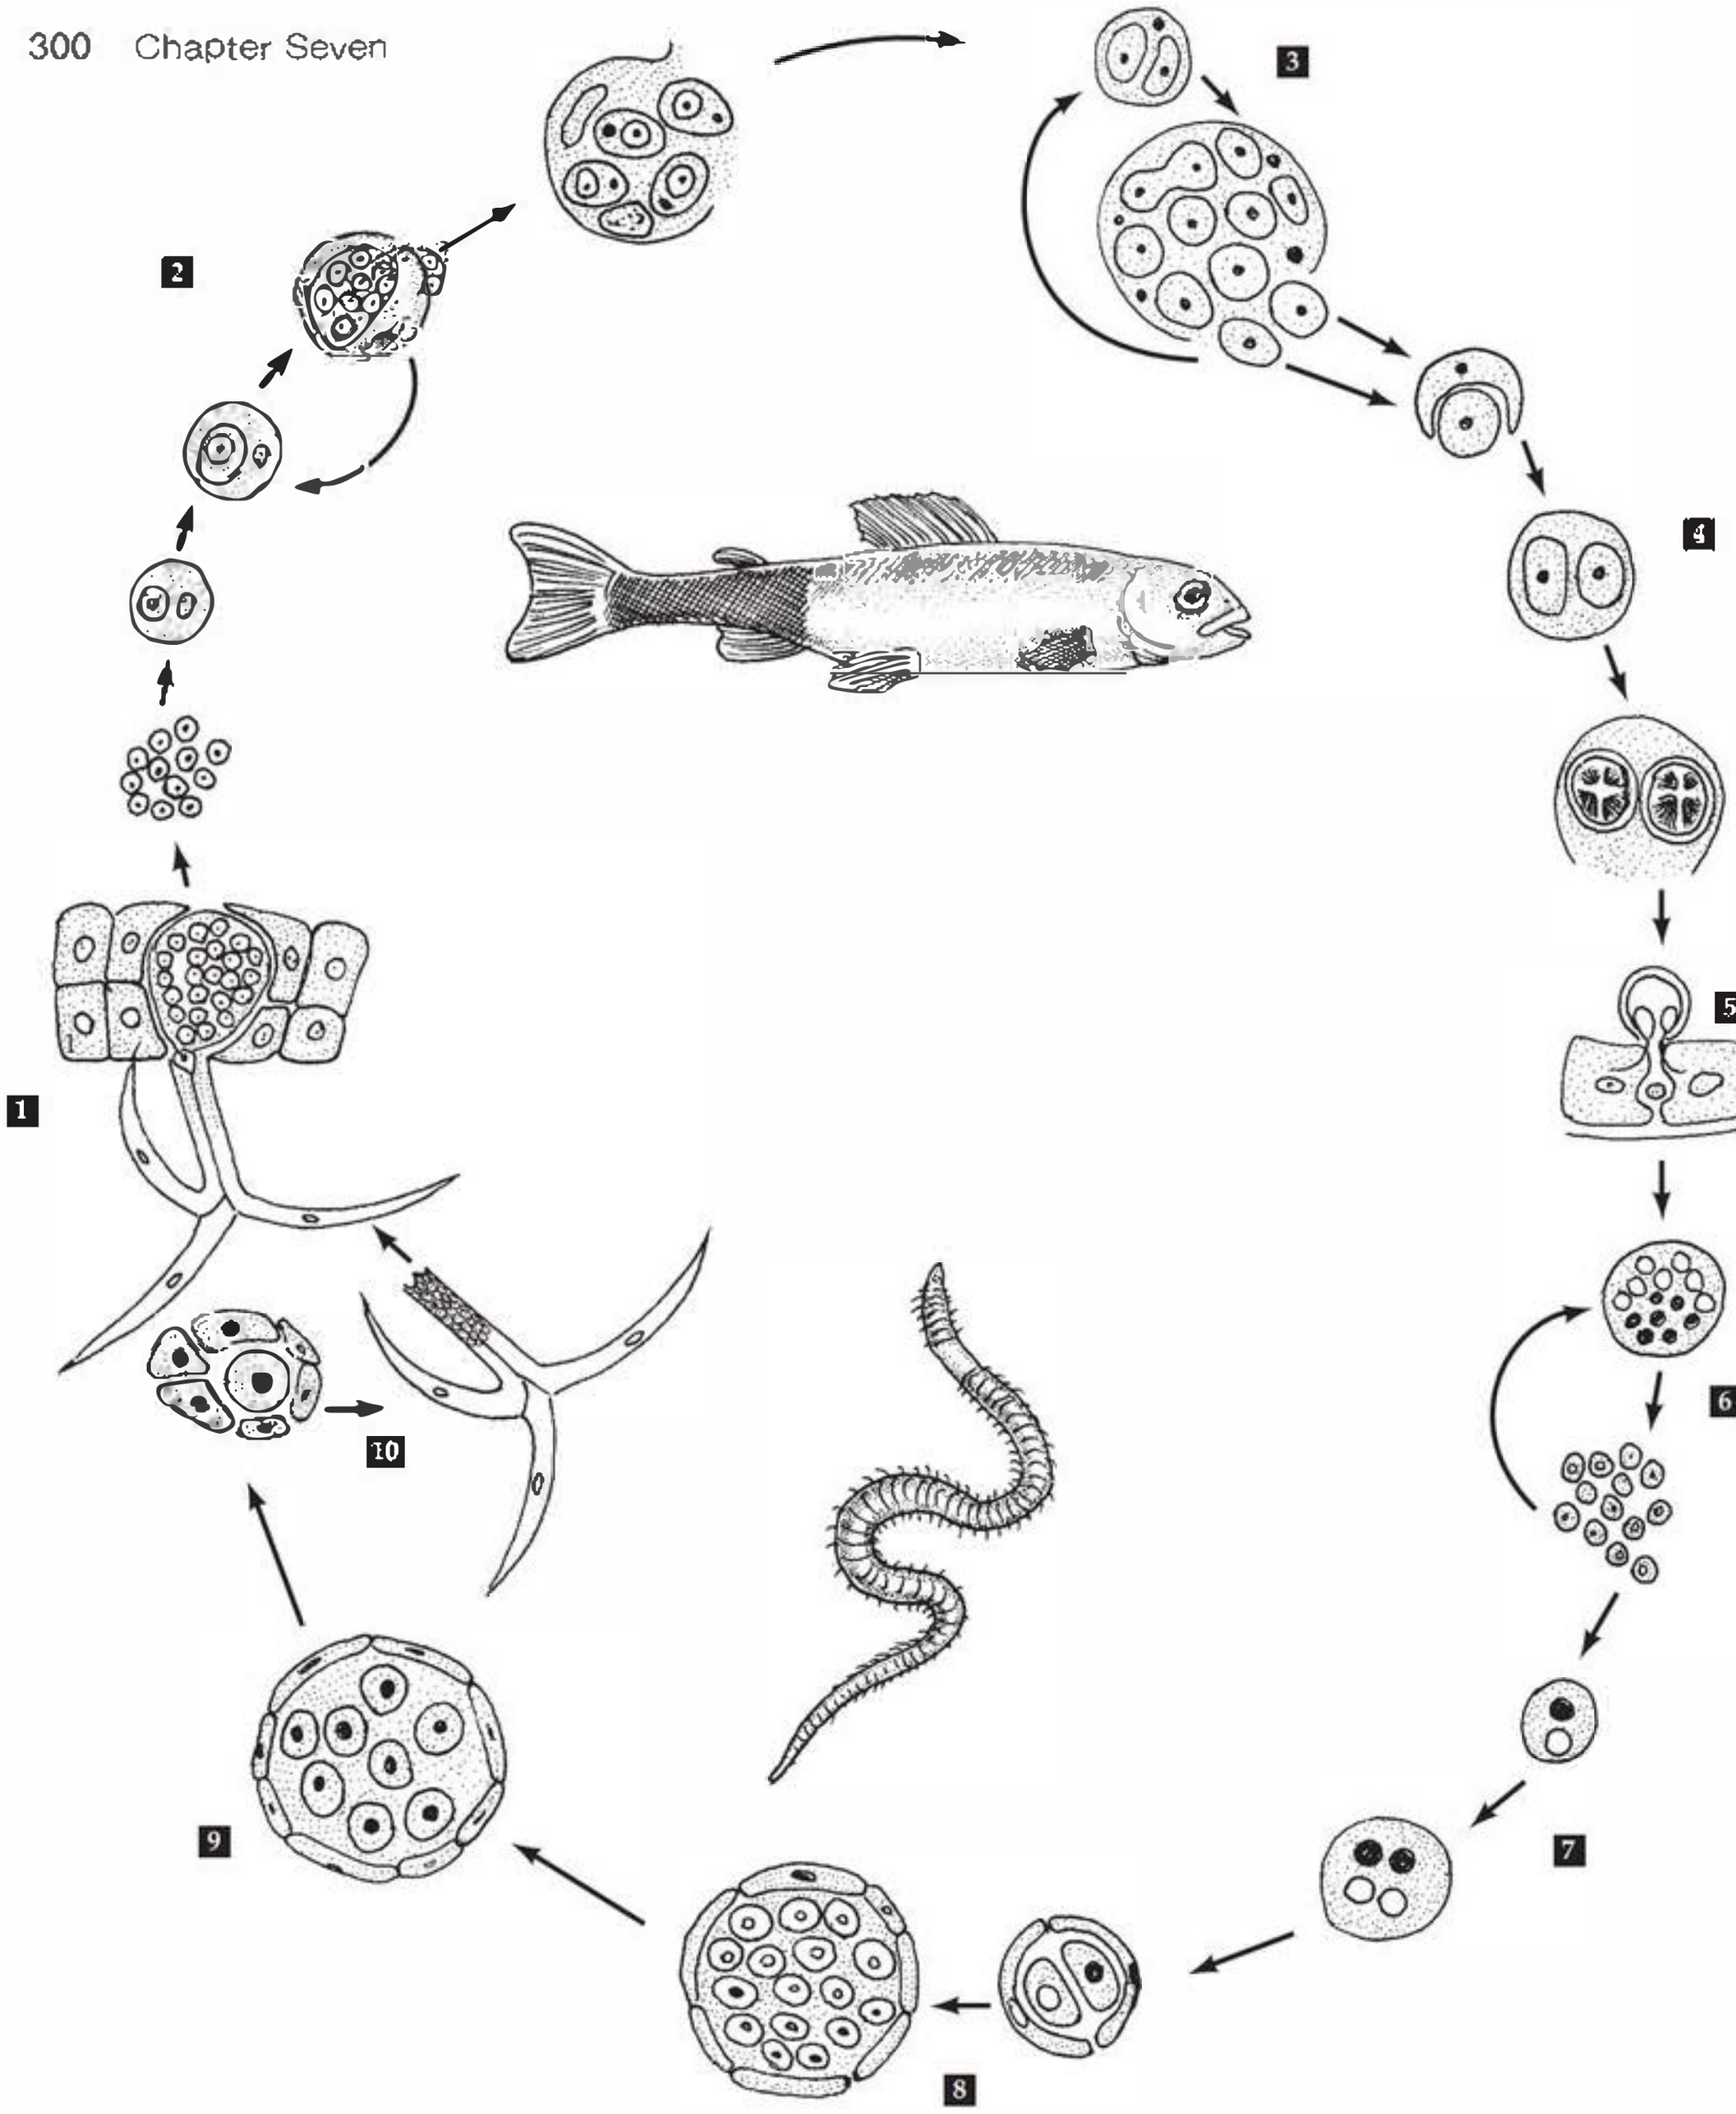

Figure 7.29 The life cycle of *Myxobolus cerebralis*: (1) Actinospore larvae attach to fish mucous membranes, extrude polar filaments and release sporoplasm into host cells. (2) Presporogonic development occurs within host cells producing infective cell-doublets, which rupture and infect other host cells; spreading infection disrupts host tissue causing a blackened tail in trout; (3) sporulation and multinucleated plasmodia develop in particular tissues (e.g., cartilage in *M. cerebralis*), further spreading infection; (4) within plasmodia, sporoblasts form internal myxospores that are (5) released by the vertebrate host and ingested by annelids, polar filaments facilitate penetration of gut cells; (6) multinucleate cells form, that infect other cells and generate plasmodia or (7) fuse with other cells to become binucleate cells, then differentiate into multinucleate cells with α or β nuclei and (8) become complimentary gametes; (9) gametes fuse to produce pansporocysts containing 8 zygotes; (10) zygotes differentiate into infective actinospores that are released in worm feces or remain within the worm's body; other fish are infected by contact with worm feces or by eating sporebearing worms.

Figure 7.30 The golden "cloak anemone" (Anthozoa, Actiniaria) *Stylobates aenus* (A,B) The anemones forming a "shell," or carcinoecium, around the hermit crab *Parapagurus dofleini*. (C) The empty carcinoecium of *S aenus*.

7 29, part 4). Polar filaments facilitate cell penetration of gut cells where multinucleate cells form by a process often called schizogony (although this is probably not the same process seen in sporozoan protists; Figure 7 29, parts 5 and 6). These cells then produce numerous uninucleate cells that may either generate other plasmodia or fuse with other cells to become binucleate within the worm gut. Binucleate cells differentiate into multinucleate cells with α or β nuclei that develop into complimentary gametes by the end of gametogony, which fuse to produce pansporocysts containing zygotes (Figure 7.29, parts 7–9). Zygotes differentiate into infective actinosporean spores that are released in worm feces or remain within the worm's body. Infection of the vertebrate host occurs when spores containing worm feces contact mucous membranes or when spore bearing worms are ingested (Figure 7 29, part 10).

Most myxozoan species appear to include both a vertebrate and an invertebrate host in their life cycle. *Myxobolus cerebralis*, a parasite of freshwater fishes (especially trout, Figure 7 1M), devours the host's cartilage, leaving the fish deformed. Inflammation resulting from the infection puts pressure on nerves and disrupts balance, causing the fish to swim in circles—a condition known as whirling disease. When an infected fish dies, *M cerebralis* spores are released from the decaying carcass and may survive for up to 30 years in sediment. Eventually, the spores are consumed by *Tubifex* worms (oligochaete annelids). They reside in this intermediate host until eaten by a new host fish.

Mutualism is common among cnidarians. Many species of hydroids live on the shells of various molluscs, hermit crabs, and other crustaceans. The hydroid gets a free ride and the host perhaps gains some protection and camouflage. Many members of the leptomedusan family Eirenidae (e.g., *Eugymnanthea*) occupy the mantle cavities of bivalves, where they protect their hosts against trematode parasites by consuming the infective sporocysts. Hydroids of the genus *Zanclea* are epifaunal on bryozoans, where they sting and discourage smaller predators and adjacent competitors, helping the bryozoan to survive and overgrow competing species. The bryozoan lends protection to the hydroid with its coarse skeleton, and the mutualism seems to allow both taxa to cover a larger area than either could individually. The bizarre, aberrant hydroid *Proboscidactyla* lives on the rim of polychaete worm tubes (Figure 7.8A) and dines on food particles dislodged by the host's activities. Another filiferan, *Brinckmannia hexactinellidophila*, lives within the tissues of Arctic glass sponges.

Some sea anemones attach to snail shells inhabited by hermit crabs. These partnerships are mutualistic; the sea anemone gains motility and food scraps while protecting the hermit crab from predators. The most extreme case of this mutualism might be that of the cloak anemones (e g., *Adamsia*, *Stylobates*), which wrap themselves around the hermit crab's gastropod shell and grow as the crab does (Figure 7.30). Initially, the anemone's pedal disc secretes a chitinous cuticle over the small gastropod shell occupied by the hermit.

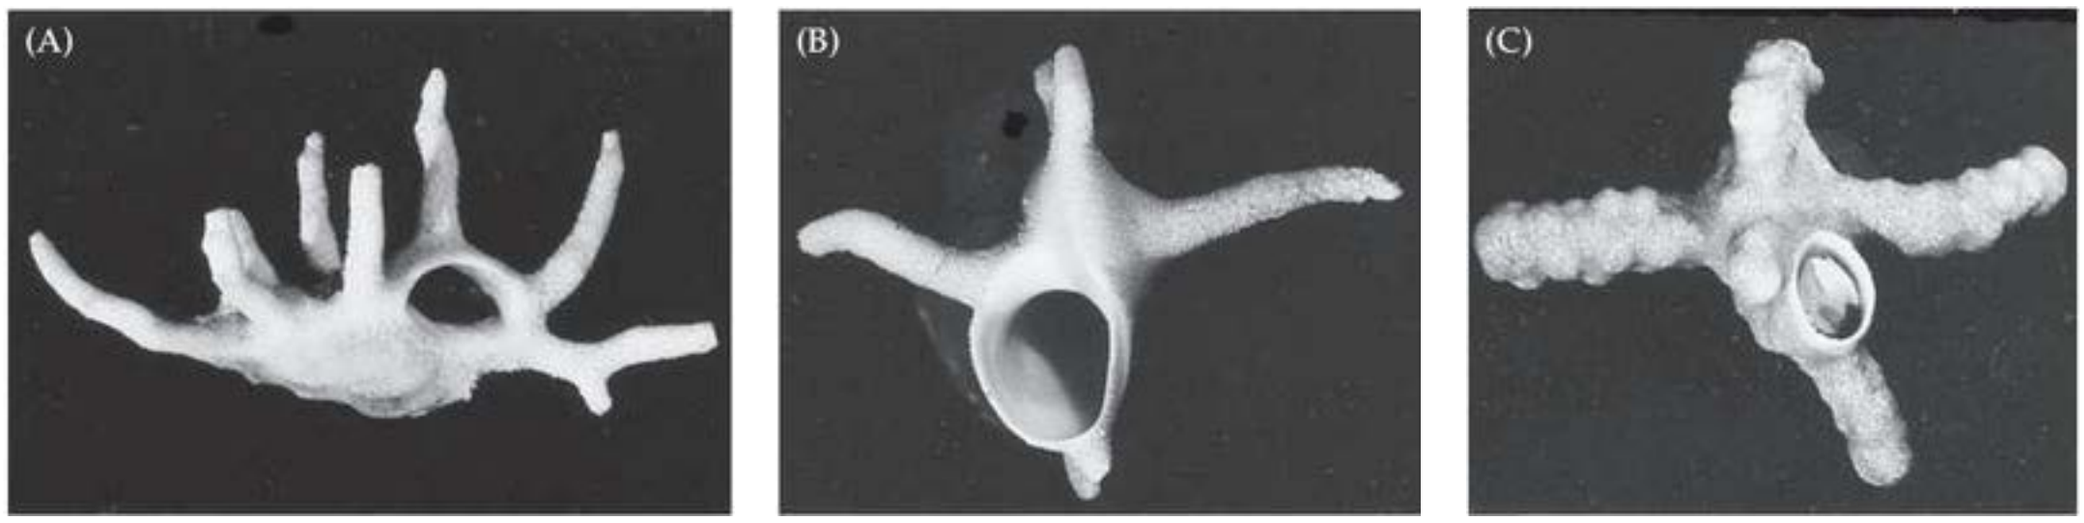

Figure 7.31 A case of remarkable evolutionary convergence. (A,B) The hydrozoan colony *Janaria mirabilis* (Athecata) forms a shell- ike corallum inhabited by hermit crabs (C) The ectoproct *Hippoporida calcarea*, which forms a similar structure, is a so inhabited by hermit crabs.

Such fortunate crabs need not seek new, larger shells as they grow, for the cloak anemone simply grows and provides the hermit with a living protective cnidarian "shell," often dissolving the original gastropod shell over time. As if it were itself a gastropod, the sea anem one grows to produce a f..exible coiled house called a carcinoecium. In fact, these odd anemone "shells" were initially described and classified as flexible gastropod shells. A similar relationship exists between some hermit crabs of the genus *Parapagurus* and certain species of *Epizoanthus*. The hydroid *Janaria mirabilis* secretes a "long spined" shell-like casing that is inhabited by hermit crabs and, in an extraordinary case of evolu tionary convergence, so does the bryozoan *Hippoporida calcarea* (Figure 7.31).

So effective are cnidae that many groups of animals have figured out ways to capture or otherwise utilize these structures for their own defense. Several aeolid sea slugs consume cnidarian prey, ingesting their unfired nematocysts and storing them in fingerlike processes on their dorsal surfaces. Once the nematocysts are in place, the sea slugs use them for their own d e fense. The ctenophore *Haeckelia rubra* feeds on certain hydromedusae and incorporates their nematocysts into its tentacles. The freshwater turbellarian flatworm *Microstoma caudatum* feeds on *Hydra*, risking being eaten itself, and then uses the stored nematocysts to capture its own prey Several species of hermit crabs and brachyuran crabs carry sea anemones (e.g , *Calliactis, Sagartiomorpha*) on their shells or claws and use them as living weapons to deter would-be predators. The hermit crabs transfer their anemone partners to new shells, or the anemones move on their own, when the hermits take new shells. Some hermit crabs of the genus *Pagurus* often have their shell covered by a mat of symbiotic colonial hydroids (e.g., *Hydractinia, Podocoryne*). The presence of the hydroid coat deters more aggressive hermits (e.g., *Clibinarius*) from commandeering the pagurid's shell.

Several cases of fish--cnidarian symbiosis have been documented. The well known association of anemone fishes (clown fishes) and their host sea anemones serves an obvious protective function for the fish. About a dozen species of sea anemones participate in this interesting relationship. The fish's ability to live among the sea anemone's tentacles is still not fully understood. However, the sea anemone does not voluntarily fail to spend its nematocysts on its fish partner; rather, the fish alters the chemical nature of its own mucous coating, perhaps by accumulating mucus from the sea anemone, thereby masking the normal chemical stimulus to which the anemone's cnidae would respond. *Neomus* are small fishes that live symbiotically among the tentacles of *Physalia* and appear to survive by simply avoiding direct contact with the beast. When stung accidentally, however, it shows a much higher survival rate than do other fishes of the same size. *Neomus* feeds on prey captured by its host.

A number of associations are known between cnidarians and crustaceans. Nearly all amphipods of the suborder Hyperiidea are symbionts on gelatinous zooplankters, including medusae. The nature of many of these associations is unclear, but various species of the amphipods are known to use their hosts as a nursery for the young and perhaps for dispersal. Some actually live among and eat the nematocyst bearing parts of the host, such as the tentacles or oral arms. Many are commonly found inside the medusa's coelenteron, where they seem unaffected by the host's digestive enzymes. In a relationship similar to that of anemone fish, a few cases of anemone shrimp are known, a t least one that is obligate for the shrimp (*Periclimenes brevicarpalis*).

One of the most noteworthy evolutionary achievements of cnidarians is their close relationship with unicellular photosynthetic partners. The relationship is widespread and occurs in many shallow water cnidarians. The symbionts of freshwater hydrozoans (e.g., *Chlorohydra*) are single-celled species of green algae (Chlorophyta) called **zoochlorellae**. In marine cnidarians, the protists are unicellular cryptomonads and dinoflagellates called **zooxanthellae** (probably several genera including *Zooxanthella* [= *Symbiodinium*] and others) (Figure 7.32). These algae are capable of living

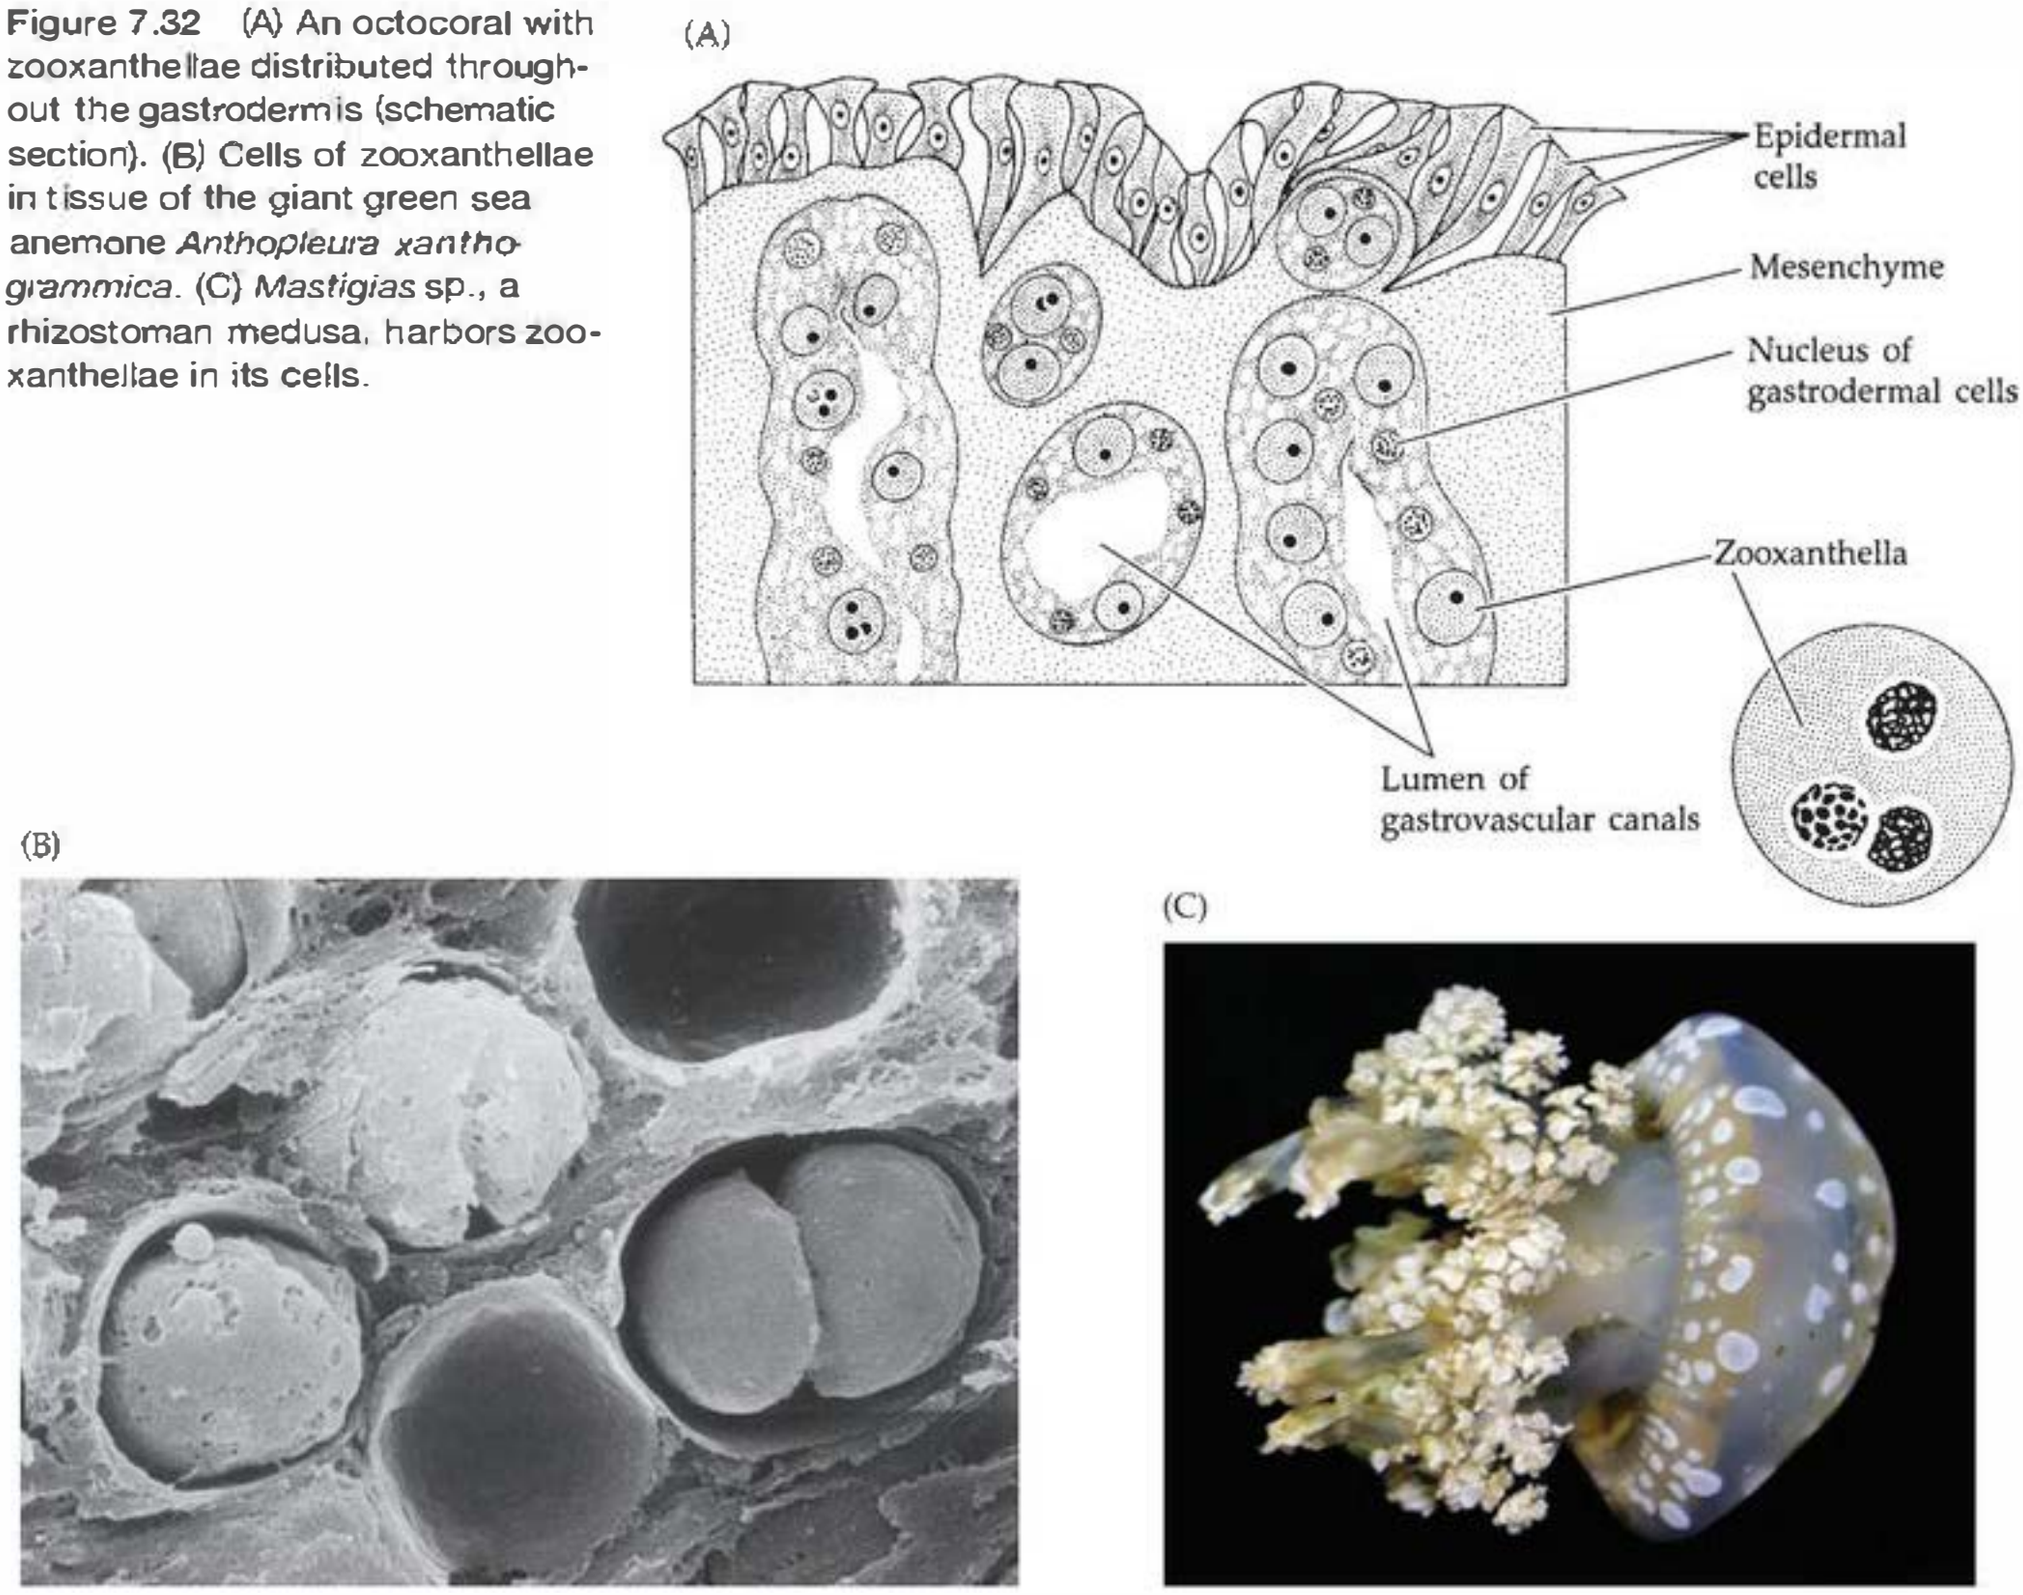

Figure 7.32 (A) An octocoral with zooxanthellae distributed throughout the gastrodermis (schematic section). (B) Cells of zooxanthellae in tissue of the giant green sea anemone *Anthopleura xanthogrammica*. (C) *Mastigias* sp., a rhizostoman medusa, harbors zooxanthellae in its cells.

free from their hosts, and perhaps do so normally, but very little is known about their natural history. The algae typically reside in the host's gastrodermis or epidermis, although some cnidarians harbor extracellular zooxanthellae in the mesoglea. It is usually the algal symbionts that give cnidarians their green, blue-green, or brownish color. Corals that are reef-builders (i.e., hermatypic corals) typically harbor zooxanthellae (they are "zooxanthellate corals"). Resident populations of zooxanthellae in these corals may reach a density of 30,000 algal cells per cubic millimeter of host tissue (or from 1 to 2 $\times 10^6$ cells per square centimeter of coral surface). Zooxanthellae also occur in many tropical octocorals, anemones, and zoanthids.

Surprisingly, both zoochlorellae and zooxanthellae occur within the tissues and cells of one group of sea anemones, *Anthopleura* of the northeast Pacific coast (*A. elegantissima* and *A. xanthogrammica*). Data suggest that zoochlorellae in these anemones photosynthesize more efficiently and grow faster at lower temperatures and light, whereas zooxanthellae do so under higher temperatures or light regimes. The two anemones are the most abundant rocky intertidal anemones in their range, from Alaska to Baja California, and the distributions of their two symbionts have been shown to be (predictably) related to latitude and intertidal position.

Even some scyphozoans harbor large colonies of zooxanthellae in their bodies, and it is now known that these protist colonies produce much of the energy required by their host jellyfish (e.g., *Cassiopea*, *Linuche*, *Mastigias*). Some of this information comes from studies on the scyphomedusa *Mastigias* (Figure 7.32C), which live in marine lakes on the islands of Palau, where they may occur in densities exceeding 1,000 per m^3. In these lakes, *Mastigias* makes daily vertical migrations between the oxygenated, nutrient-poor upper layers and the anoxic, nutrient-rich lower layers, as well as horizontal migrations to track the movement of the sun across the lake. This behavior appears to be related to the light and nutrient requirements of its symbiotic zooxanthellae. Unlike the zooxanthellae in benthic cnidarians, which tend to reproduce more-or-less evenly over a 24-hour period, the zooxanthellae of *Mastigias* show a distinct reproductive peak during the hours when their host occupies a position in the deeper nitrogen-rich layers of the lakes. This reproductive peak may be a result of the alga's use of free ammonia as a nutrient source.

Many cnidarians seem to derive only modest nutritional benefit from their algal symbionts, but in many others a significant amount of the hosts' nutritional needs appears to be provided by the algae. In such cases, a large portion of the organic compounds produced by photosynthesis of the symbiont may be passed on to the cnidarian host, probably as glycerol but also as glucose and the amino acid alanine In return, metabolic wastes produced by the cnidarian provide the symbiotic alga with needed nitrogen and phosphorus. In corals, the symbiosis is thought to be important for rapid growth and for efficient deposition of the calcareous skeleton, and many corals can only form reefs when they maintain a viable dinoflagellate population in their tissues Different coral species serve as hosts to genetically distinct algal symbiont taxa, which each appear to be adapted to their host as well as that host's particular ambient light regime. Although the precise physiological-nutritional link between corals and their zooxanthellae has been elusive, the algae clearly seem to increase the rate of calcium carbonate production. Corals and other cnidarians can be deprived of their algal symbionts by experimentally placing the hosts in dark environments. In such cases the algae may simply die, they may be expelled from the host, or they may (to a limited extent) actually be consumed directly by the host. Because they are dependent on light, zooxanthellate corals can live to depths of only 90 m or so. Most zooxanthellate corals also require warm waters and thus occur almost exclusively in shallow tropical seas (although zooxanthellae occur in some high altitude anemones). Deep water and cold water corals also exist but tend to be entirely carnivorous. They grow at extremely slow rates and thus tend to produce reefs that have existed for thousands and even millions of years, providing a detailed record of changes in sea temperature

Under stress, such as unusually high temperatures, corals may lose their zooxanthellae—a process known as coral bleaching. The long-term impact of coral bleaching, now accelerating throughout the world's tropics, perhaps due to a combination of warming seas and changes in oceanic acid–base balance due to increased atmospheric CO_2, is unclear. Certainly it seems detrimental in the short run, and often leads to death of entire coral colonies. In addition, anthropogenic pollution such as increases in phosphates, nitrates, and ammonia in the sea are enhancing growth of algae and bacteria that compete with coral. Caribbean reefs have been devastated over the last two decades, having lost about 80% of their coral cover. Interestingly, a few recent studies have suggested that bleaching might be an adaptive mechanism providing opportunity for acquiring new types of zooxanthellae better adapted to the changing environment. If true, it would remain to be seen if this symbiont switch could take place quickly enough to keep up with today's rapidly changing ocean chemistry. Evidence that selectivity between symbiotic partnerships may exist could mean slower symbiotic reassociations (i.e., certain combinations of hosts and algae are favored while others are impossible).

Loss of zooxanthellae by corals usually results in loss of the ability to secrete the calcium carbonate skeleton. The widespread disappearance of Caribbean corals is now considered responsible for a 32–72% decrease in reef fish populations, a potentially catastrophic change for coastal communities dependent on fishing. Coral reef biodiversity correlates with reef area, thus the long term effects of reef loss are likely to be cumulative and difficult to reverse. However, one recent experiment found that colonies of some coral species that lost their calcium carbonate skeleton continued to exist as soft bodied polyps. These recent discoveries have suggested a possible explanation for the geologically "sudden" appearance of the modern stony corals (Scleractinia) in the Middle Triassic, when geochemically perturbed oceans returned to "normal." Before this time, corals and reefs had disappeared from the fossil record for millions of years, but perhaps they continued to exist as "naked corals" (and thus not contributing to the fossil record).

Circulation, Gas Exchange, Excretion, and Osmoregulation

There is no independent circulatory system in cnidarians. The coelenteron serves this role to a limited extent by circulating partly digested nutrients through the interior of the body, absorbing metabolic wastes from the gastrodermis, and eventually expelling waste products of all types through the mouth. But large anemones and large medusae confront a serious surface area:volume dilemma. In such cases, the efficiency of the gastrovascular system as a transport device is enhanced by the presence of mesenteries in the anemones and the radially arranged canal system in the medusae. Cnidarians also lack special organs for gas exchange or excretion. The body wall of most polyps is either fairly thin or has a large internal surface area, and the thickness of many medusae is due largely to the gel like mesoglea or mesenchyme. Thus, diffusion distances are kept to a minimum. Gas exchange occurs across the internal and external body surfaces. Facultative anaerobic respiration occurs in some species, such as anemones that are routinely buried in soft sediments. Nitrogenous wastes are in the form of ammonia, which diffuses through the general body surface to the exterior or into the coelenteron. In freshwater species there is a continual influx of water into the body. Osmotic stress in such cases is relieved by periodic expulsion of fluids from the gastrovascular cavity, which is kept hypoosmotic to the tissue fluids

Nervous System and Sense Organs

Consistent with their radially symmetrical body plan, cnidarians generally have a diffuse, noncentralized

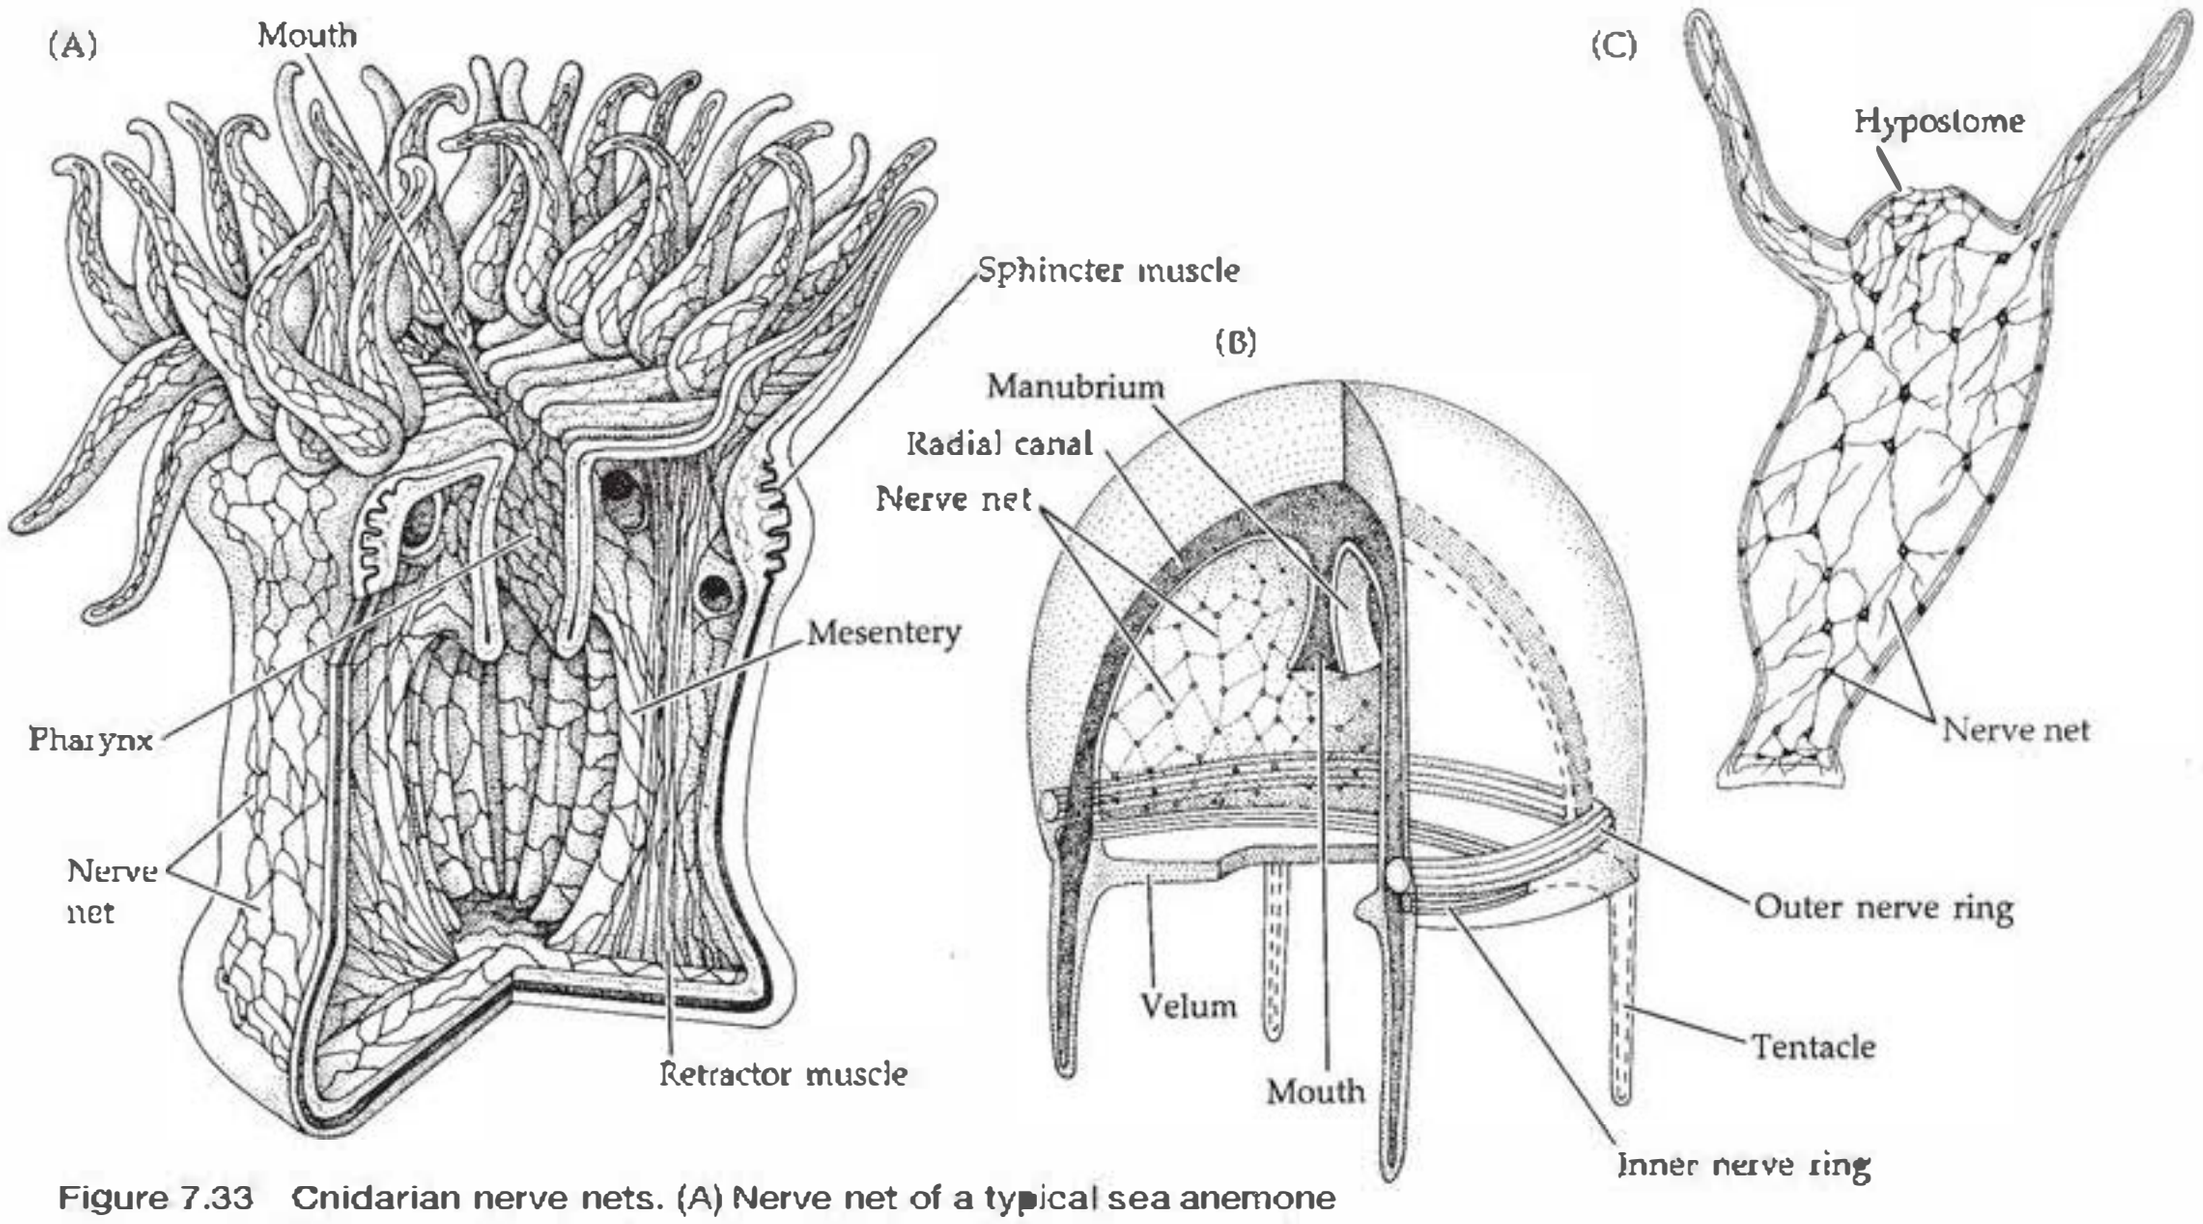

Figure 7.33 Cnidarian nerve nets. (A) Nerve net of a typical sea anemone (Anthozoa). (B) Nerve net in a hydromedusa (Hydrozoa). (C) Nerve net of *Hydra* (Hydrozoa).

nervous system, however great variation exists. Strong centralization is seen in many hydrozoans and cubozoans, and some workers feel those even qualify as central nervous systems. Nonetheless, the neurosensory cells of the system are the most primitive in the animal kingdom, being naked and largely nonpolar. Usually the neurons are arranged in two reticular arrays, called nerve nets, one between the epidermis and the mesenchyme and another between the gastrodermis and the mesenchyme (Figure 7.33). The presence of both ectodermal and endodermal nerve nets is unique to the Cnidaria. The subgastrodermal net is generally less well developed than the subepidermal net and is absent altogether in some species; in cubozoan polyps there is a nerve net *within* the gastrodermis. Some hydrozoan medusae possess one or two additional nerve nets, whereas in the polyps of hydrozoans and cubozoans there appears to be only a single epidermal nerve ring. Despite the seeming simplicity of cnidarian nervous systems, it has been shown that they possess at least some of the classic interneuronal and neuromuscular synapse neurotransmitters seen in Bilateria, including serotonin, suggesting that both catecholamine and indolamine neurotransmitters may be present (at least in sea anemones).

A few nerve cells and synapses are polarized and allow for transmission in only one direction, but most cnidarian neurons and synapses are nonpolar—that is, impulses can travel in either direction along the cell or across the synapse. Thus, sufficient stimulus sends an impulse spreading in every direction. In some cnidarians where both nerve nets are well developed, one net serves as a diffuse slow-conducting system of nonpolar neurons, and the other as a rapid through-conducting system of bipolar neurons.

Polyps generally have very few sensory structures. The general body surface has various minute hairlike structures developed from individual cells. These serve as mechanoreceptors, and perhaps as chemoreceptors, and are most abundant on the tentacles and other regions where cnidae are concentrated. They are involved in behavior such as tentacle movement toward a prey or predator and in general body movements. Some appear to be associated specifically with discharged cnidae, such as the ciliary cone apparatus of anthozoan polyps, which is believed to function like the cnidocil in hydrozoan and scyphozoan nematocysts (Figure 7.34). Oddly, these structures do not appear to be connected directly to the nerve nets. In addition, most polyps show a general sensitivity to light, not mediated by any known receptor but presumably associated with neurons concentrated in or just beneath the translucent surface of epidermal cells.

As might be expected, motile medusae have more sophisticated nervous systems and sense organs than do the sessile polyps (Figure 7.35). In many groups, especially the hydromedusae, the epidermal nerve net of the bell is condensed into two nerve rings near the bell

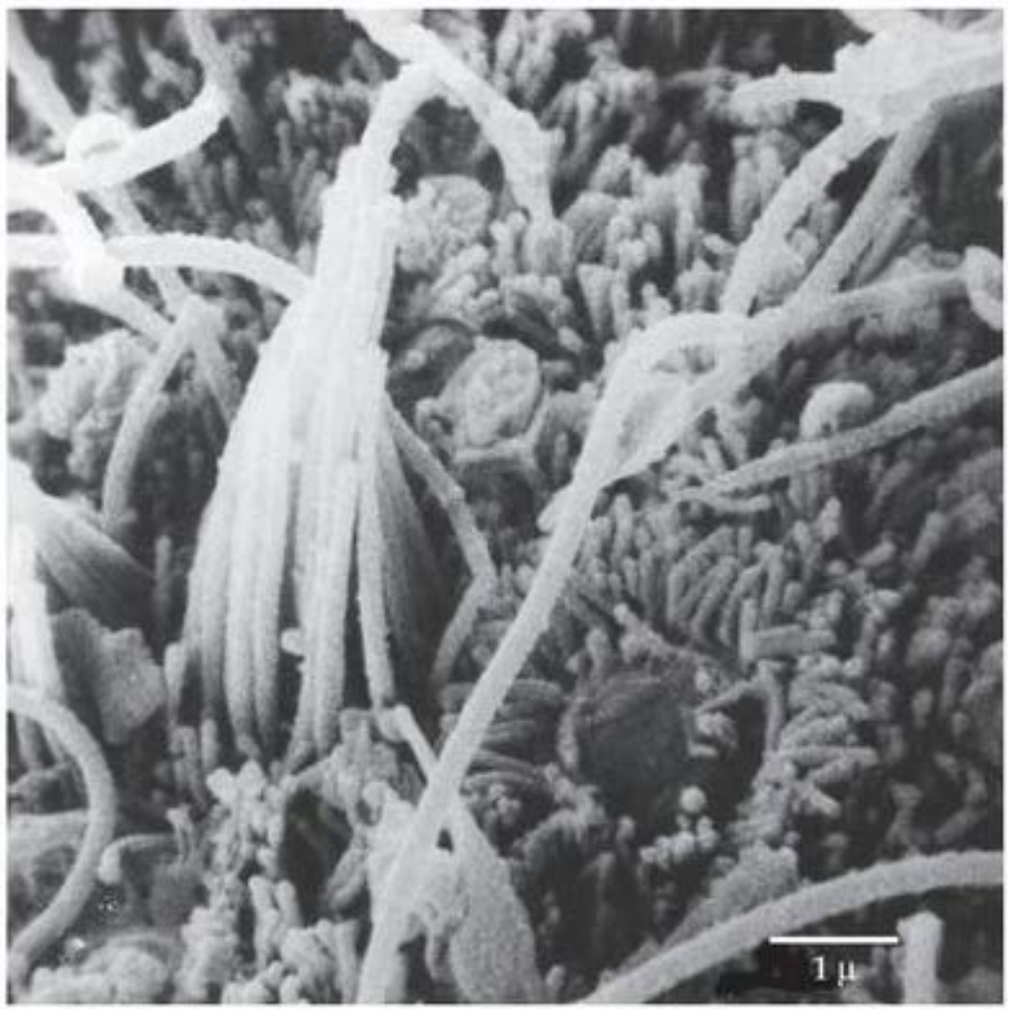

Figure 7.34 A ciliary cone on the tentacle of the coral-limorpharian anemone *Corynactis californica* lies adjacent to cnidocyte (the circle of microvilli).

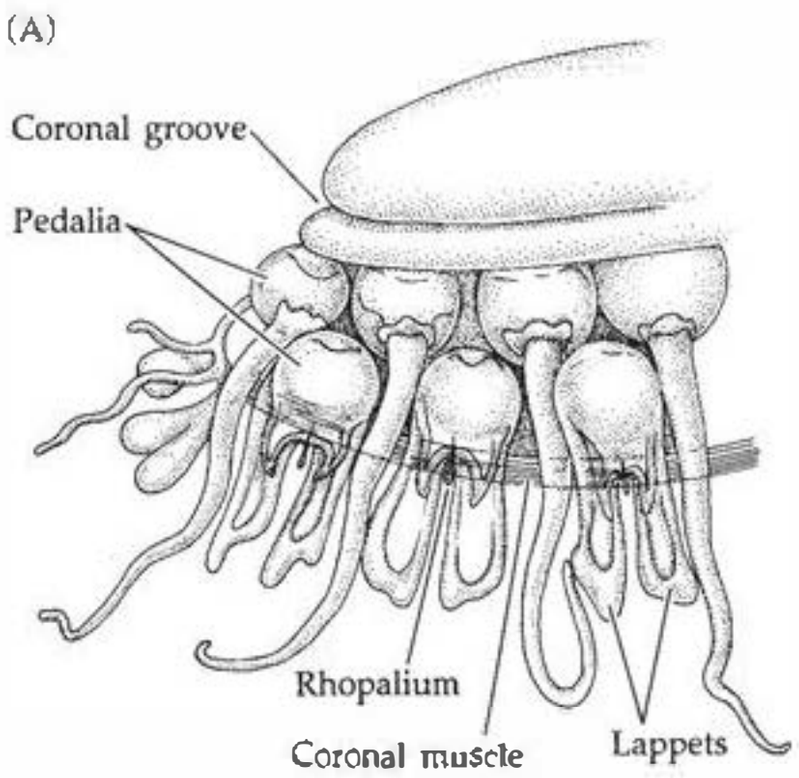
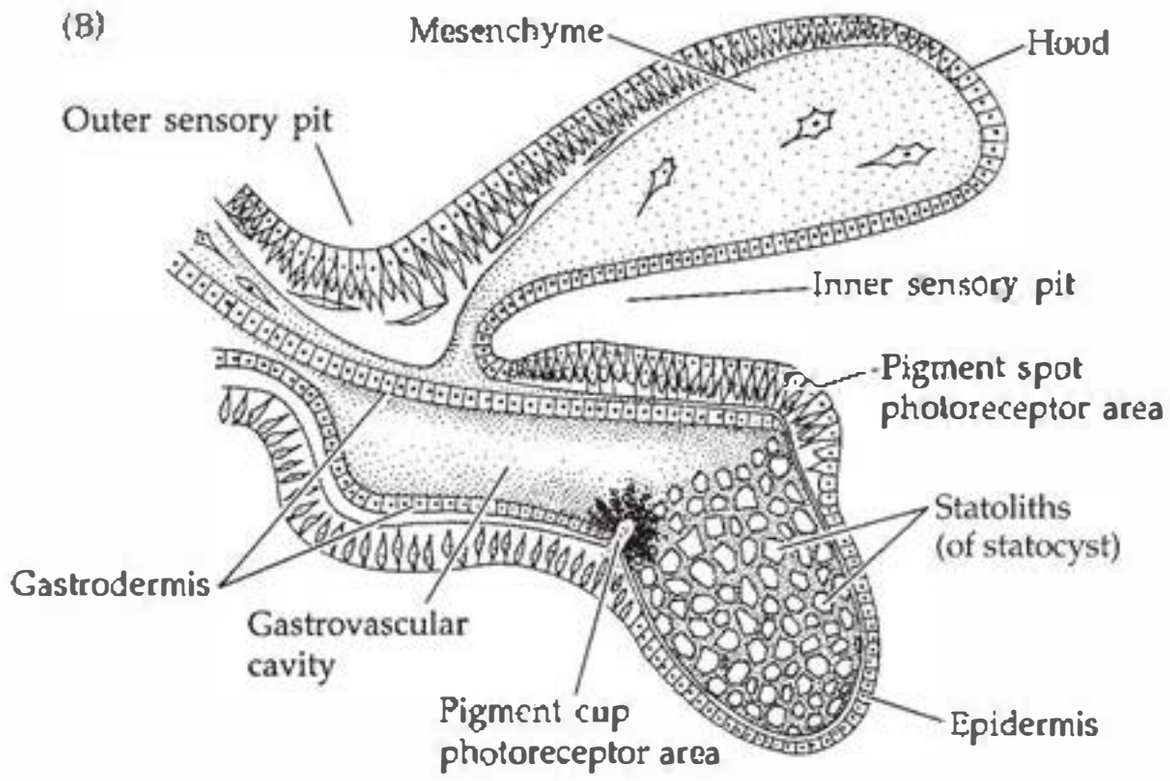
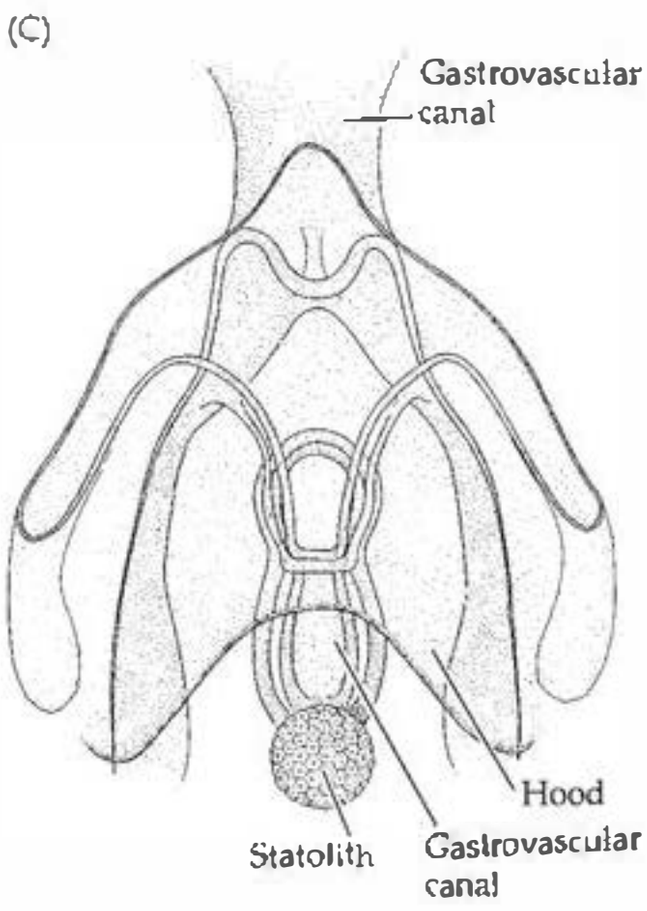
margin. These nerve rings connect with fibers enervating the tentacles, muscles, and sense organs. The inner ring stimulates rhythmic pulsations of the bell. This ring is also connected to statocysts, when present, on the bell margin, which is supplied with general sensory cells and with radially distributed ocelli and (probably) chemoreceptors. The general sensory cells are neurons whose receptor processes are exposed at the epidermal surface. The ocelli are usually patches of pigment and photoreceptor cells organized as a disc or a pit. Statocysts may be in the form of pits or closed vesicles, the latter housing a calcareous statolith adjacent to a sensory cilium. When one side of the bell tips upward, the statocysts on that side are stimulated. Statocyst stimulation inhibits adjacent muscular contraction and the medusa contracts muscles on the opposite side. Many medusae maintain themselves in a particular photoregime by directed swimming behaviors. This action is seen especially in those medusae harboring large populations of zooxanthellae, such as the medusa *Cassiopea*, which lies upside down on the shallow sea floor, exposing to light the dense zooxanthellae population residing in tissues of its tentacles and oral arms.



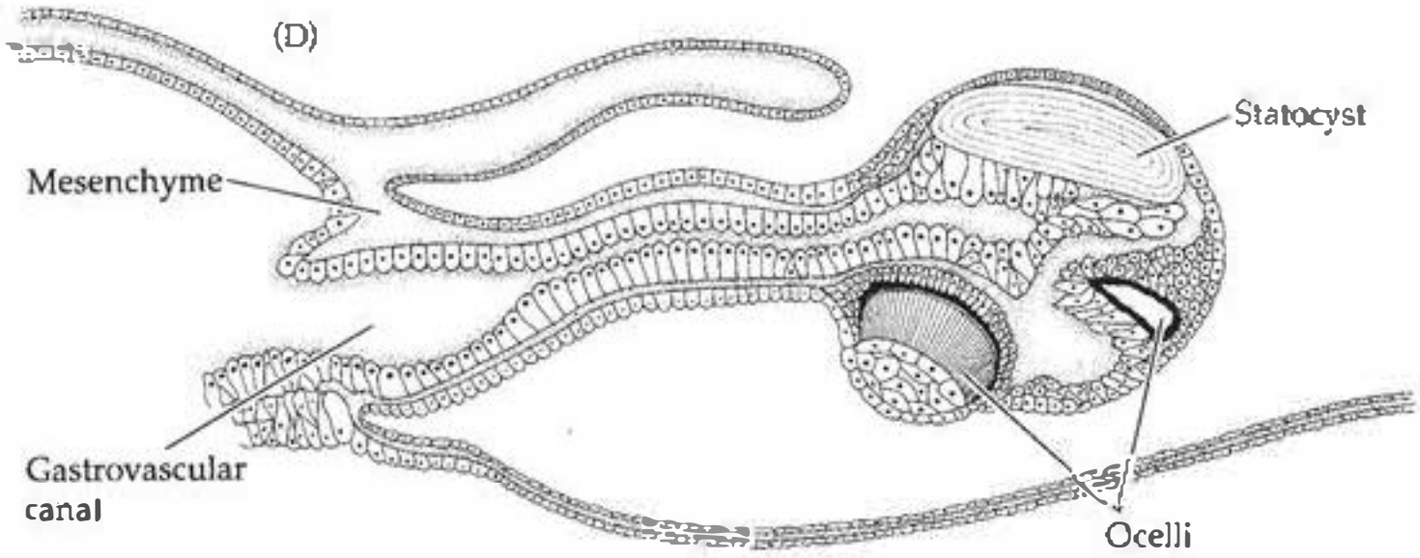
There is great variation among hydrozoan medusae visual systems. Some have structural eyes, but others have only a generally photosensitive neuronal system. The structural eyes are usually well-defined ocelli that very in complexity from a simple ectodermal layer with sensory and pigment cells, through pigment cup eyes, to small camera-type eyes with pigmented retina and lens- or cornea-like structures. The axons of the photosensory cells may join in bundles that collect to form an "optic nerve," that runs to the outer nerve ring in the bell. In addition, hydrozoans have been shown to possess a cytoplasmic conducting system similar in nature to that of sponges. Epidermal cells and muscle elements appear to be the principal components of the system. Although the impulse seems to move slowly, it is initiated by nerve cells and relies on gap junctions.



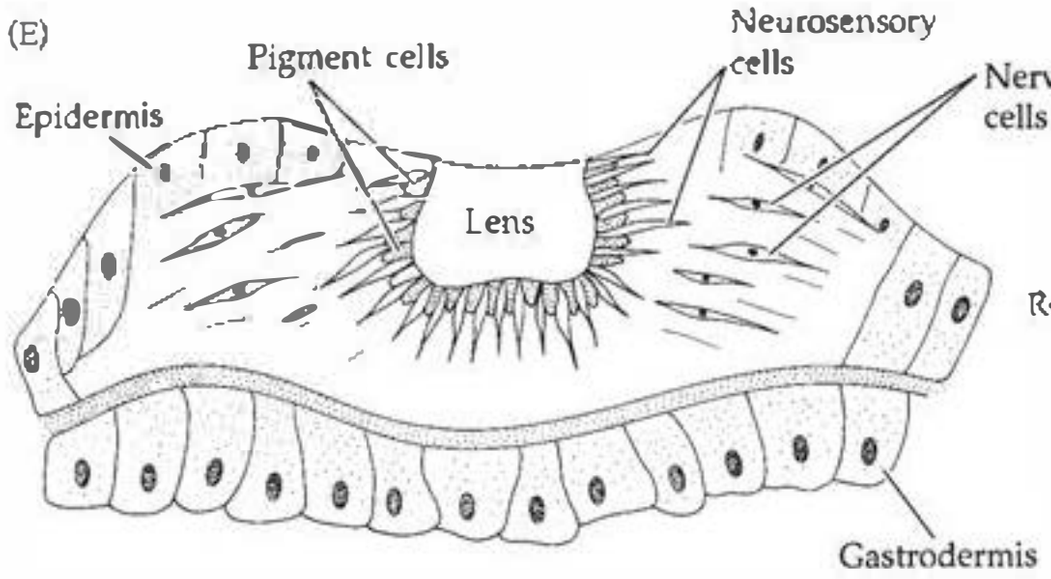
In the codonophoran siphonophores, a linear condensation of the nerve net produces longitudinal "giant axons" in the stem and the nerve tracts in the tentacles. This longitudinal "giant axon" is actually a neuronal syncytium that originates by fusion of neurons from the nerve net of the stem. The high-speed impulses in these large diameter nerve tracts enable codonophorans to contract rapidly and initiate a fast escape reaction.



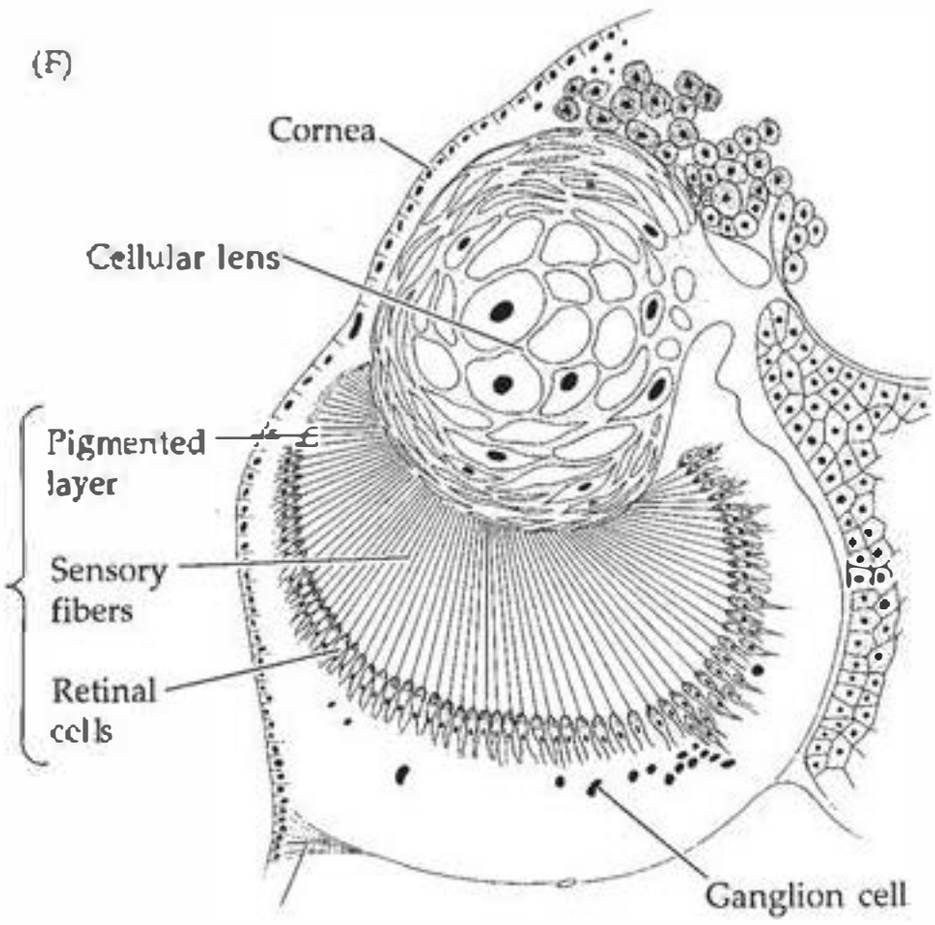
The bell margins of cubomedusae and scyphomedusae usually bear club shaped structures—called **rhopalia** that are situated between a pair of flaps, or **lappets** (Figure 7.35A). The rhopalia are sensory centers, each containing a concentration of epidermal neurons, a pair of chemosensory pits, a statocyst, and eyes of various design One pit is located on the exumbrellar side of the hood of the rhopalium, the other on the subumbrellar side.



Cubomedusae are strong swimmers that are able to make rapid directional changes in response to visual stimuli. They have been shown to be attracted to light, to avoid dark objects, and even to navigate around obstacles. They are active predators that "sleep" at night. Although cubomedusae have the basic cnidarian nerve net and subumbrellar nerve ring close to the bell margin (sometimes called the ring nerve), they also have the most elaborate visual system in Cnidaria, located on four rhopalia (sensory complexes). Each rhopalium has three sets of eyes: paired pitshaped pigment cup eyes, paired slitshaped pigment cup eyes, and two complex cameratype eyes with cornea, lens, and retina (one small upper lensed eye, and one large lower lensed eye). Although the retina of the camera eye is only one cell thick, it is multilayered, containing a sensory layer, a pigmented layer, a nuclear layer, and a region of nerve fibers. There number of sensory cells, or photoreceptors, in each of these remarkable eyes varies from about 300 to 1,000, depending on the species. Each rhopalium also has a crystalline concretion, the statolith, which is often called a statocyst. Neuronal signals from the rhopalia are presumably transmitted to swimming pacemaker neurons to direct visually-guided swimming movements. Giant neurons have been identified on either side of the cubomedusan rhopalium.



Despite the structural simplicity of the cubozoan planula larva, being composed of only six cell types, they possess rhabdomeric photoreceptors of the pigment-cup ocelli type. These comprise 10–15 ocelli arranged as individual photoreceptor cells. Each contains



screening pigment in a cavity filled with microvilli (the sites of photoreception) and a single cilium. The cilium is the typical 9+2 structure and is likely motile, rather than sensory. There is no synaptic or electrical (gap junction) connection between the ocelli and any other cell in the larva. The ocelli of cubozoan planulae appear to represent one of the simplest visual systems in the animal kingdom.

Scyphozoan medusae have structurally simple visual eyespots located in the rhopalia, which also contain

Figure 7.35 Sensory structures in medusae. (A) The rhopalia of the scyphomedusa *Atolla* are situated between the marginal tappets. (B) A rhopalium (section) has various sensory regions. (C) A rhopalium of *Aurelia* (diagrammatic). A portion of the gastrovascular canal has been cut away. (D) A cubozoan rhopalium (note the lower eye is not shown in this oblique section). (E) A pigment-cup ocellus (cross section) of a hydrozoan medusa. (F) The eye of a cubozoan (*Carybdea*) (cross section).

gravity-sensing structures, the statocysts. The eyespots are simple ectodermal pigment cup eyes, consisting of photosensory cells containing pigment granules, or of photosensory cells alternating with pigment cells, or pigment cup eyes with ectodermal sensory cells and gastrodermal pigment cells. The sensory cells make contact with the ectodermal nerve net.

Bioluminescence is common in cnidarians and has been documented in all classes except the Cubozoa and the poorly known Staurozoa. In some forms (e g., many hydromedusae), luminescence consists of sin gle flashes in response to a local stimulus. In others, bursts of flashes propagate as waves across the body or colony surface (e g , sea pens and sea pansies). One of the most complicated luminescent behaviors occur in hydropolyps, where a series of multiple flashes is propagated. The sea pansy *Renilla* (an octocoral) also has very elaborate luminescent displays. Propagated luminescence is probably controlled by the nervous system, although this phenomenon is not well understood. In at least one hydromedusa (*Aequorea*), luminescence appears not to be the result of the usual luciferin luciferase reaction. Rather, a high-energy protein, named aequorin, emits light in the presence of calcium.

Reproduction and Development

Asexual reproduction takes many forms in cnidarians, and regeneration after major injuries is common. Many anemones can be cut in half, and the two halves regenerate flawlessly. Sometimes injuries to the oral region result in the production of two or more mouths, each with its own set of feeding tentacles.

Sexual reproductive processes in cnidarians are intimately tied to the alternation of generations that characterizes this phylum. As you have already read, cnidarian life cycles often involve an asexually reproducing polyp stage, alternating with a sexual medu soid stage that produces a characteristic planula larva. Thus, we generally find a complex indirect or mixed life history that includes phases of asexual reproduc tion. Anthozoan development is least complex, usually involving a motile planula larva that settles and grows into a sessile adult polyp. Cubozoans also have motile planulae, which settle to grow into polyps that in turn produce sexual medusae. Scyphozoans too follow the planula to sessile-polyp mode, but the polypoid stage generates multiple juvenile medusa, called **ephyrae**, by transverse fission or strobilation at the polyp's oral end; ephyrae later mature as the sexual medusoid stage. Planulae, polyps, and medusa all appear in many hydrozoan species' life cycles. Medusae, when present, develop from a laterally budding tissue mass called the entocodon, but polyp or medusa stages may be entirely missing from certain life cycles. Because of these many variations in life cycle, we will discuss the cnidarian classes separately.

Anthozoan reproduction Members of this class are exclusively polypoid, and the variety of ways that new individuals can be produced asexually nearly defies imagination. Asexual reproduction is common in sea anemones, and longitudinal fission of polyps can result in two separate individuals, or the daughter anemones can remain close together to produce large groups (clones) of genetically identical individuals (e.g., seen in some species of *Anthopleura*, *Diadumene*, and *Metridium*). During longitudinal fission, the body column stretches to the point of ripping itself apart, each half then regen erating its missing parts. The less common process of pedal laceration (e g , seen in some acontiate sea anemones· *Diadumene*, *Haliplanella*, *Metridium*) can also lead to clonal populations. During pedal laceration, the pedal disc spreads and the anemone simply glides away, leaving behind a circle of small fragments of the disc, each of which develops into a young sea anemone. This behavior is easily observed in aquaria, where anemones often affix themselves to the glass walls.

In addition to these two common modes of asexual reproduction, at least a few species of sea anemones undergo transverse fission (e.g., *Edwardsiella lineata*, *Nematostella vectensis*). Transverse fission is usually by way of a constriction and then separation in the lower part of the column that results in the formation of a small aboral compartment and a larger oral region, each of which then grows its missing region. Transverse fis sion has also been reported by a process called "polarity reversal," i n which the aboral end spontaneously sprouts new tentacles and a new mouth; eventually a new physa forms in the midsection of the anemone and the two individuals separate (e.g., *Gonactinia*). Certain sagartiid sea anemones engage in intratentacular budding, wherein multiple mouth openings result from repeated longitudinal fission through the pharynges of existing individuals. This process produces band-like like colonies that resemble the elongated polyps of certain meandroid corals. Also, certain populations of *Anthopleura* engage in mesenterial budding of tiny polyps, which are brooded within the gastrovascular cavity before release from the parent anemone. In these anemones, no evidence of gonadal or gametic development has been found, suggesting that these populations are primarily if not entirely asexual.

One family of sea anemones (Boloceroidae) swims actively and produces new individuals from longitudinal fission, pedal laceration, and a bizarre process called tentacular shedding (or tentacle budding) in which tentacle fragments are pinched off at basal sphincters and brooded internally before dispersal. Additionally, certain anemones and at least one scleractinian coral (*Pocillopora damicornis*) are known to produce planula larvae parthenogenetically and brood them until release. Most surprising is the recent discovery that some sea anemones internally brood young that are asexually produced, by a mechanism not yet understood.

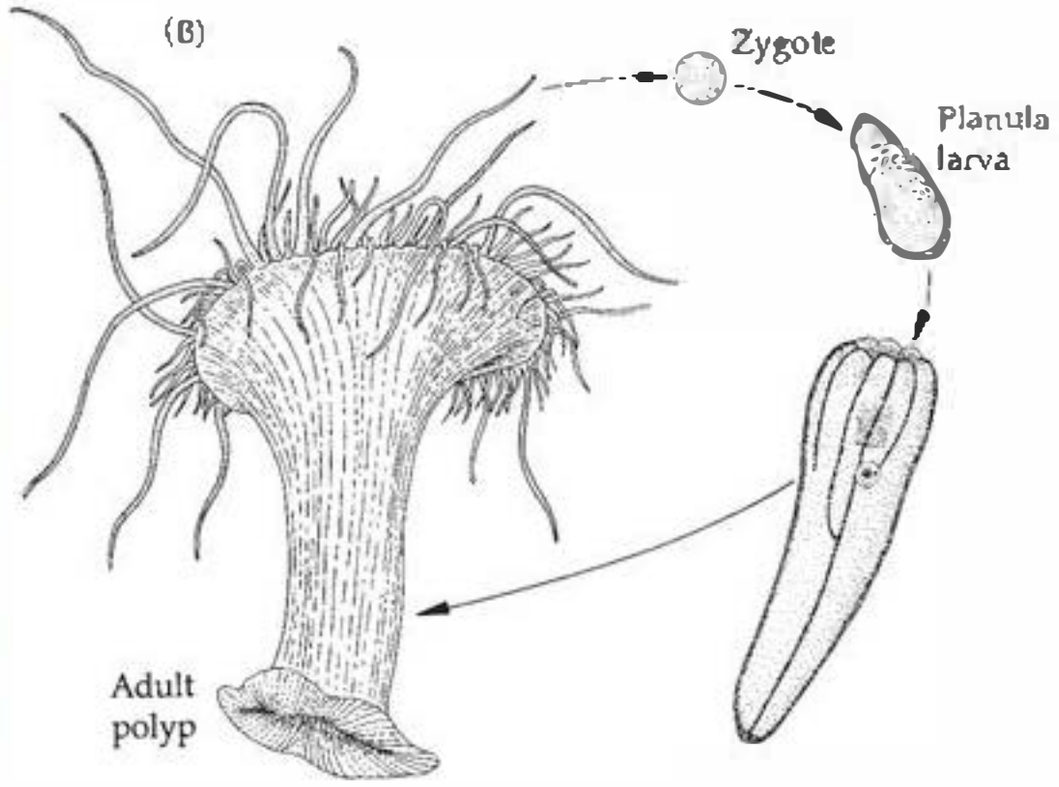


Figure 7.36 Reproduction in Anthozoa. (A) Asexual reproduction by longitudinal fission in the aggregating anemone *Anthopleura elegantissima*. (B) A typical anthozoan sexual life cycle: the adult polyp releases gametes which fuse externally, or fertilized eggs are released, and zygotes develop into a planula larvae; the larvae settle and transform directly into young polyps.

Anthozoans are typically gonochoristic, although most scleractinian corals are hermaphroditic. Fertilization can take place internally, but in most species it occurs externally, in the open sea. Eggs are free, or occasionally pooled into a gelatinous egg mass (even through fertilization). Sperm is usually equipped with flagellar and mitochondrial structures suited for propelling sperm to eggs, although structural differences among anthozoan sperm are remarkable indeed. Cleavage is typically radial and holoblastic, resulting in a hollow spherical, uniformly ciliated, coeloblastula. Gastrulation occurs by way of ingression or invagination, to produce distinct ectodermal and endodermal germ layers, and thence a ciliated planula larva. When invagination occurs, the blastopore remains open and sinks inward, drawing with it a tube of ectoderm that becomes the adult pharynx. Because the mouth forms at the site of gastrulation (at the animal pole), anemones/cnidarians are, by definition, true protostomes, suggesting that protostomy predated the cnidarian–bilaterian divergence. The planula larva may develop one or a few pairs of tentacles at the oral end, as well as a rudimentary pharynx and mesenteries, before settling. Some anthozoan planulae are planktotrophic, although very yolky ones do not feed. The ability of some larvae to feed allows them a potentially longer larval life, enhancing dispersal and selection of an appropriate settlement site. Anthozoan planulae (*Anthopleura*) also appear to obtain zooxanthellae by ingestion. In some species, the planulae develop up to eight complete mesenteries before settling, and this is the so-called edwardsia stage, named after the octamesenterial genus *Edwardsia*. The larva eventually settles on its aboral end and tentacles grow around the upwardly directed mouth and oral disc. A typical anthozoan life cycle is shown in Figure 7.36.

Octocorals are usually gonochoristic and often spawn synchronously, although the timing of gonadal development appears to be highly variable among temperate and tropical species, evidently due to variability in water temperature or resource availability, respectively. Although little is known about the reproductive biology of most ceriantharians, antipatharians, anemones, and stony corals may be gonochoristic or hermaphroditic. In some species, colonial forms can contain males, females, and hermaphrodites. The gametes arise from patches of tissue on the gastrodermis of all or only some mesenteries. Eggs are fertilized either in the coelenteron, followed by early development in the gut chambers, or more commonly outside the body, in the sea. A number of anemones brood their developing embryos internally or on the external body surface. The northeast Pacific sea anemone *Aulactinia incubans* releases its brooded young through a pore at the tip of each tentacle! Some corals undergo internal fertilization, brooding, and then release of planula larvae. The solitary coral *Balanophyllia elegans* builds skeletal chambers within which oocytes and embryos may be carried apart from the main digestive cavity, a structural arrangement that allows continued brooding through advanced developmental stages. These calcareous structures are preserved in the fossil record, perhaps providing clues to how parental care in these species evolved. Some octocorals (e.g., *Briareum*, *Alcyonium*) brood their embryos in a mucous coat on the body surface; then the planula larvae escape. Others shed their gametes and rely on external fertilization and planktonic development. *Heliopora coerulea* is a gonochoristic, hermatypic octocoral that broods its planulae at the surface of female colonies before their annual release.

Some coral planula larvae are long-lived, spending several weeks or months in the plankton, an obvious

means of dispersal. Other corals release benthic planulae that crawl away from the parent and settle nearby. Many coral populations undergo synchronous spawning over large areas on reefs, a process mediated by moonlight sensitive molecules called cryptochromes, which have also been associated with control of circadian activity in vertebrates and insects. In some cases this synchrony is restricted to colonies of a single species, or is only loosely correlated with lunar cycles, but widespread synchronous spawning events involving over 100 different coral species have been reported (on the Great Barrier Reef, Australia), perhaps to satiate predators. Such events create a pulse of nutrients into the surrounding ecosystem, and may lead to hybridization within and among scleractinian corals. Verified cases of hybridization between members of different coral genera exist, and this may explain the great range of polymorphism seen in many coral "species." Because hybrid individuals can become secondarily clonal they may persist within populations for considerable durations, but the degree to which interbreeding by hybrids or their introgression into parental populations occurs remains unclear

Sagartia troglodytes is the only sea anemone known to copulate. The coupling starts when a female glides up to a receptive male, whereupon their pedal discs are pressed together in such a way as to create a chamber into which the gametes are shed and fertilization occurs. The copulatory position, which forms a temporary marsupium, is maintained for several days, presumably until planula larvae have developed. This behavior may be an adaptation to areas of great water movement that might otherwise scatter gametes and reduce the probability of successful fertilization

Recent work on the sea anemone *Nematostella vectensis* has revealed cnidarians to possess some (but not all) of the genes involved in dorsal ventral patterning in the Bilateria. Although these homologs are expressed in somewhat haphazard ways during development, their expression has suggested to some workers the possibility that the oral aboral polarity of cnidarians might be equivalent to the anterior posterior polarity of bilaterians In fact, homologues of 5 Hox genes known to regulate anterior–posterior axis patterning in Bilateria are also known from *N vectensis*. These genes show a staggered domain expression in the oral aboral axis patterning of the anemone. This suggests that the earliest stages of what was to become bilaterality had its roots at least as deep in the evolution of the Metazoa as the Cnidaria. Thus, what we recognize as "biradiality" in anemones (e.g., the right–left arrangement of feeding tentacles, pharyngeal siphonoglyph, coelenteron mesenteries) might, in fact, be a rudimentary form of bilaterality.

Scyphozoan reproduction The life cycles of most scyphozoans are poorly known because their benthic stages occur in yet unknown locations. However, known species share several common features. The asexual form of scyphozoan cnidarians is a small polyp called the scyphistoma (= scyphopolyp; Figure 7.37A). It may produce new scyphistomae by budding from the column wall or from stolons. At certain times of the year, generally in the spring, medusae are produced by repeated transverse fission of the scyphistoma, a process called strobilation (Figure 7.37B). During this process the polyp is known as a strobila. Medusae may be produced one at a time (monodisc strobilation), or numerous immature medusae may stack up like soup bowls and then be released one after the other as they mature (polydisc strobilation). Immature and newly released medusae are called ephyrae (sing. ephyra). An individual scyphistoma may survive only one strobilation event, or it may persist for several years, asexually giving rise to more scyphistomae and releasing ephyrae annually

Ephyrae are very small larval animals with characteristically incised bell margins (Figure 7.37C). The ephyral arms, or primary tentacles, mark the position of what becomes the adult lappets and rhopalia. In some genera (e.g., *Aurelia*) the number of ephyral arms is quite variable (Figure 7.37D). Maturation involves growth between these arms to complete the bell. Development into sexually mature adult scyphomedusae takes a few months to a few years, depending on the species.

The gamete-forming tissue in adult scyphomedusae is always derived from the gastrodermis, usually on the floor of the gastric pouches, and gametes are generally released through the mouth. Most species are gonochoristic. Fertilization takes place in the open sea or in the gastric pouches of the female. Cleavage and blastula formation are similar to the processes in hydrozoans. Gastrulation is by ingression or invagination, and results in a mouthless, doublelayered planula larva; when invagination occurs, the blastopore closes. The planula larva eventually settles and grows into a new scyphistoma.

The medusa phase clearly dominates the life cycles of most scyphozoans. The small polyp stage is often significantly suppressed or absent altogether For example, many pelagic scyphomedusae have eliminated the scyphistoma, and the planula larva transforms directly into a young medusa (e.g., *Atolla*, *Pelagia*, *Periphylla*). In others, the larvae are brooded, developing in cysts on the parent medusa's body (e.g., *Chrysaora*, *Cyanea*). A few genera have branching colonial scyphistomae with a supportive skeletal tube and an abbreviated medusoid stage (e.g., *Nausithoe*, *Stephanoscyphus*). None, however, has lost the medusoid stage altogether. Some scyphozoan life cycles are shown in Figure 7.38.

Cubozoan reproduction The biology of cubozoans is not yet well known and the polyps of only a few

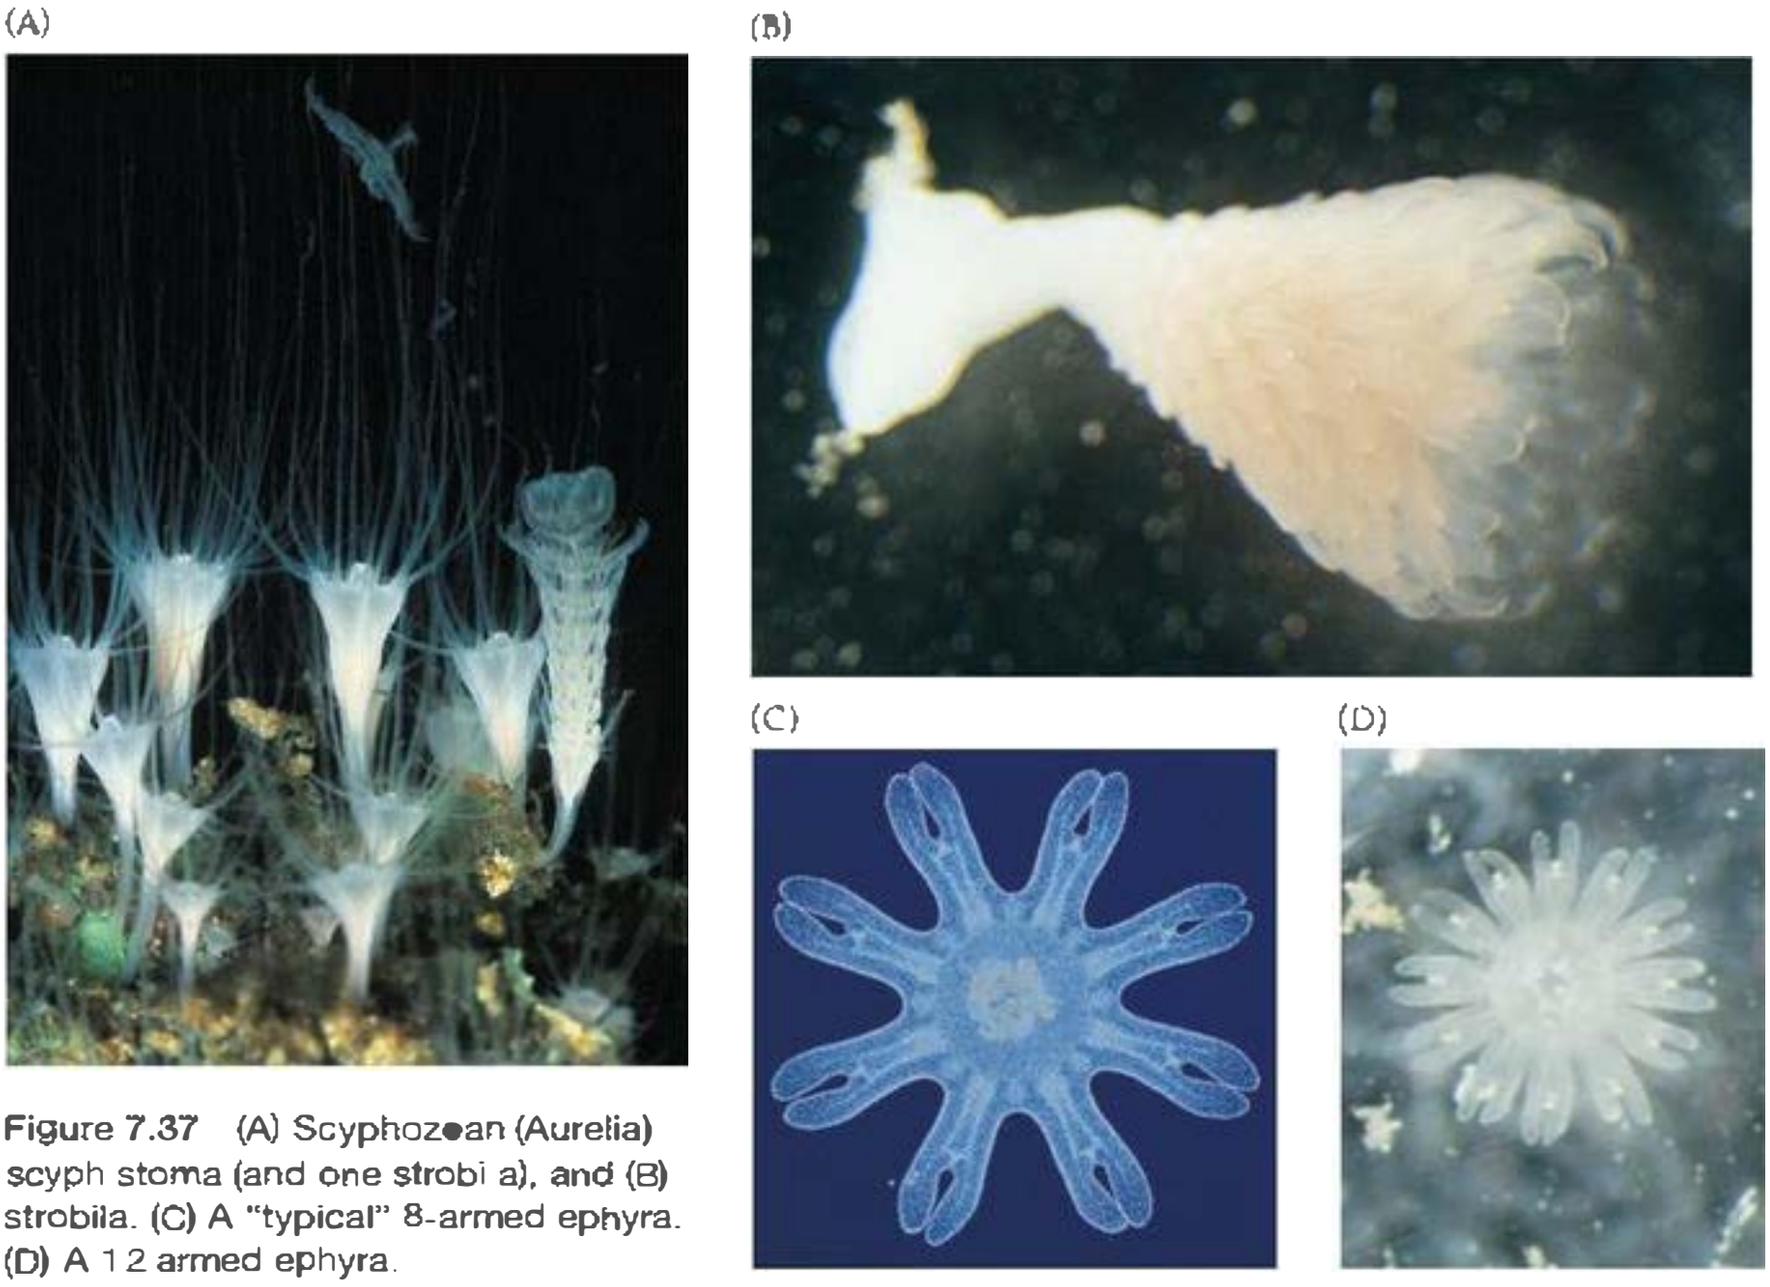

Figure 7.37 (A) Scyphozoan (*Aurelia*) scyph stoma (and one strobila), and (B) strobila. (C) A "typical" 8-armed ephyra. (D) A 12 armed ephyra.

species have been described. Apparently, each polyp metamorphoses directly into a single medusa, rather than undergoing "standard" strobilation as scyphozoan polyps do. Some cubozoan medusae engage in a form of copulation, in which sperm are transferred directly from the male to an adjacent female in the water column. In *Copula sivickisi* mature adults engage in courtship during which males transfer spermatophores to females who then insert them into their manubria. Females accept multiple spermatophores from multiple males, yet may only produce one embryostrand (a packet of fertilized ova that attaches to algae). During courtship, mature females, with bell margins greater than 5 mm, exhibit conspicuous velar spots that may provide a visual signal to courting males. Planula larvae of some cubozoans have been shown to possess many single celled eyes, but no nervous system!

Staurozoan reproduction Reproduction in staurozoans has been observed in only a few species. In mature medusae, oocytes develop within follicular cells, a unique feature within the Cnidaria. Fertilization appears to occur in situ with zygotes shed into the water in summer The zygotes then settle, and develop into creeping, nonciliated planulae, each with a fixed number of cells ($n = 16$). Planulae develop into a non feeding "microhydrula" stage which may asexually produce creeping frustrules, that later develop into stauropolyps, or the microhydrula may develop into stauropolyps themselves, which later develop into stauromedusae.

Hydrozoan reproduction Hydrozoan polyps reproduce asexually by budding. This is a rather simple process wherein the body wall evaginates as a bud, incorporating an extension of the gastrovascular cavity with it. A mouth and tentacles arise at the distal end, and eventually the bud either detaches from the parent and becomes an independent polyp or, in the case of colonial forms, remains attached. Asexual reproduction in this fashion creates larger and more complex polypoid colonies that have greater reproductive capacity and perhaps greater resistance to rapid or turbulent water flow.

Medusa buds, or gonophores, are also produced by polyps in a similar fashion, although the process is sometimes quite complex. A rather special kind of budding occurs in the siphonophores, in which the floating colonies produce chains of individuals called **cormidia**, which may break free to begin a new colony.

Certain hydromedusae also undergo asexual reproduction, either by the direct budding of young medusae (Figure 7.39) or by longitudinal fission. The latter process often involves the formation of multiple gastric pouches (**polygastry**) followed by longitudinal splitting, which produces two daughter medusae. In some species (e.g., *Aequorea macrodactyla*), direct fission

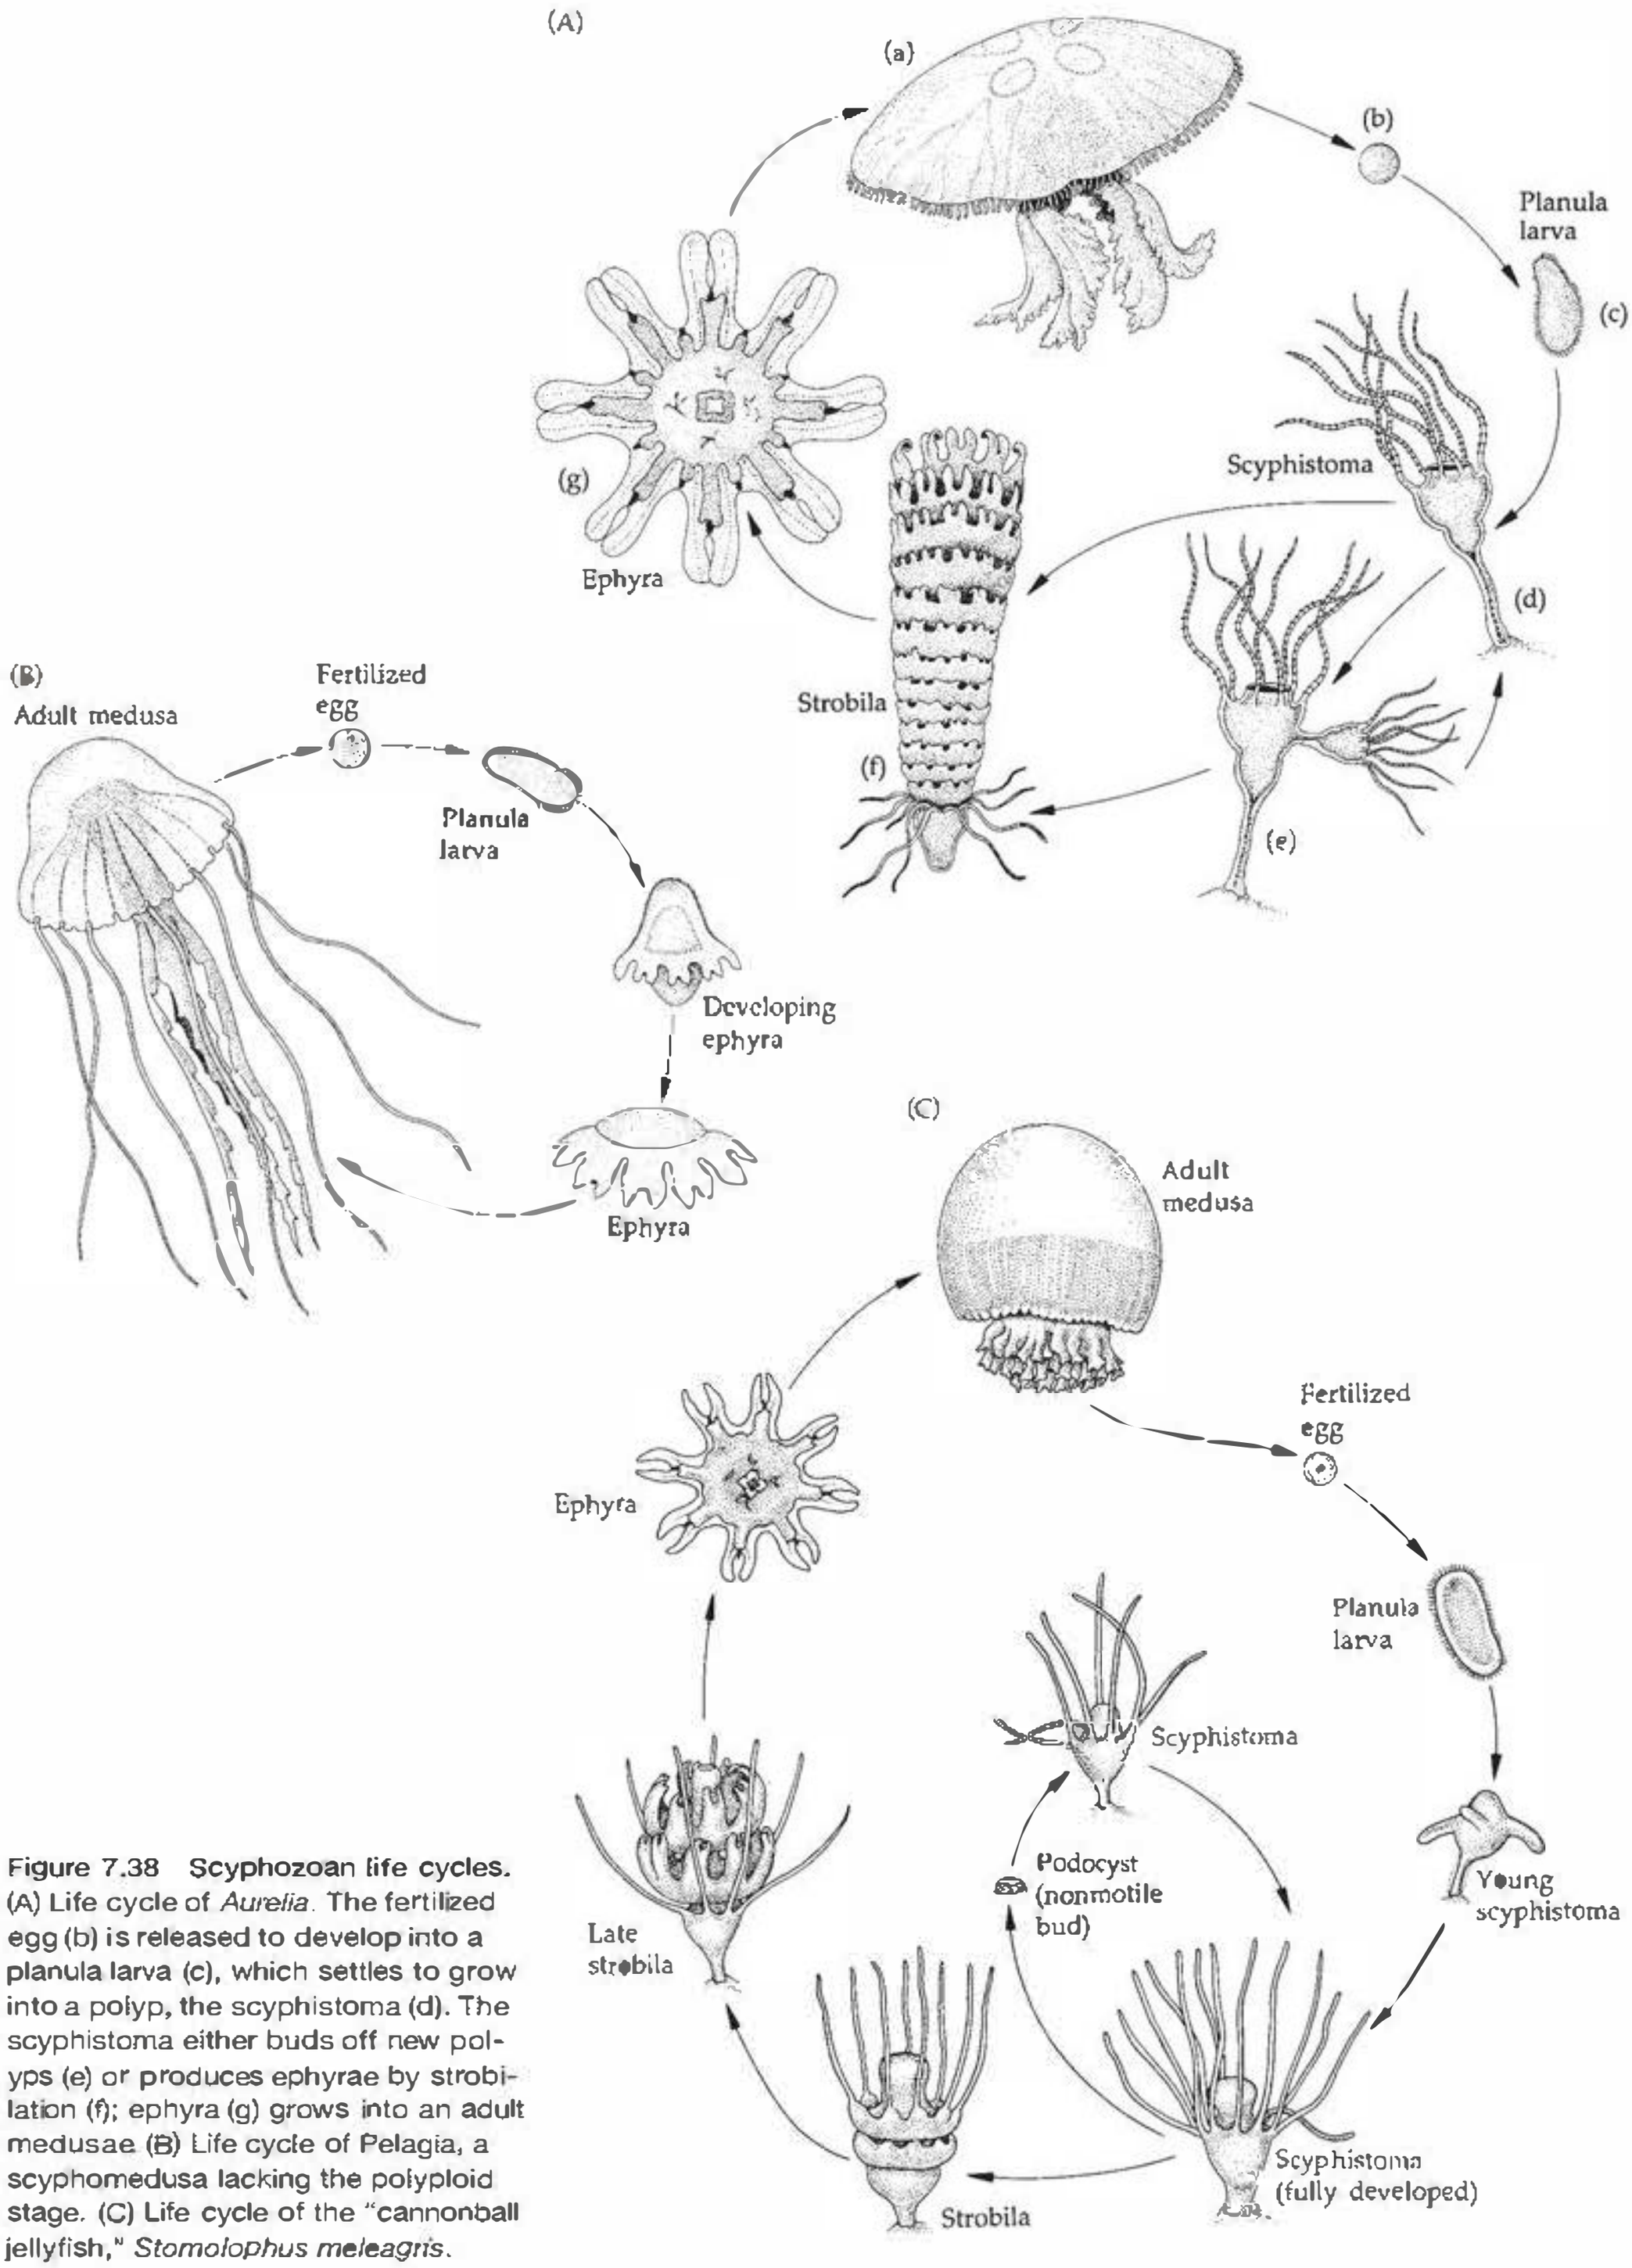

Figure 7.38 Scyphozoan life cycles. (A) Life cycle of *Aurelia*. The fertilized egg (b) is released to develop into a planula larva (c), which settles to grow into a polyp, the scyphistoma (d). The scyphistoma either buds off new polyps (e) or produces ephyrae by strobilation (f); ephyra (g) grows into an adult medusae (B) Life cycle of Pelagia, a scyphomedusa lacking the polyploid stage. (C) Life cycle of the "cannonball jellyfish," *Stomolophus meleagris*.

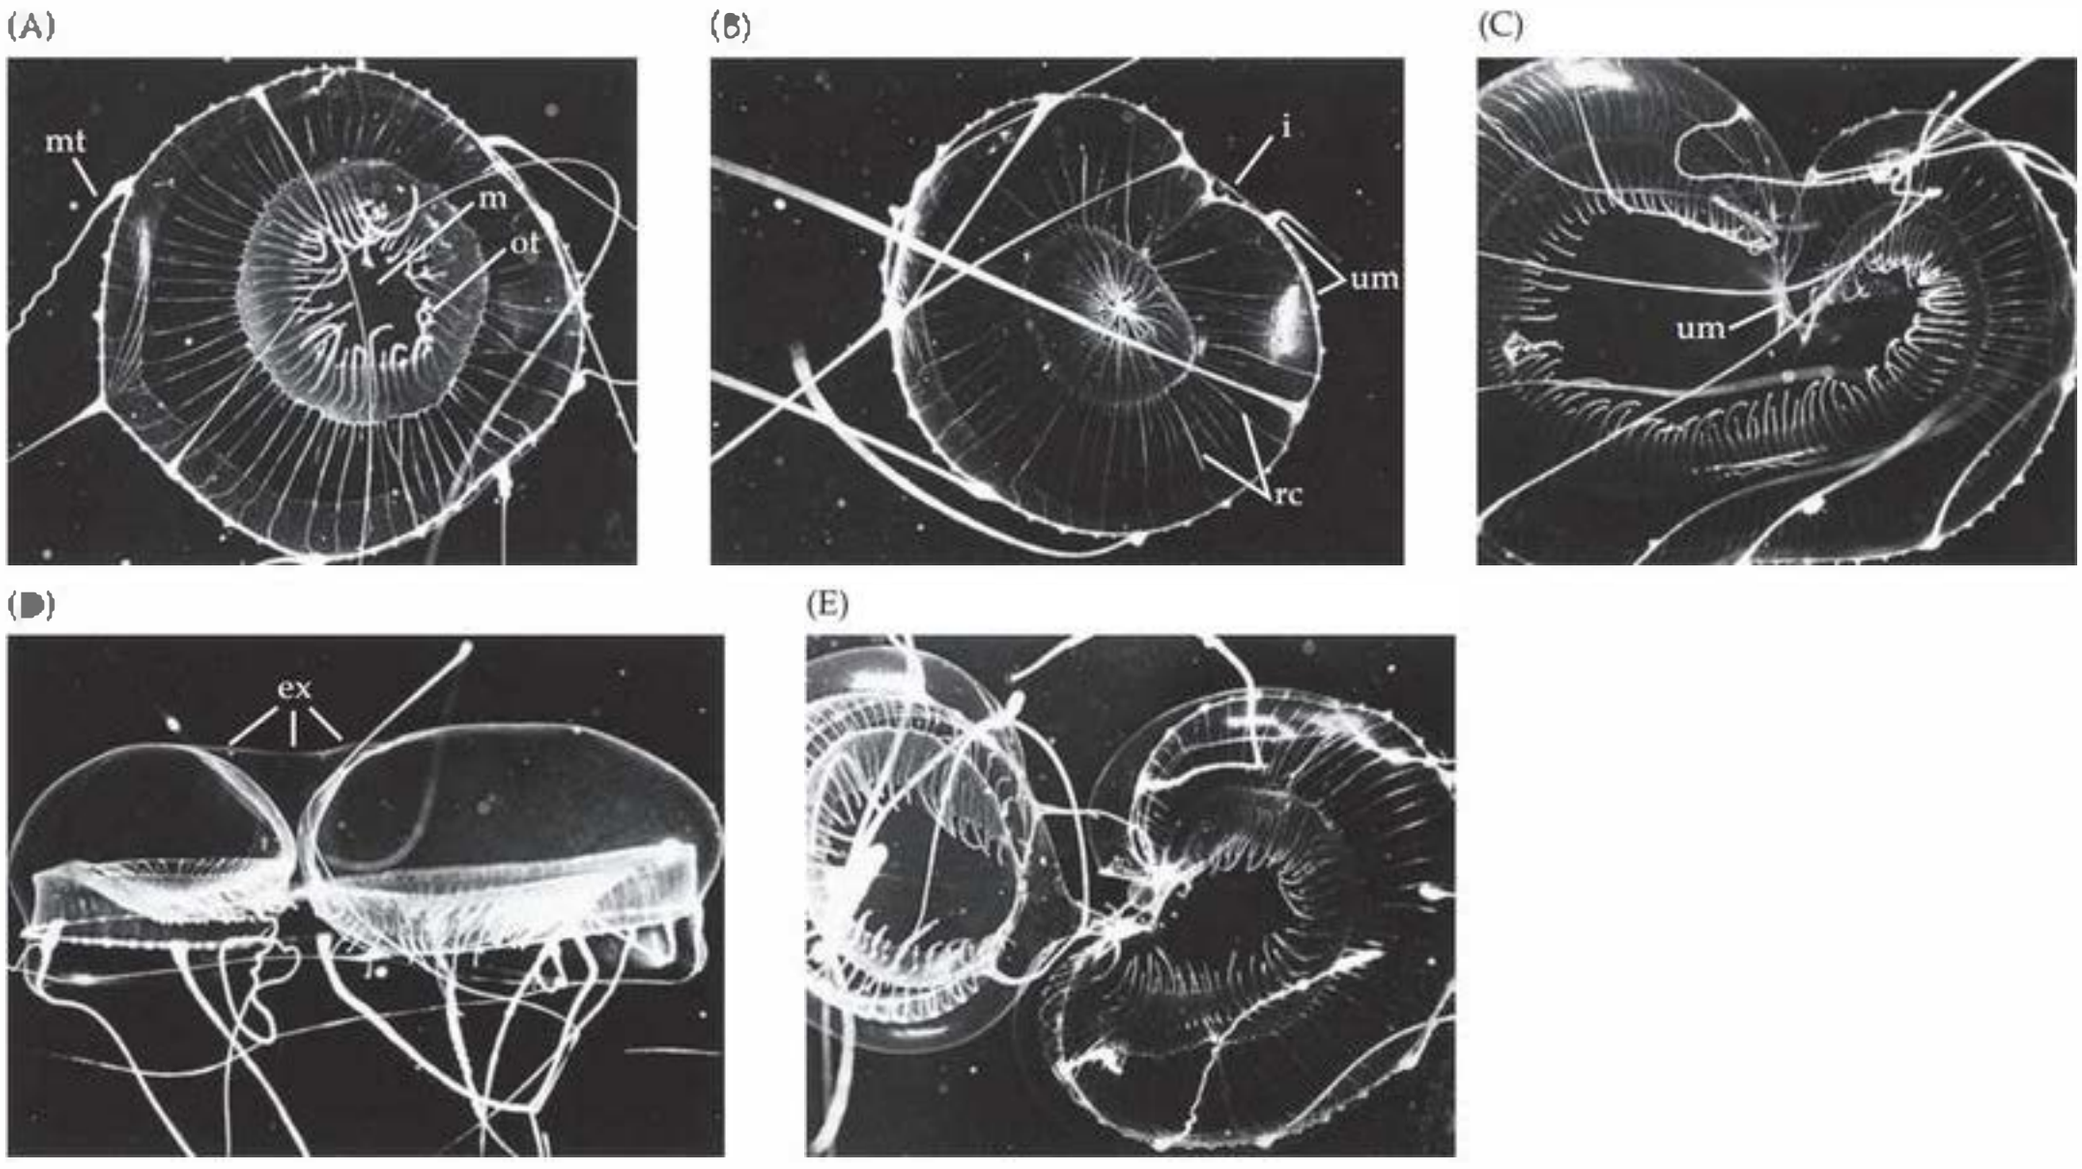
may take place. Polygastry does not occur during this process; instead, the entire bell folds in half, severing the stomach, ring canal, and velum (Figure 7.40). Eventually the whole medusa splits in half and each part regenerates the missing portions.

Cnidarians in general have a great capacity for regeneration, as exemplified by experiments on *Hydra*. The eighteenthcentury naturalist Abraham Trembley had the clever idea of turning a *Hydra* inside out—and he did. To his delight, the animal survived quite well,



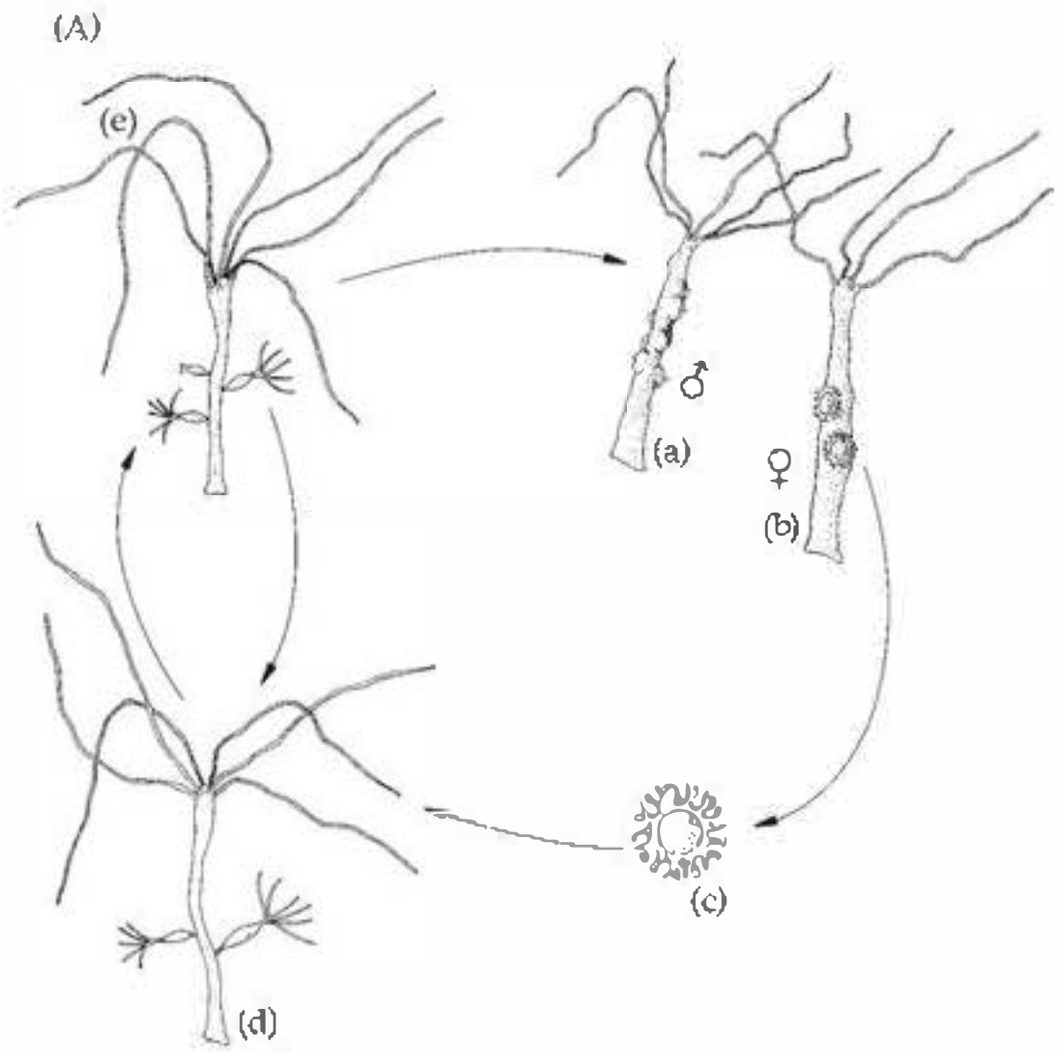


Figure 7.40 Asexual reproduction in the hydromedusa *Aequorea*. The sequence of photographs shows the direct fission of *A. macrodactyla*. (A) This oral view shows a nondividing medusa with its marginal fishing tentacles (mt) deployed. (B) Initiation of invagination (i). (C–E) A progression of the direct fission process. The oral (C) and marginal (D) views illustrate the severing of the umbrellar margin (um) and the separation of exumbrellar halves; (E) shows the exumbrellar surface (ex) beginning to pull apart, producing free-swimming daughter medusae; healing is nearly complete in the smaller daughter medusa on the left. ot: oral tentacles; m: mouth; rc: radial canals.

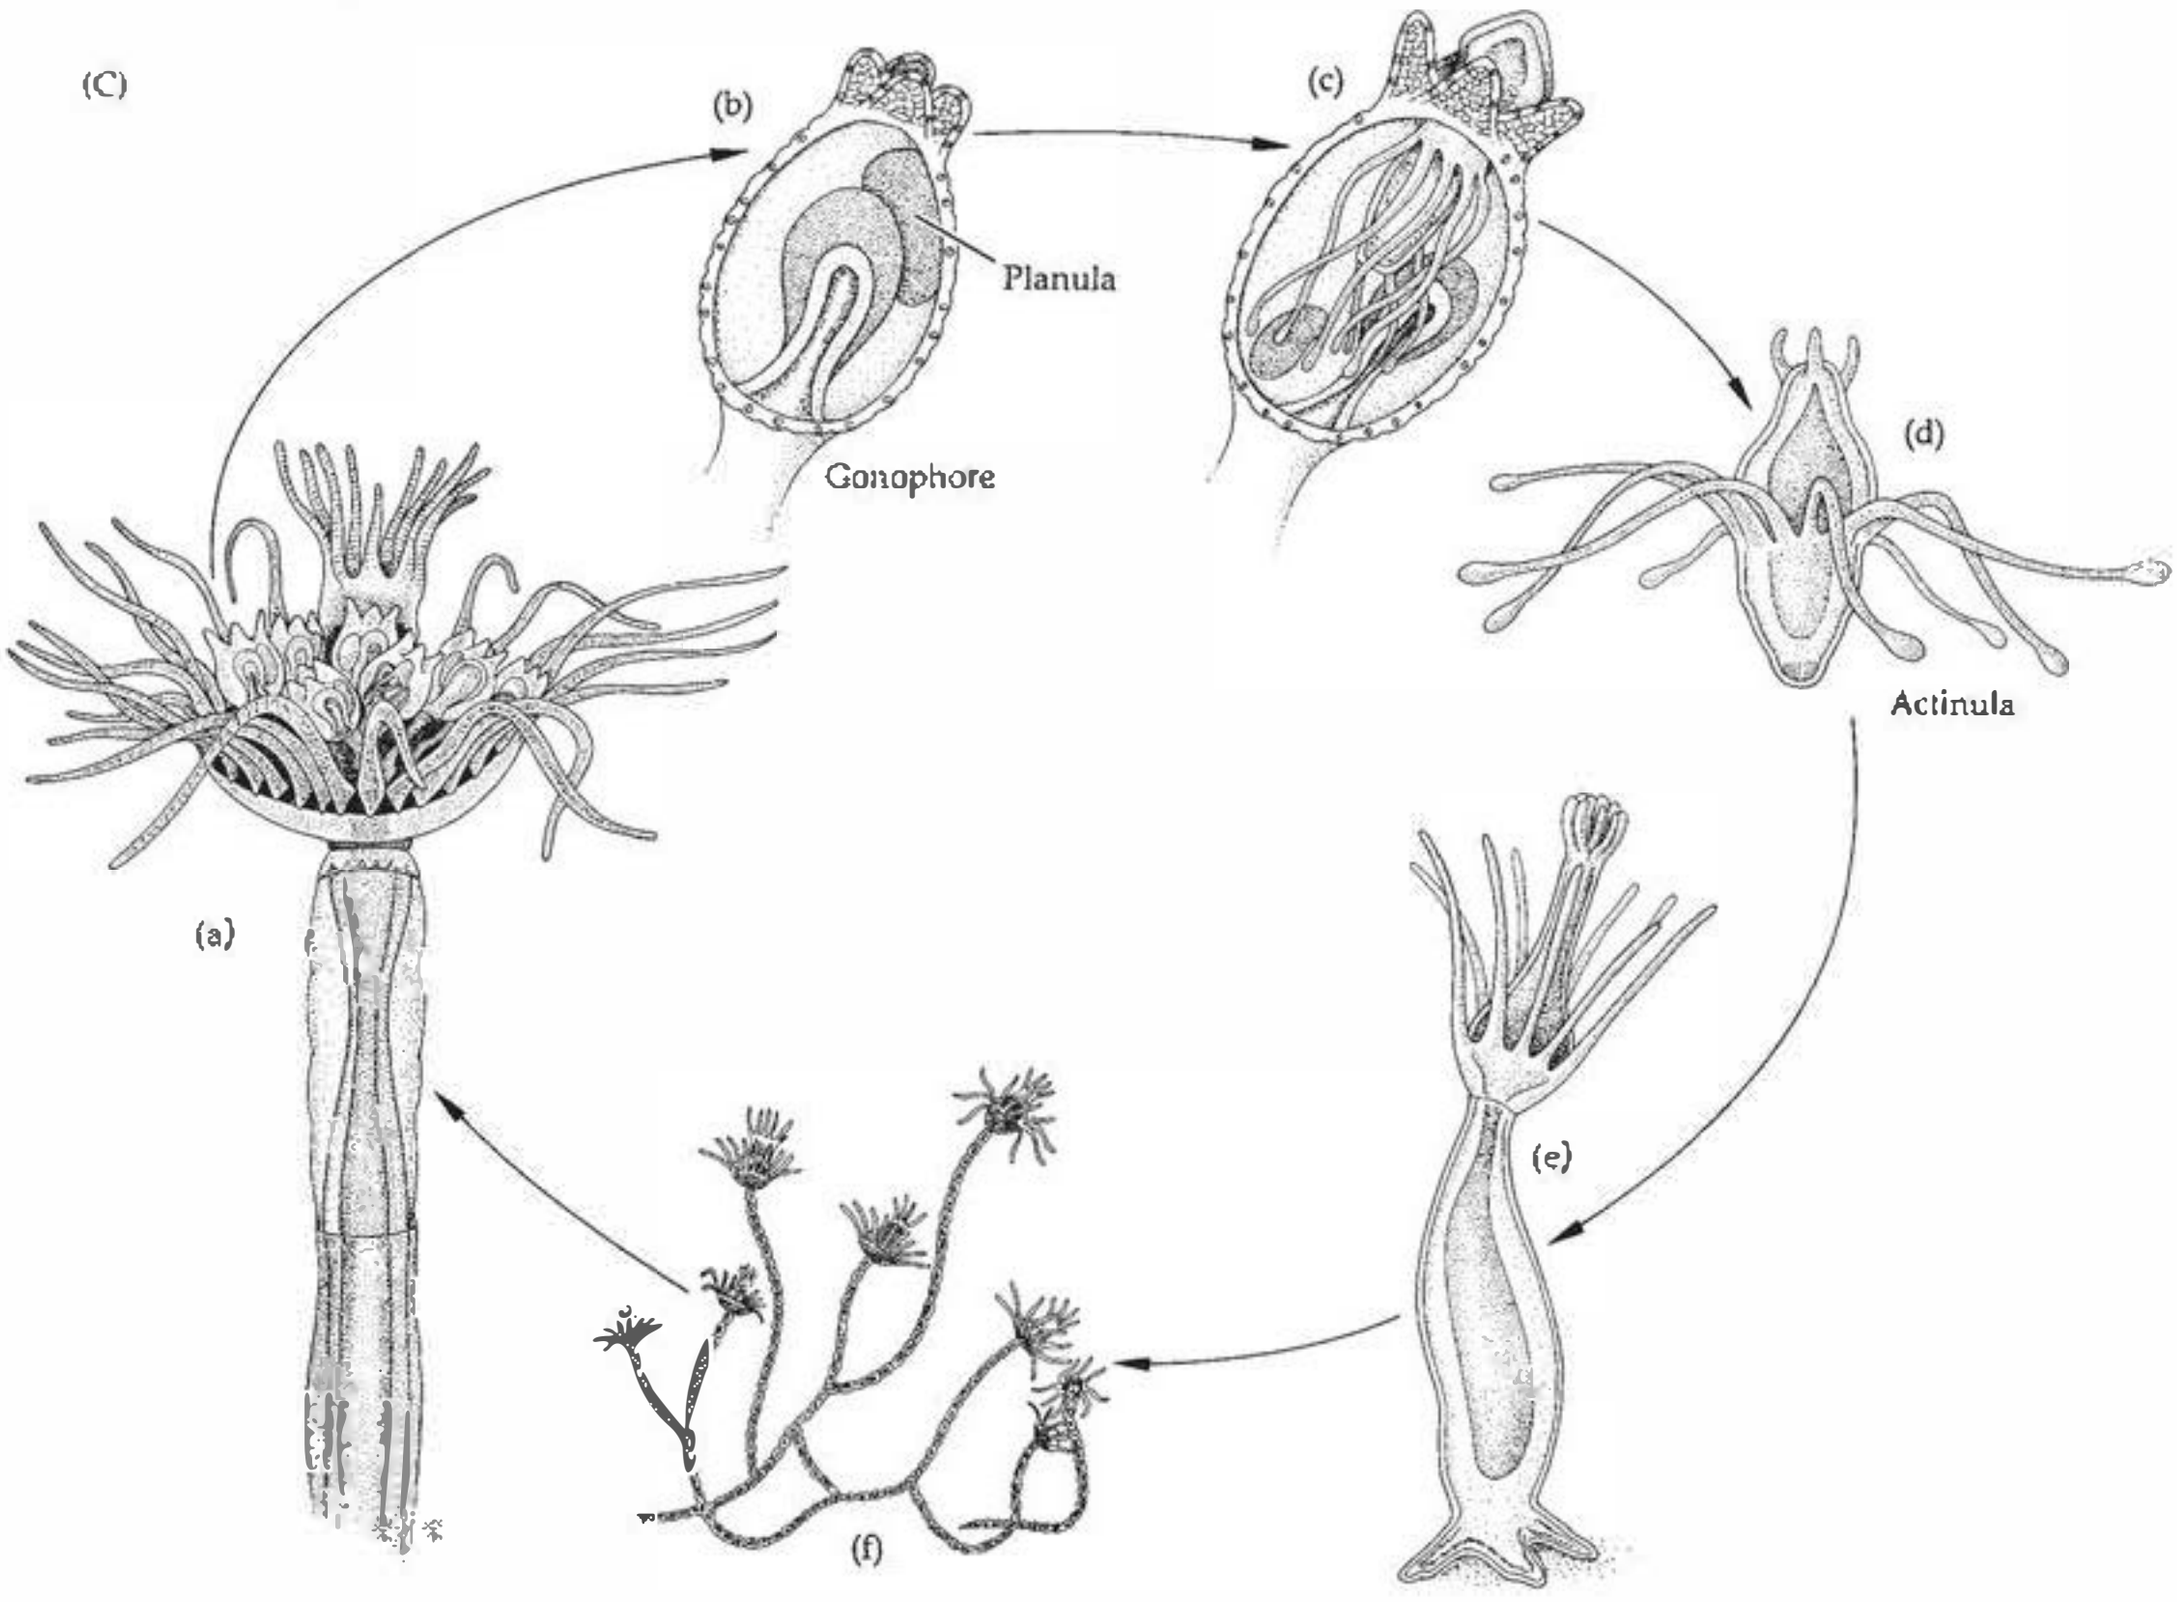

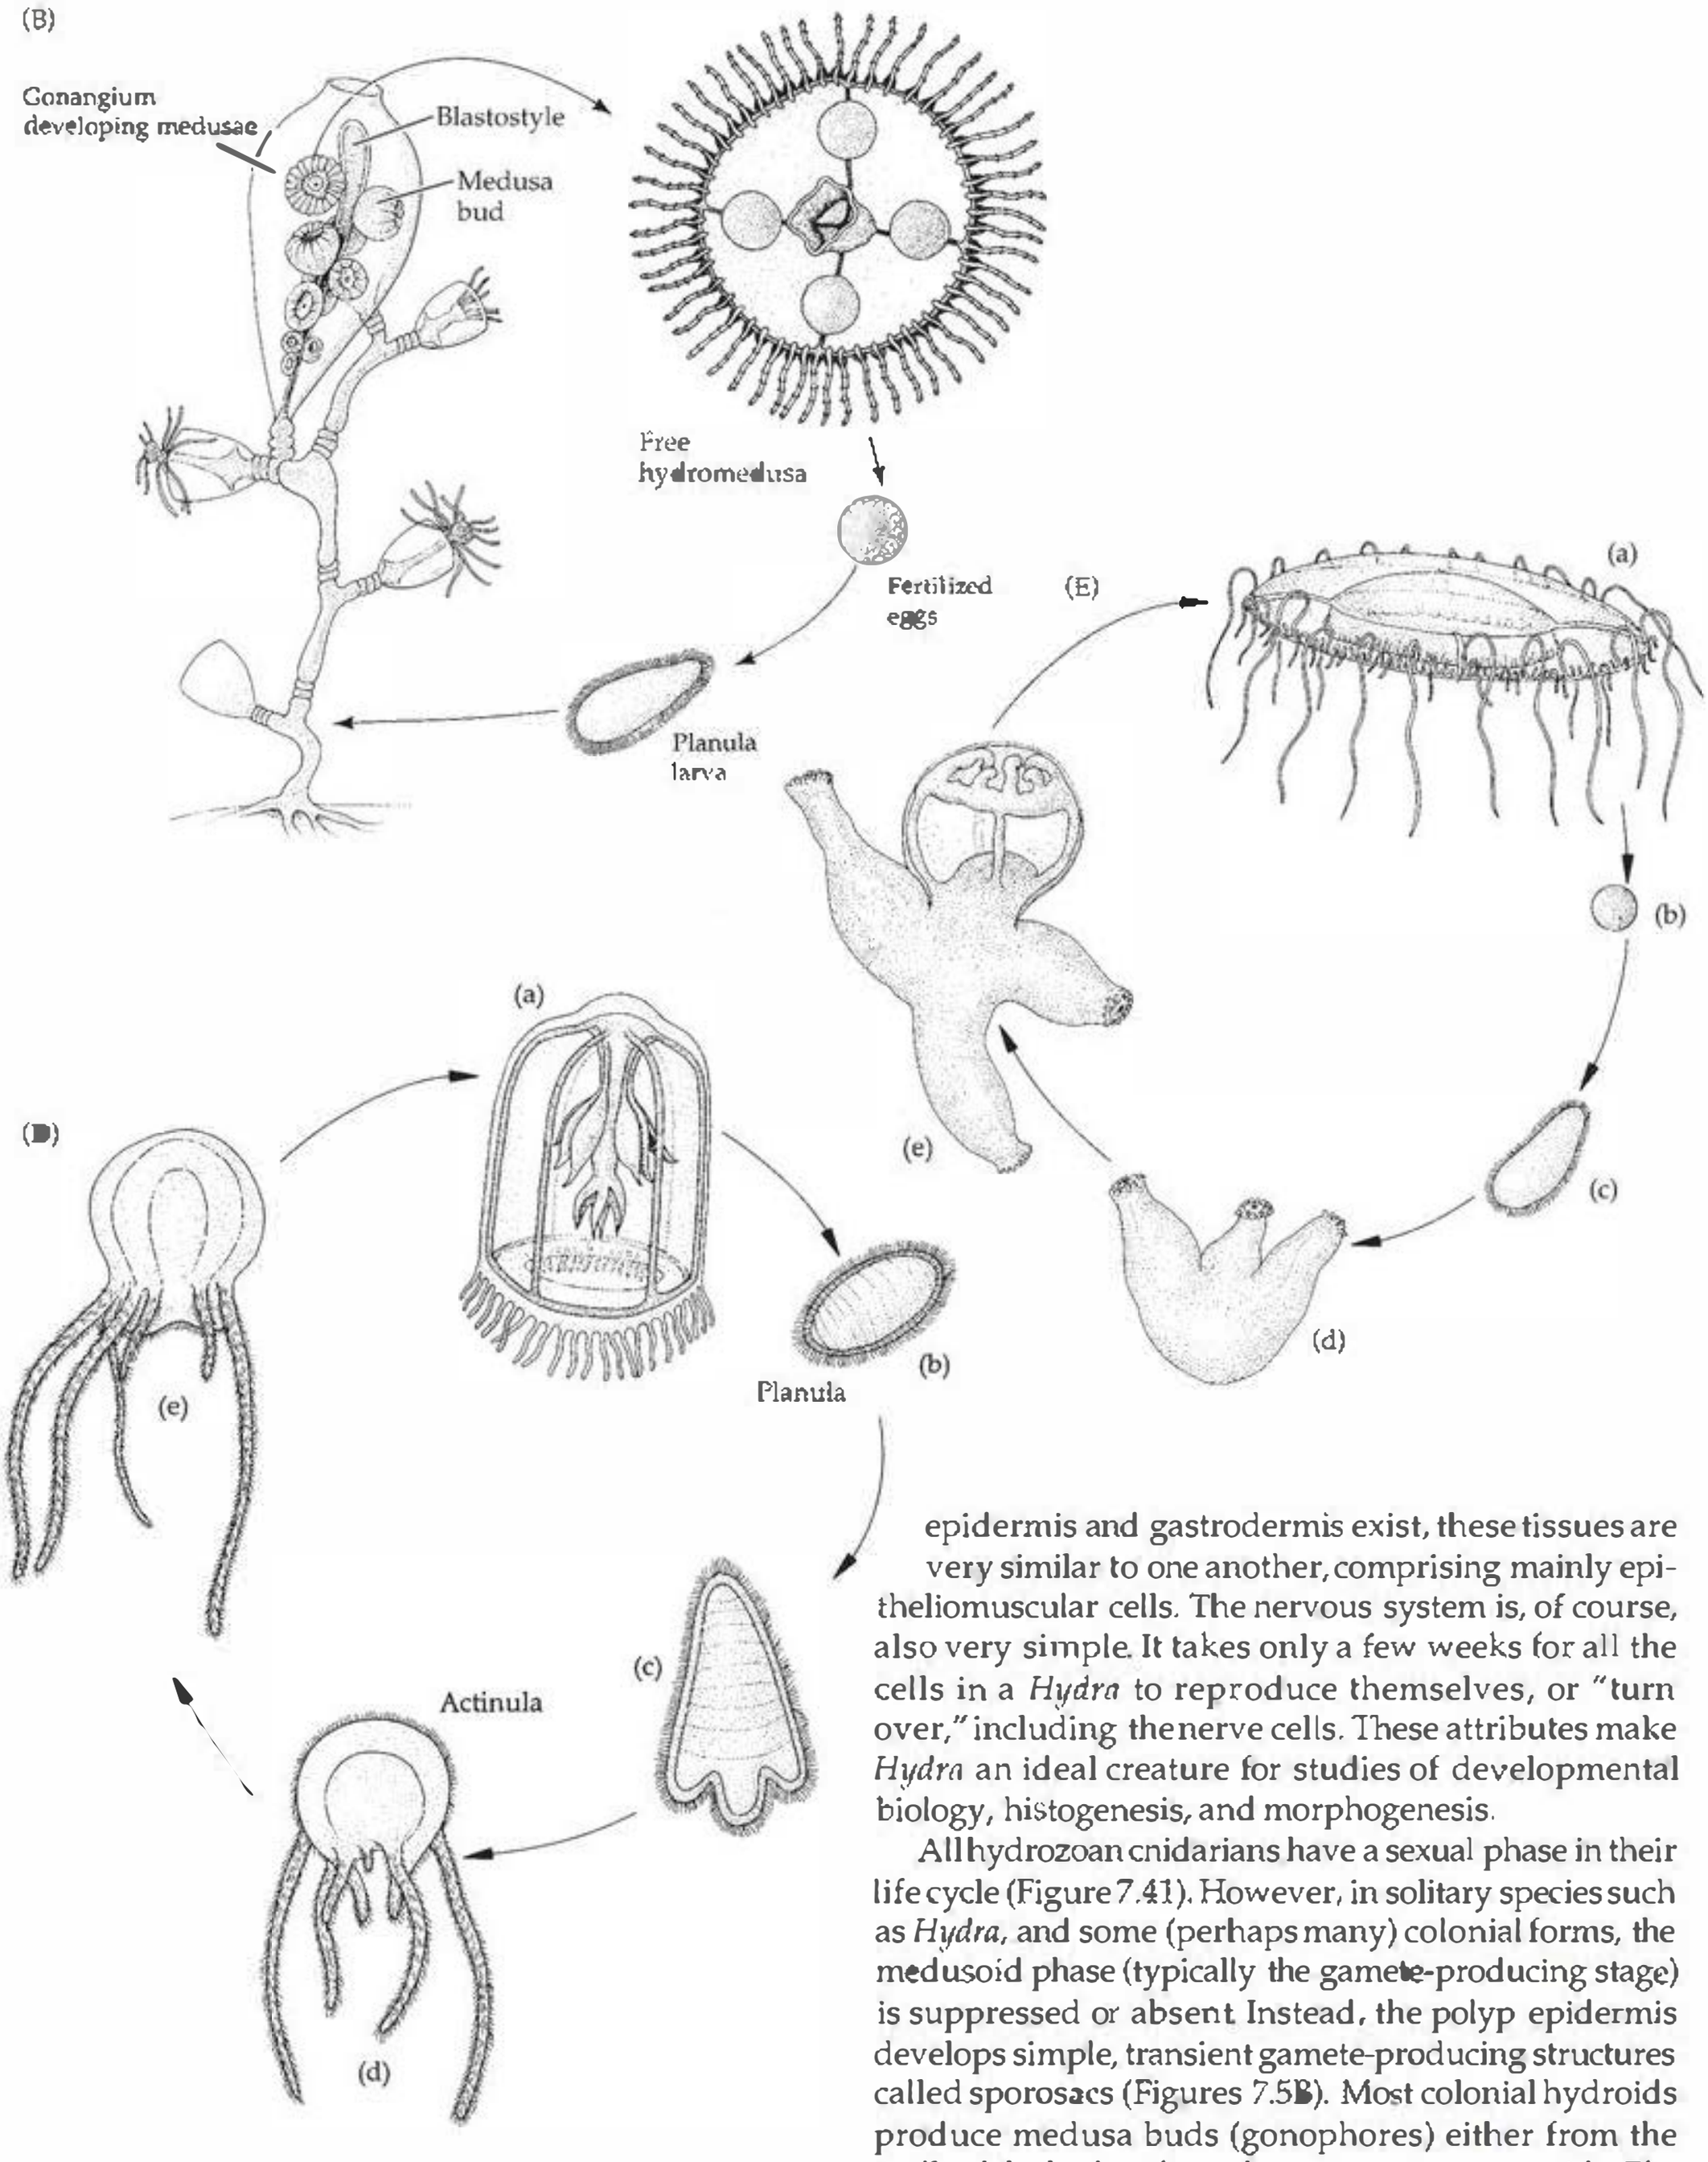

Figure 7.41 Some hydrozoan life cycles. (A) Life cycle of *Hydra*. Sperm produced by the male polyp (a) fertilizes the eggs of the female polyp (b). During cleavage, the eggs secrete a chitinous theca about themselves. After hatching, the embryos (c) grow into polyps that reproduce asexually by budding (d), until environmental conditions again trigger sexual reproduction. (B) Life cycle of *Obelia*, a thecate hydroid with free medusae. (C) Life cycle of *Tubularia*, an athecate hydroid that does not release free medusae. The polyp (a) bears many gonophores, whose eggs develop in situ into planulae (b) and then into actinula larvae (c) before release (d); the liberated actinula larvae (d) settle and transform directly into new polyps (e), which each proliferate to form a new colony (f). (D) Life cycle of a trachyline hydrozoan medusa without a polypoid stage (*Aglaura*). After fertilization, a gonochoristic adult (a) releases a planula larva (b), which adds a mouth and tentacles (c) to become an actinula larva (d). Subsequently the actinula larva becomes a young medusa (e). (E) Life cycle of a trachyline hydrozoan with a polypoid stage, the freshwater *Limnocnida*. Gonochoristic medusae (a) release fertilized eggs (b) that grow into planula larvae (c). Planula larvae settle to form small hydroid colonies (d), which bud off new medusae (e).

with the gastrodermal cells functioning as the "new epidermis" and vice versa. Cells removed from the body of a *Hydra* also have a modest degree of reaggregative ability, like that seen so dramatically in sponges. In some cases, entire animals will reconstruct from cells taken only from the gastrodermis or only from the epidermis. Although *Hydra* is an unusual and atypical cnidarian, this great capacity for cellular reorganization is

a reflection of the primitive state of tissue development in the animals belonging to this phylum.

A typical *Hydra* consists of only about 100,000 cells of roughly a dozen different types. Although distinct epidermis and gastrodermis exist, these tissues are very similar to one another, comprising mainly epitheliomuscular cells. The nervous system is, of course, also very simple. It takes only a few weeks for all the cells in a *Hydra* to reproduce themselves, or "turn over," including the nerve cells. These attributes make *Hydra* an ideal creature for studies of developmental biology, histogenesis, and morphogenesis.

All hydrozoan cnidarians have a sexual phase in their life cycle (Figure 7.41). However, in solitary species such as *Hydra*, and some (perhaps many) colonial forms, the medusoid phase (typically the gamete-producing stage) is suppressed or absent. Instead, the polyp epidermis develops simple, transient gamete-producing structures called sporosacs (Figures 7.5B). Most colonial hydroids produce medusa buds (gonophores) either from the walls of the hydranths or from separate gonozooids. The gonophores may grow into medusae that are released as free-living sexually reproducing individuals, or they may remain attached to the polyps as incipient medusae that produce gametes in place.

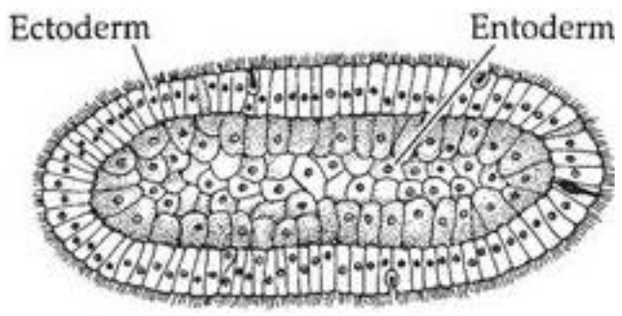

Figure 7.42 A typica sol d hydrozoan planula arva resulting from ingression.

Milleporid hydrozoans produce short lived sexual medusae that are released over several days during particular seasons. Temporal segregation of spawning seems to occur among colonies of different species. Colonies within species are gonochoristic and so release exclusively male medusae, bearing a sperm sac located at the vestigial manubrium, or female medusae bearing 3 to 5 ova in the subumbrella cavity. Male m e dusae appear to be released into the water column by their corallae a few hours before female medusae are released. Gametes are released by both medusa types, and fertilization occurs externally.

In free living hydromedusae, germinal cells arise from interstitial epidermal cells that migrate to specific sites on the bell surface, where they consolidate into a temporary gonadal mass. Subsequently, gametogenic tissue appears on the surface of the manubrium, beneath the radial canals, or on the general subumbrellar surface. Hydromedusae are typically gonochoristic, with either sperm or eggs usually being released directly into the water, where fertilization occurs. In some, only sperm are released and fertilization occurs on or in the female medusa's body. Free hydromedusae are espe cially common in temperate waters, where they may be very abundant seasonally and easily collected in plankton nets. Siphonophores appear to be ancestrally gonochoristic but hermaphroditic forms exist among the Physonecta and exclusively among the Calycophorae (Codonophora). Planktonic dispersal of sexual forms would seem to mitigate against genetic differentiation of coastal populations, but considerable genetic population structure has been demonstrated among morphological ly similar populations of *Obelia geniculata*, with estimated divergence times among reciprocally monophyletic lineages exceeding several million years.

Although several cleavage patterns occur in the Hydrozoa, the overall motif is fundamentally radial and holoblastic. A coeloblastula forms, which gastrulates by uni- or multipolar ingression to a stereogastrula. The interior cell mass is endoderm; the exterior cell layer is ectoderm (Figure 7.42). The stereogastrula elongates to form a unique, solid or hollow, nonfeeding, free-swimming planula larva (Figure 7.43). The planula larva is radially symmetrical, but it swims with a distinct "anterior posterior" orientation. The ectoder mal cells are monociliated and destined to become the adult epidermis; the endoderm is destined to become the adult gastrodermis. The trailing end of the larva (of all cnidarians) becomes the oral end of the adult, and even in the larval stage a mouth sometimes develops at this end. Hydrozoan planulae swim about for a few hours, a few days, or a few weeks before settling by a t taching at the leading end. If the larva i s still solid, then the endoderm hollows to form the coelenteron. The mouth opens at the unattached oral end and tentacles develop as the larva metamorphoses into a young solitary polyp. Studies have shown that a dramatic reorganization of the hydrozoan nervous system takes place during metamorphosis of the planula into the primary polyp (in *Pennaria*). The larval neurons degenerate and new neurons differentiate to reform a nerve net, and the overall distribution pattern of the nervous system changes dramatically.

This overview of the hydrozoan reproductive cycle covers most species (Figure 7 41), but in fact even more variety actually exists than we have space to discuss. For example, in some trachylines, the polypoid stage is apparently lost altogether. The medusae produce planula larvae that develop into actinula larvae, which metamorphose into adult medusae, bypassing any sessile polypoid phase. Some trachylines and some siphonophores undergo direct development, bypassing the larval stage altogether. Within the Trachylina, members of the family Rhopalonematidae (formerly within the order Actinulida) exhibit minute interstitial polyps that lack a medusoid stage (or possibly these forms represent creeping medusae) and have suppressed the larval phase. The adult polyp is ciliated and resembles an actinula larva (hence the name).

Myxozoan reproduction Myxozoan cnidarians have such aberrant life cycles that is it impossible to identify either polypoid or medusa stages within them. No planula stage is known to exist. Such marked d i f ferences from other cnidarian taxa no doubt contributed to the uncertain status of myxozoans within the phylum to date. Nevertheless, an alternation of sexual and asexual generations within vertebrate and annelid hosts does occur, albeit as parasitic forms as described above. Asexual reproduction occurs within the vertebrate host, producing infective myxospores as already described (Figure 7.29). Sexual reproduction occurs within annelids and other coelomate worms, gener ating infective actinosporean larvae The separation of the sexual and asexual stages of the life cycle of these parasites is similar to that which occurs in other parasitic species and could suggest that that some developmental genetic homologies exist between the asexual and sexual stages of myxozoans and the polyp and medusa stages of other cnidarians. However, the reproductive modes of most myxozoans remain poorly known.

Cnidarian Phylogeny

Ediacaran Cnidaria?

Cnidarians have one of the longest fossil histories among the Metazoa. The first apparent cnidarian fossils date from the Ediacaran period, from the famous Ediacara Hills of South Australia, which contain possible medusae and polypoid colonies (e.g., sea pen-like creatures) that lived nearly 600 million years ago. However, these early circular and frondlike impressions cannot be unequivocally assigned to any modern Cnidarian taxa. Some researchers doubt that they represent true cnidarians, even though some of the circular forms have marginal tentacles such as seen in most medusae. Other possible neoproterozoic polypoids include impressions that may be the floats of the pelagic "chondrophorans," and fossils with triradiate symmetry (e.g., *Tribrachidium*), as well as pentiradiate and octoradiate symmetry, thus differing fundamentally from any living cnidarians. Some workers consider these fossils to be parts of other organisms, such as isolated holdfast structures; others have placed them into an extinct class of Cnidaria, the Trilobozoa. Still others view them as primitive triradiate echinoderms. It helps to have a good imagination if you're a paleontologist.

In the 1980s, Adolf Seilacher, frustrated by attempts to assign these Neoproterozoic era fossils to modern phyla, created an entirely new phylum, the Vendobionta (or Vendozoa) suggesting that it might be a sister-group to the Eumetazoa (metazoans above the poriferan grade). The Vendozoa, Seilacher noted, seemed to have a quiltlike construction of thin, lightly sclerotized but flexible, outer skin separated into compartments by more rigid internal struts (which in fossil impressions appear to be sutures). Later workers placed these fossils into an extinct cnidarian order, the Rangeomorpha, and called other, more bilaterally symmetrical forms Erinettomorpha. One of the most famous of these latter forms is the oval-shaped *Dickinsonia*, which may have measured over a meter in length but been only a few millimeters thickness. Some workers consider *Dickinsonia* to be medusa-like, but it has also been assigned to the Platyhelminthes, the Annelida (due to hints of possible body segmentation), to an extinct phylum (Proarticulata), and to an entirely new kingdom!

Attempts to place the Ediacaran fossils within the Cnidaria (or other extant phyla) have met with limited success until 2014. For example, differences in apparent growth patterns and frond structure between extant cnidarians (e.g., pennatulaceans) and frondlike Ediacaran species have argued against a direct cnidarian relationship. Then, in 2014, a 560-million-year-old likely-cnidarian fossil (named *Haootia quadriformis*) was reported from Newfoundland, with quadraradial symmetry and clearly preserved bundled muscular fibers. *Haootia* appears to be a nearly 6 cm long polyp, or perhaps an attached medusa—it greatly resembles modern species of Staurozoa.

Early trace fossils have also been assigned to the phylum Cnidaria. Burrows assigned to sea anemones occur in the early Cambrian, and some strata have meandering tracks that appear to be traces left from mucous trails of creeping anemones (some modern anemones move in this fashion, using ciliary activity). Remarkable embryos of probable scyphozoan affinity have also been reported form the Lower Cambrian of China.

A recent discovery of two new species of enigmatic diploblastic animals from southern Australian seabeds could provide an example of Ediacaran Cnidaria-like animals that survived to modern times. *Dendrogramma enigmatica* and *D. discoides* (Figures 7.44 and 7.45) possess a polyp-like structure, an asymmetrical branching digestive system with no apparent anus, a thick gelatinous mesoglea between the epidermis and gastrodermis, and other structural similarities shared with both ctenophores and cnidarians. But they lack the adhesive or stinging structures that characterize those taxa. *Dendrogramma* has an intriguing similarity to the fossil medusoid Ediacaran creatures (e.g., *Albumares*, *Anfesta*, *Margaritiflabellum*, and *Rugoconites*) that possessed a disk containing forked and radiating channels and a central stalk, possibly also with a terminal mouth. Initial preservation of *Dendrogramma* specimens in formalin has so far hindered molecular classification,

Figure 7.44 This new animal, *Dendrogramma enigmatica* was collected in deep waters off southern Australia in 1986. (A,B) Lateral views, (C) aboral view, (D) oral view.

leaving unresolved the possibility that Ediacaran medusoids still persist 540 million years after their presumed extinction. For now, the two living species have been placed in their own family, Dendrogrammatidae, as Metazoa *incertae sedis*.

Cnidarian Origins

The origin of the cnidarians is closely tied to the origin of the Metazoa themselves. Like Porifera, cnidarian body plans appear to have remained essentially unchanged since the Cambrian. The prevailing theory of metazoan origin sometimes called the **colonial theory**, depicts a colonial flagellated protist (e.g., a choanoflagellate) that gave rise to a hollow metazoan ancestor, termed a **blastea**, which in turn gave rise to a diploblastic planuloid animal called a **gastrea**. It is from these hypothetical ancestral forms that the Porifera and Cnidaria are said to have evolved. On the other hand, another view suggests that the ancestors of cnidarians were triploblastic, acoelomate organisms, perhaps something like rhabdocoel turbellarians, that underwent "degenerative evolution" to produce what we recognize today as the cnidarians. This view, called the **triploblastic theory** (or the **turbellarian theory**), usually holds the Anthozoa to be the most primitive cnidarian class and cites the "remnants" of bilateral symmetry in that class as evidence of a bilateral ancestry. As noted earlier in this chapter, certain molecular and developmental evidence supports this idea, but the weight of evidence is against this interpretation, and despite *Buddenbrockia*'s putative vestigial musculature, no living cnidarians show remnants of what might have been a triploblastic ancestry, either in their anatomy or their development. The triploblastic hypothesis remains controversial because many contemporary zoologists find it weak on several counts. "Degenerative evolution" (a poor choice of words) is a phenomenon primarily associated with the evolution of parasites or the exploitation of smallness (e.g., interstitial forms), wherein it may result in the reduction of certain systems and the specialized adaptive development of others. The idea of a free-living, triploblastic, bilateral, motile creature (such as a flatworm) taking up a sessile existence and transforming into a radially symmetrical, diploblastic, anthozoan polyp appears to be a highly unlikely evolutionary scenario. The adoption of radiality (or at least "functional" radiality) of bilaterally symmetrical animals is well documented in some taxa (e.g., Echinodermata), but does

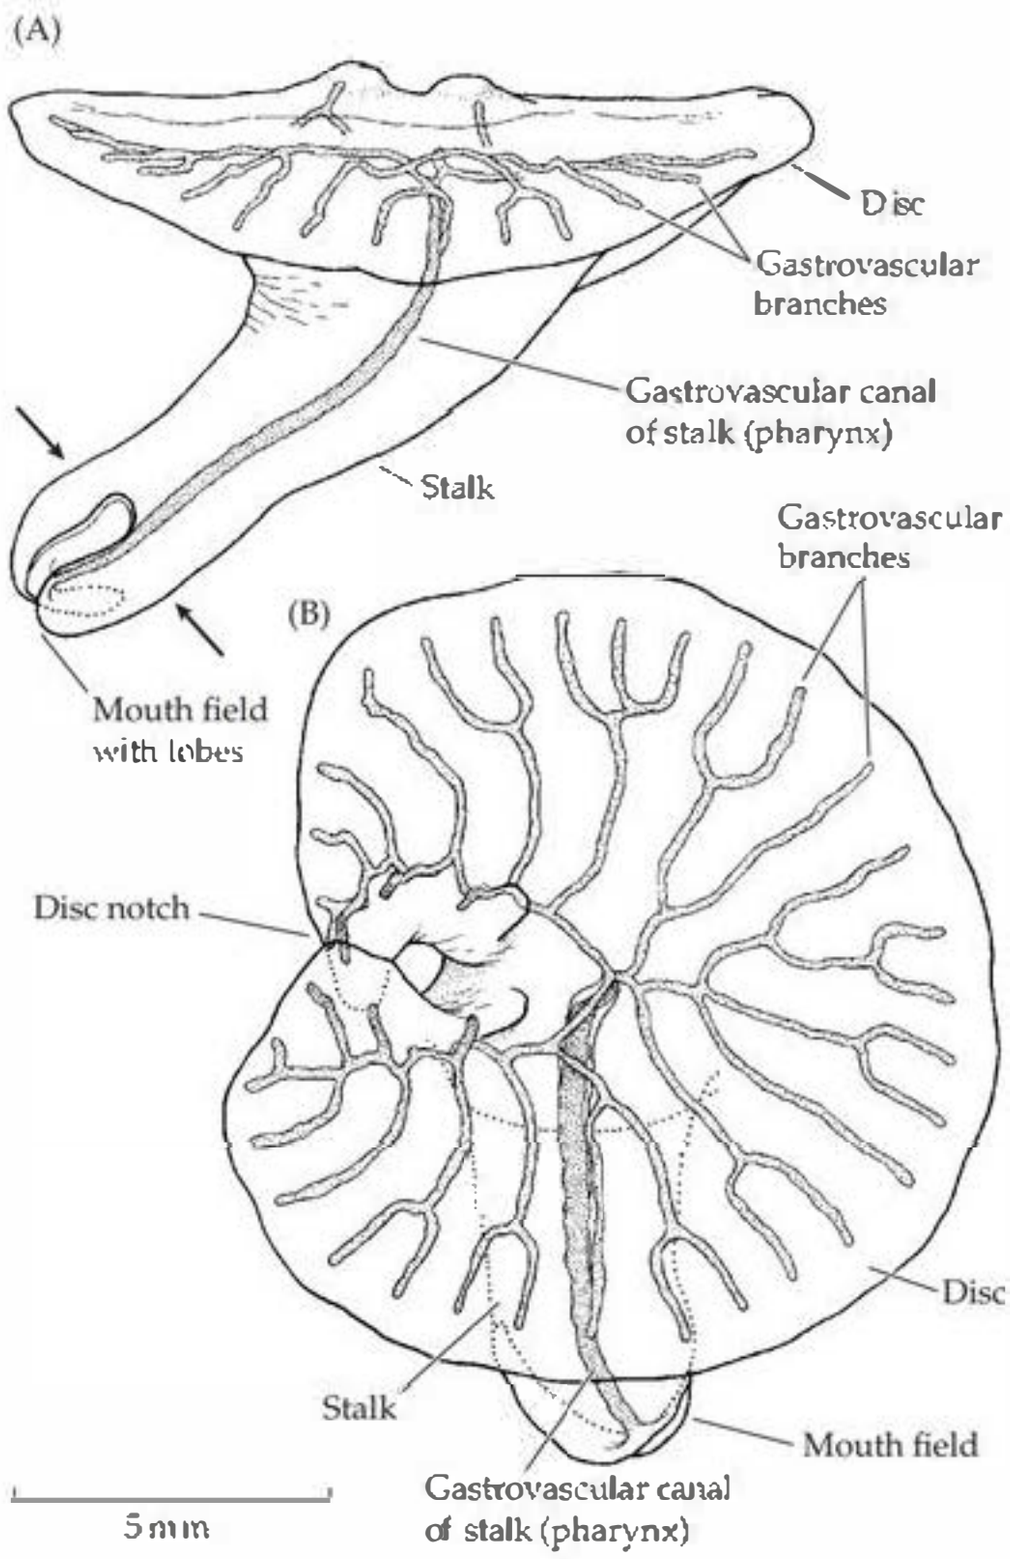

Figure 7.45 Diagrammatic rendering of *Dendrogramma*. (A) Lateral view, (B) aboral view.

not involve the kinds of "degeneration" required by the turbellarian theory. The transformation suggested by the triploblastic or turbellarian theory is complicated; it involves the loss or drastic simplification of many complex systems (notably the urogenital system) and major changes in fundamental body design. Both larvae and adults of extant cnidarians maintain a fundamental radial symmetry. The so-called remnant bilaterality of anthozoan polyps is not true bilaterality at all, but biradiality about an oral–aboral axis, which develops late in the ontogeny of these animals. The triploblastic/turbellarian theory is also weak on embryological grounds, such as differences in cleavage patterns and germ layer formation. And, perhaps most importantly, the most recent multigene phylogenetic analyses clearly position Cnidaria below the origin of bilaterality and likely as the sister group to the Bilateria.

In Chapter 5 we reviewed the important embryological differences between the coelomate metazoan clades known as the protostomes and deuterostomes. To the extent that these traits occur in noncoelomate Metazoa, it is of phylogenetic importance to note them. For example, radial cleavage is characteristic of the deuterostomes, but probably arose very early in metazoan evolution; it occurs in cnidarians and, in a slightly different form, in most sponges. Thus it appears to be the plesiomorphic type of cleavage among animals. Spiral cleavage, on the other hand, defines an entire clade of protostomes (the Spiralia), suggesting it is a more derived cleavage pattern in Metazoa. In fact, as more is learned about cnidarian genomes, the evidence seems to suggest that their genes share more similarities to deuterostome genes than to those of protostomes.

Relationships within Cnidaria

Anatomical evidence has been equivocal on the question of which living class of Cnidaria is the most ancestral. Some workers have favored a view that the first cnidarian was a medusa, based largely the conjecture that the sexual stage must have appeared first (the **medusoid hypothesis**). Other workers have favored the view that the polypoid form is primitive within Cnidaria, because polyps occur in all classes of the phylum, except the parasitic Myxozoa, and thus they represent part of the primitive cnidarian body plan (the **polypoid hypothesis**). Recent molecular work has clarified many relationships within Cnidaria, yet whether anthozoans or medusozoans represent the "basal" cnidarian group still remains debatable. Of course, the phylogenetic hypothesis that one adopts has great implications for interpreting character evolution within this group—and the weight of the evidence currently favors anthozoans as ancestral. Nevertheless, more work is needed to substantiate this view. Next, we present the implications of each hypothesis, knowing that further work will eventually substantiate or refute the following frameworks.

The polypoid hypothesis suggests that the exclusively polypoid class Anthozoa is closest to the ancestral cnidarian. This hypothesis has received increasing support and is the scheme presented in this chapter (Figure 7.46). Molecular and genetic data supporting this view continue to accumulate. For example, 18S rDNA sequence analyses place anthozoans as a sister group to all other cnidarians. In addition, we now know that, among cnidarians, only the anthozoans possess circular mitochondrial DNA, a trait they share with other Metazoa (including the Placozoa). Members of the Medusozoa clade all have linear mtDNA, viewed as a derived condition within cnidarians.

In the polypoid hypothesis, the ancestral cnidarian would possess some or all of the traits that define modern day Anthozoa, whereas the clade comprising Staurozoa, Hydrozoa, Cubozoa, and Scyphozoa (i.e., the Medusozoa) is defined by the evolution of the cnidocil and linear mtDNA. Most workers also place the origin of the medusa at the base of the Medusozoa line, suggesting that all cnidarian medusae are homologous, whereas others have suggested that hydromedusae and scyphomedusae (and cubomedusae) arose independently. In any case, in the polypoid hypothesis, the medusa represents a derived dispersal stage. The position of the Myxozoa is still unclear.

In contrast, *the medusoid hypothesis* suggests that the Cnidaria arose from a swimming or creeping, ciliated, planuloid-like ancestor that, with the development of tentacles resulted an animal resembling an actinula larva. The transition from planula to actinula in the modern medusa form can be seen today in the life cycle of certain hydrozoans. Asexual reproduction, such as budding, by a benthic actinula larva could have secondarily led to the establishment of a distinct polypoid stage. If so, the polyp can be viewed as an extended larval form specialized for asexual reproduction and benthic existence. In this scenario, once the polypoid form became established some cnidarians began to suppress the medusoid phase of their life cycles, various degrees of which can be seen among modern hydrozoans. The epitome of this trend would be the class Anthozoa, whose members have no medusa stage at all. The sister-group of Cubozoa + Scyphozoa (known as the Acraspeda) would be defined by the same synapomorphies in both the polypoid and medusoid hypotheses—loss of gut mesenteries, loss of gastrodermal nematocysts, reduction of cells in the mesoglea, movement of the gamete-forming tissue to the epidermis, and the evolution of acraspedote medusae.

Phylogeny within each of the cnidarian classes is equally interesting but largely beyond the scope of this text. However, a few generalizations can be made about some important events. Coloniality has been a common and important evolutionary theme within Cnidaria. Coloniality in the hydrozoans probably arose by retention of young polyps during

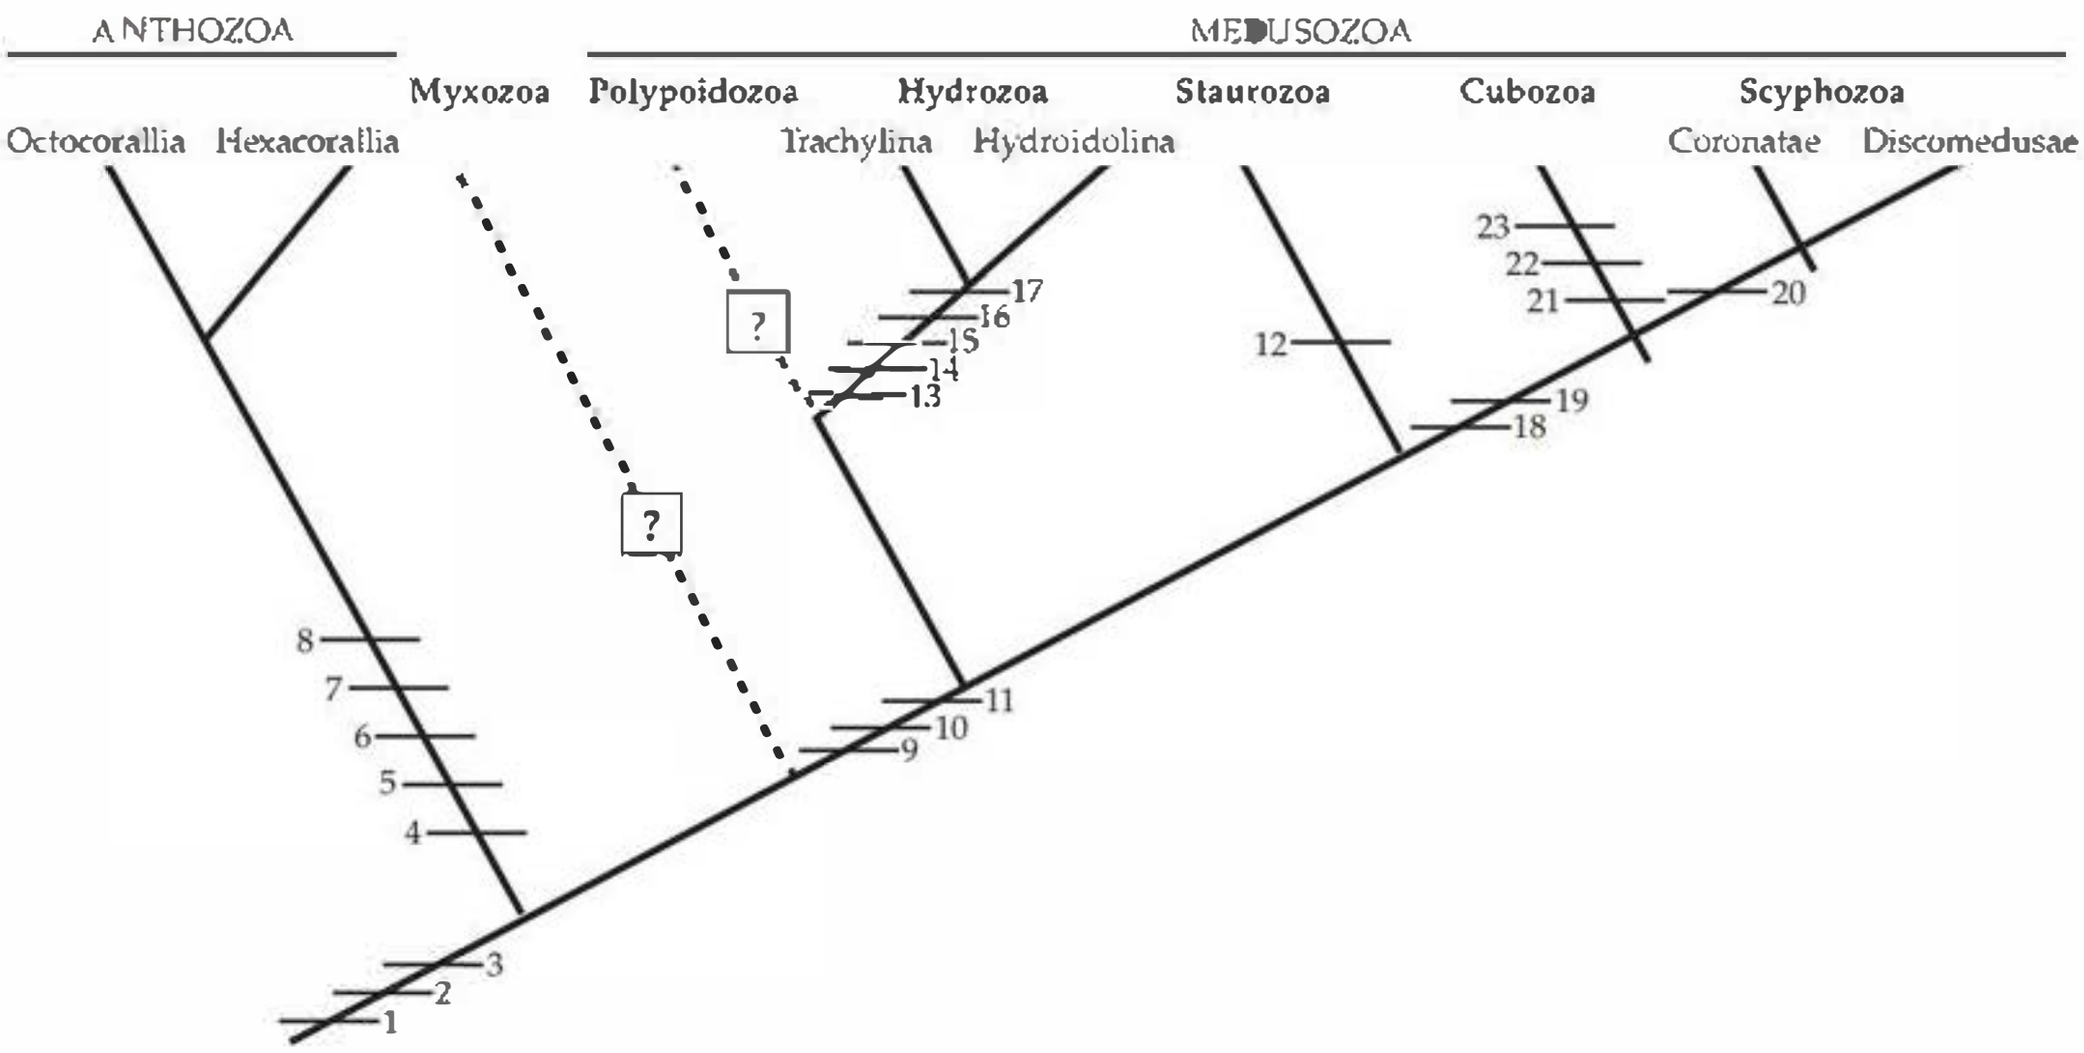

Figure 7.46 A molecular-based phylogeny of the Cnidaria, overlaid with key synapomorphies of the major lineages.
Synapomorphies of Cnidaria: (1) Cnidae; (2) Epithelio-muscular cells; (3) Planula larva.
Synapomorphies of Anthozoa: (4) Hexaradial/Octaradial symmetry; (5) Actinopharynx; (6) Siphonoglyph; (7) Mesenterial filaments in coelenteron; (8) Tripartite series of flaps on cnidae.
Synapomorphies of Medusozoa: (9) Medusae and alternation of generations; (10) Linear DNA; (11) Operculate cnidae (with cnidocil).
Synapomorphies of Staurozoa: (12) Evolution of unique life cycle, with stauropolyps and sessile stauromedusae.
Synapomorphies of Hydrozoa: (13) Relocation of gamete-forming tissue to epidermis; (14) Loss of gut mesenteries; (15) Simplification of middle layer to an acellular mesoglea; (16) Evolution of craspedote medusa form; (17) Loss of gastrodermal nematocysts.
Synapomorphies of Cubozoa-Scyphozoa: (18) Reduction or loss of polyp; (19) Rhopalia.
Synapomorphies of Scyphozoa: (20) Strobilation.
Synapomorphies of Cubozoa: (21) Boxlike medusae form; (22) Lensed rhopaliar eyes; (23) Velarium.

asexual reproduction, and this development ultimately led to the highly specialized colonial groups such as the Siphonophora, Milleporidae, and Stylasteridae. In the class Scyphozoa, evolution has clearly favored increasing specialization of the pelagic medusoid form and diminishing importance of the polypoid stage in their life cycle. Scyphomedusae and cubomedusae have evolved large size, special musculature, a cellular or fibrous mesenchyme, a complex gastrovascular system, and a fairly sophisticated sensory system.

Anthozoans are characterized by several unique synapomorphies: hexaradial or octaradial symmetry (transformed into biradial symmetry in most); the actinopharynx, siphonoglyphs, and unique mesenterial filaments in the coelenteron; absence of a cnidal operculum and cnidocil; tripartite flaps on the cnidae; and special ciliary cones associated with the cnidocytes. Anthozoans also possess a more complex gastrovascular and nervous system than seen among the Medusozoa, as well as a greater degree of cellularity of the mesenchyme.

Among members of the class Anthozoa, evolution has produced a grand series of experiments in colonial polypoid living, resulting in such "superorganisms" as stony corals, octocorals, pennatulaceans, and zoanthidians. Within the Hexacorallia, stony corals (scleractinians) first appear in the fossil record in the Middle Triassic period, about 237 million years ago, although the first scleractinians were not reef builders. Scleractinian origins (and radiations) are still not well understood. Suggested extinct ancestors of Scleractinia include three Paleozoic coral groups: the Rugosa, the Heterocorallia, and the Tabulata. The Rugosa (sometimes called horn corals) and Heterocorallia had their polyps divided by septa into 4 cycles (rather than 6 as in Scleractinia) and the septa arose in a pinnate fashion (rather than cyclically as in Scleractinia). Tabulate corals were nonseptate. The connection between rugose corals, which formed calcite skeletons, and modern scleractinians, whose skeletons are aragonite, is tightened by the discovery of Cretaceous scleractinians with calcite skeletons.

Within the Scleractinia, molecular evidence appears to confirm the existence of two clades, "robust" species with solid, heavily calcified skeletons forming

massive or platelike structures, and "complex" species with lighter, more porous and more complex skeleton structures. Within these clades, only the Poritiina and Dendrophiliina appear to be monophyletic, suggesting that relationships based on morphology alone are likely to be misleading in this group. Possibly contributing to this diversity, recent evidence suggests that coloniality and symbiosis with zooxanthellae have been repeatedly acquired and lost throughout the history of stony corals, a tendency that may have allowed scleractinians to diversify within reef and non-reef communities, as well as recover from repeated local extinctions over evolutionary time. An increase in polyp size within the Anthozoa seems to have occurred over time, along with the evolution of complex structural components of the mesenchyme and increasingly efficient musculature. Anthozoans, of course, have greatly exploited a commensal relationship with zooxanthellae more so than members of the other classes. Convergent evolution has occurred frequently throughout the Cnidaria, as witnessed by such features as colonies, calcareous skeletons, the velum-velarium structures, and various means of suppressing the medusoid or polypoid stage in the life cycle.

The two recently recognized cnidarian lineages, Myxozoa and Polypoidozoa, represent experiments in parasitic life histories, with the first more successful than the second. Myxozoans now appear to be comprised of nearly 2,200 species that clearly fall within the Cnidaria, but whose relationships to one another are still uncertain. The morphology of the Polypoidozoa suggests that they arose from within the Medusozoa. However, the precise phylogenetic position of both taxa is uncertain at this time. Additional phylogenetic analyses of the Cnidaria in the coming years are certain to produce exciting new results.

CHAPTER 8

Phylum Ctenophora

The Comb Jellies

Ctenophores (Greek *ctes*, "comb"; *phero*, "to bear")--commonly called comb jellies, sea gooseberries, or sea walnuts—are transparent, gelatinous animals. Most of them are planktonic, living from surface waters to depths of at least 3,000 meters, and a few species are epibenthic. Their transparency and fragile nature make them difficult to capture or observe by traditional sampling methods such as towing or trawling with nets, and until the recent advent of manned submersibles and "blue water" SCUBA techniques they were thought to be only modestly abundant. However, they are now known to form a major portion of the planktonic biomass in many areas of the world, and they may periodically be the predominant zooplankters in some areas. About 100 species have been described, but there are probably many deep-sea forms yet to be discovered.

The ctenophores are radially (biradially) symmetrical, probably diploblastic animals, resembling cnidarians in many respects. This similarity is immediately obvious, for example, in features such as symmetry, a gelatinous mesenchyme or collenchyme, the absence of a body cavity between the gut and the body wall, and a relatively simple, netlike nervous system. Some zoologists, however, have viewed these similarities as convergent features resulting from adaptations to pelagic lifestyles. Ctenophores are significantly different from cnidarians in their more extensively organized digestive system, their wholly mesenchymal musculature, and certain other features (Box 8A). There remains uncertainty as to the origin of the ctenophoran mesenchyme; some evidence suggests it is primarily ectodermally derived, yet other evidence favors an endodermal origin. The latter possibility might at first suggest developmental homology with the true mesoderm of bilaterians. However, sequencing of the genome of *Pleurobrachia bachei* has shown that the genes involved in mesoderm development in bilaterians have no homologous counterpart in the mesenchymal development of Ctenophora.

Ctenophores also differ fundamentally from cnidarians in that they are monomorphic throughout their life histories, are never colonial, and lack

any trace of an attached sessile stage. Ctenophores lack a hard skeleton, an excretory system, and a respiratory system. Most are simultaneous hermaphrodites capable of self-fertilization an unusual quality among the Metazoa. A distinctive larval stage, the **cydippid larva**, is usually produced. Ctenophores are exclusively marine. They display a wonderful variety of shapes, and they range in size from less than 1 cm in height to ribbon-shaped forms 2 m long (Figure 8.1). Some have evolved rather bizarre body forms, and a few have taken up a benthic creeping existence. They occur in all the world's oceans and at all latitudes. Desiccated specimens of the genus *Pleurobrachia* are often found washed ashore after storms. However, in their planktonic environment, ctenophores are some of the most elegant and graceful creatures in the sea, and observing them in their natural habitat is a memorable experience.

Taxonomic History and Classification

Perhaps because many well-known ctenophores are brilliantly luminescent and are commonly seen from ships, the group has been known since ancient times. The first recognizable figures of ctenophores were drawn by a ship's doctor and naturalist in 1671. Linnaeus placed them in his group Zoophyta, along with various other "primitive" invertebrates. Cuvier classified them with medusae and anemones in Zoophytes. In the early nineteenth century, Johann Friedrich von Eschscholtz designed the first rational classification of pelagic medusae and ctenophores by creating the orders Ctenophorae (for comb jellies), Discophorae (for all the solitary cnidarian medusae), and Siphonophorae (for the colonial siphonophorans and chondrophorans). Eschscholtz viewed these orders as subdivisions of the class Acalepha, regarding them as intermediate between Zoophytes and Echinodermata (on the basis of the common presence of radial symmetry). Recall that it was Leuckart who, in 1847, first separated the Coelenterata from the echinoderms, although his Coelenterata also included sponges and ctenophores Raspailia Vosmaer (in 1877) was responsible for removing the sponges and Hatschek (in 1889) for removing the ctenophores as separate groups.

Until recently, two classes of ctenophores were recognized: Nuda, for species lacking tentacles (the single order Beroida); and Tentaculata, for those species with tentacles (all other orders). However, the monophyly of these two groups had been questioned. Recent molecular analyses indicate that while the Ctenophora overall are monophyletic, the presence or absence of tentacles may provide little phylogenetic information.

BOX 8A Characteristics of the Phylum Ctenophora

1. Diploblastic (or possibly triploblastic) Metazoa, with ectoderm and endoderm separated by a cellular mesenchyme
2. Biradial symmetry; the body axis is oral–aboral
3. With adhesive exocytotic structures called colloblasts
4. Gastrovascular cavity (gut) is the only "body cavity"; gut with stomodeum and canals that branch complexly throughout body; gut ends in two small anal pores
5. Without discrete respiratory, excretory, or circulatory systems (other than the gut)
6. Nervous system in the form of a nerve net or plexus, but more specialized than that of cnidarians
7. Musculature always formed of true mesenchymal cells
8. Monomorphic, without alternation of generations and without any kind of an attached sessile life stage
9. With eight rows of ciliary plates (combs or ctenes) at some stage in their life history; comb rows controlled by unique apical sense organ
10. Some adults and most juveniles with a pair of long tentacles, often retractable into sheaths
11. Most are hermaphroditic; typically with a characteristic cydippid larval stage

Until more robust phylogenetic trees are achieved, we follow Rich Harbison and Larry Madin (1983) in simply dividing the ctenophores into 7 orders (containing 19 families). Figure 8.2 illustrates the general anatomy of the major groups. The position of the Ctenophora among the basal Metazoa is still under debate. Some molecular phylogenetic studies have suggested they might be basal animals, but most have found Porifera to be the basalmost Metazoa, with Ctenophora being close to Cnideria in the tree of life.

(L) Order Lobata, *Deiopea*.

PHYLUM CTENOPHORA

ORDER CYDIPPIDA (Figures 8.1A and 8.2A,B). Pelagic; with well developed comb rows; tentacles long and retractable into sheaths; body globular or ovoid, occasionally flattened in the stomodeal plane; meridional canals end blindly, paragastric canals (when present) end blindly at mouth. This order is widely viewed as polyphyletic and in need of revision. (e.g., *Aulococtena, Bathyctena Callianira Dryodora, Euplokamis, Haeckelia Hormiphora Lampea, Mertensia, Pleurobrachia, Tinerfe*)

ORDER PLATYCTENIDA (Figure 8.2F-H). Planktonic or benthic; most species greatly flattened, with part of stomodeum everted as a creeping sole; often with tentacle sheaths; tentacle canals bifid; gastrovascular system complex and anastomosing; most species possess anal pores; many are ectocommensals on other organisms (e.g., corals). Unlike most ctenophores, fertilization is often internal, and many platyctenids brood their embryos to the larval stage; asexual reproduction is common. (e.g., *Coeloplana, Ctenoplana, Gastra, Lyrocteis Planoctena Savangia, Tjalfiella, Vallicula*)

ORDER CESTIDA (Figures 8.1E and 8.2I). Pelagic; body extremely compressed in tentacular plane, and greatly elongated in stomodeal plane, producing a ribbon like form up to 1 m long in some species; substomodeal comb rows elongated, extending along entire aboral edge; subtentacular meridional canals arise under subtentacular comb rows (*Cestum*) or equatorially from interradial canals (*Velamen*); paragastric canals extend along oral edge and fuse with meridional canals; tentacles and tentacle sheaths present. Two genera *Cestum* and *Velamen*

ORDER GANESHIDA (Figure 8.2C). Pelagic; body form somewhat intermediate between Cydippida and Lobata, compressed in tentacular plane; tentacles branched and with sheaths; interradial canals arise from infundibulum and divide into adradial canals, which join the aboral ends of the meridional canals; meridional canals and paragastric canals join and form a circumoral canal (as in Beroida); mouth large and expanded in tentacular plane; without auricles or oral lobes. One genus, *Ganesha*, with two known species

ORDER LOBATA (Figures 8.1D,F-H and 8.2J-L). Pelagic; body compressed in tentacular plane; with a pair of characteristic oral lobes and four flaplike auricles; a ciliated auricular groove extends to base of auricles from each side of each tentacle base; paragastric and subtentacular meridional canals unite orally. (e.g., *Bolinopsis, Deiopea, Leucothea, Mnemiopsis, Ocyropsis*)

ORDER THALASSOCALYCIDA Pelagic; body extremely fragile, expanded orally into medusalike bell, to 15 cm along tentacular axis; body slightly compressed in stomodeal plane; tentacle sheaths absent; tentacles arise near mouth and bear lateral filaments; comb rows short; mouth and pharynx borne on central conical peduncle; meridional canals long, describing complex patterns in bell; all meridional canals end blindly aborally Monotypic: *Thalassocalyce inconstans*.

ORDER BEROIDA (Figures 8.1B-C and 8.2D,E). Pelagic; body cylindrical or thimble-shaped and strongly flattened in tentacular plane; tentacles and sheaths absent; aboral end rounded (*Beroe*) or with two prominent keels (*Neis*); stomodeum greatly enlarged; aboral sense organ well developed; comb rows present; meridional canals with numerous side branches; paragastric canals simple or with side branches. Without a cydippid larva phase. Two genera: *Beroe* and *Neis*.

The Ctenophoran Body Plan

Although ctenophores are among the most ancient of living animals, they do possess true tissues. Between the epidermis and the gastrodermis is a well-developed middle layer, which is always a cellular mesenchyme. Within this mesenchyme true muscle cells develop, a condition that also characterizes the triploblastic Metazoa although by different developmental pathways.

As we noted in the preceding chapter, a critical essence of the cnidarian and ctenophoran body plans is radiality (or biradiality); we have explained some of the structural constraints and advantages that derive from this symmetry. Thus, predictably, the nervous system of ctenophores is in the form of a simple, noncentralized nerve net, and the locomotor structures are arranged radially about the body. Other features that characterize the Ctenophora include: retractile **tentacles** and often **tentacle sheaths**; **anal pores**; adhesive prey-capturing structures called **colloblasts**; locomotor structures called **ctenes** or comb plates, arranged in **comb rows**; and an **apical sense organ** containing a statolith that regulates the activity of the comb rows. The sheathed tentacles, colloblasts, comb plates, and nature of the apical sense organ are unique features of ctenophores. Figures 8.2 and 8.3 illustrate ctenophoran anatomy.

Most ctenophores are spherical or ovoid in shape, although some species have evolved flattened shapes through compression and elongation in one of the two planes of body symmetry (Figures 8.1E and 8.2I). The general body plan can best be understood by first examining a generalized cydippid ctenophore (Figure 8.3). Specialists have long considered the cydippids to be ancestral within the phylum, although recent evidence suggests that the order Cydippida is probably polyphyletic. As in cnidarians, the principal axis is oral-aboral. The mouth is at the oral pole; the aboral pole bears the apical sense organ. On the surface of the body are eight equally spaced **meridional rows** of comb plates. Each comb plate, or ctene, is composed of a transverse band of long, fused (= compound) cilia. On each side of the body of many species is a deep, ciliated epidermal pouch (the tentacle sheath) from whose inner wall a tentacle arises. The tentacles are typically very long and contractile, and bear lateral branches called **filaments**, or **tentillae**. The epidermis of both the

tentacle and the lateral tentillae is richly armed with colloblasts. Most species can retract the tentacles into the sheaths with muscles. It is the tentacles and certain aspects of the internal anatomy that give ctenophores a biradial symmetry (although some workers have described a more nuanced version of this in ctenophores, called "rotational symmetry"). The elongate stomodeum lies on the oral–aboral axis of the body. It is distinctly flattened in one plane of body symmetry, the stomodeal plane (Figure 8.3B). Bisecting the animal along the stomodeal plane separates the two tentacular halves of the body. The second plane of body symmetry, called the tentacular plane, is defined by the position of the tentacle sheaths.

Some variations of the basic ctenophoran body plan are illustrated in Figures 8.1 and 8.2. In members of the unique order Lobata (Figure 8.2J–L and chapter opener

Figure 8.4 *Thalassocalyce inconstans*, in the monotypic order Thalassocalycida, with its expanded oral lobes that form a medusa-like bell.

photo), the body is compressed in the tentacular plane and the oral end is expanded on each side into rounded, contractile oral lobes. The mouth sits on an elongate region, the base of which bears four long flaps called auricles. The tentacles are reduced and lack sheaths. From either side of each tentacle base, a ciliated auricular groove arises and extends to the auricles.

Members of the order Cestida (Figures 8.1E and 8.2I) are also compressed in the tentacular plane and extremely elongated in the stomodeal plane, giving these ctenophores a striking snake- or ribbon-like appearance. The sheathed tentacles are reduced and shifted alongside the mouth. Beroida are thimble-shaped and also flattened in the tentacular plane (Figure 8.1B,C and 8.2D,E). They lack tentacles and sheaths. In the single species of Thalassocalycida (*Thalassocalyce inconstans*), the body is expanded around the mouth to form a medusa-like bell (Figure 8.4).

The oddest ctenophores are members of the order Platyctenida (Figures 8.1I and 8.2G–H). Platyctenids are benthic and small, often less than 1 cm in length; in contrast to most pelagic ctenophores, they are pigmented rather than transparent. The body is oval and markedly flattened. Despite these unusual features, early naturalists recognized them as ctenophores by the presence of an apical sense organ, comb rows, and a pair of tentacles. Detailed studies have shown that the flattened oral surface is actually an everted portion of the pharynx! The platyctenid pharynx was, in a sense, preadapted to serve a dual purpose as a creeping foot or sole by its intrinsic musculature. Most of these animals crawl about on the sea bottom, but some are ectocommensals on alcyonarian cnidarians, echinoderms, or pelagic salps.

Support and Locomotion

Ctenophores rely primarily on their elastic mesenchyme for structural support. The watery gelatinous mesenchyme makes up most of the body mass; ctenophore dry weights are only about 4 percent of their live wet weights. The mesenchyme contains both elastic supportive cells and muscle cells, the general tonus of the latter being primarily responsible for maintaining body shape. Figure 8.5 shows a highly stylized cutaway section of a cydippid ctenophore and illustrates the arrangement of the supportive mesenchymal muscle fibers. Tension in the looped muscles tends to maintain the spherical geometry. Action of the radial muscles diminishes the radius and hence the circumference, and also serves to open the pharynx. These two muscle sets work antagonistically to one another.

Most ctenophores are pelagic. The gelatinous body and low specific gravity maintain relatively neutral buoyancy, allowing these creatures to float about with the ocean currents. Neutral buoyancy appears to be maintained by passive osmotic accommodation. Because buoyancy adjustments take time, ctenophores may temporarily accumulate at discontinuity layers in the sea, where a water mass of one density overlies a water mass of a slightly different density.

The beating of the ctenes provides most of the modest locomotor power that allows ctenophores to move up and down in the water column and to locate richer feeding sites or preferred environmental conditions. Each comb row comprises many ctenes. Each ctene consists of a transverse band of hundreds of very long, partly fused cilia (to 3.5 mm in length) that beat together as a unit. Ctenophores are the largest animals known to use cilia for locomotion. Each cilium has a typical 9+2 microtubule structure, but each also possesses a unique set of lamellae at the 3 and 8 doublets; these lamellae protrude to link together the adjacent cilia.

Ctenophores are beautiful animals to observe in life because their beating comb rows appear iridescent over a wide range of light intensities. This feature of

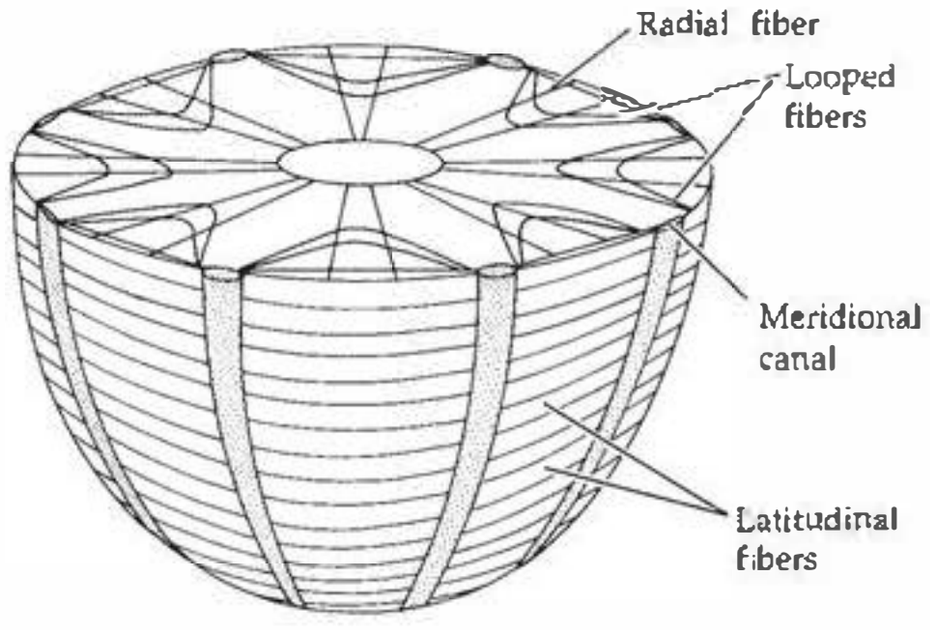

Figure 8.5 Stereogram of the arrangement of muscle fibers in *Pleurobrachia*, a cydippid ctenophore. The diagram depicts a transverse section through the region of the pharynx; the gastrovascular system and tentacle sheaths have been omitted for clarity.

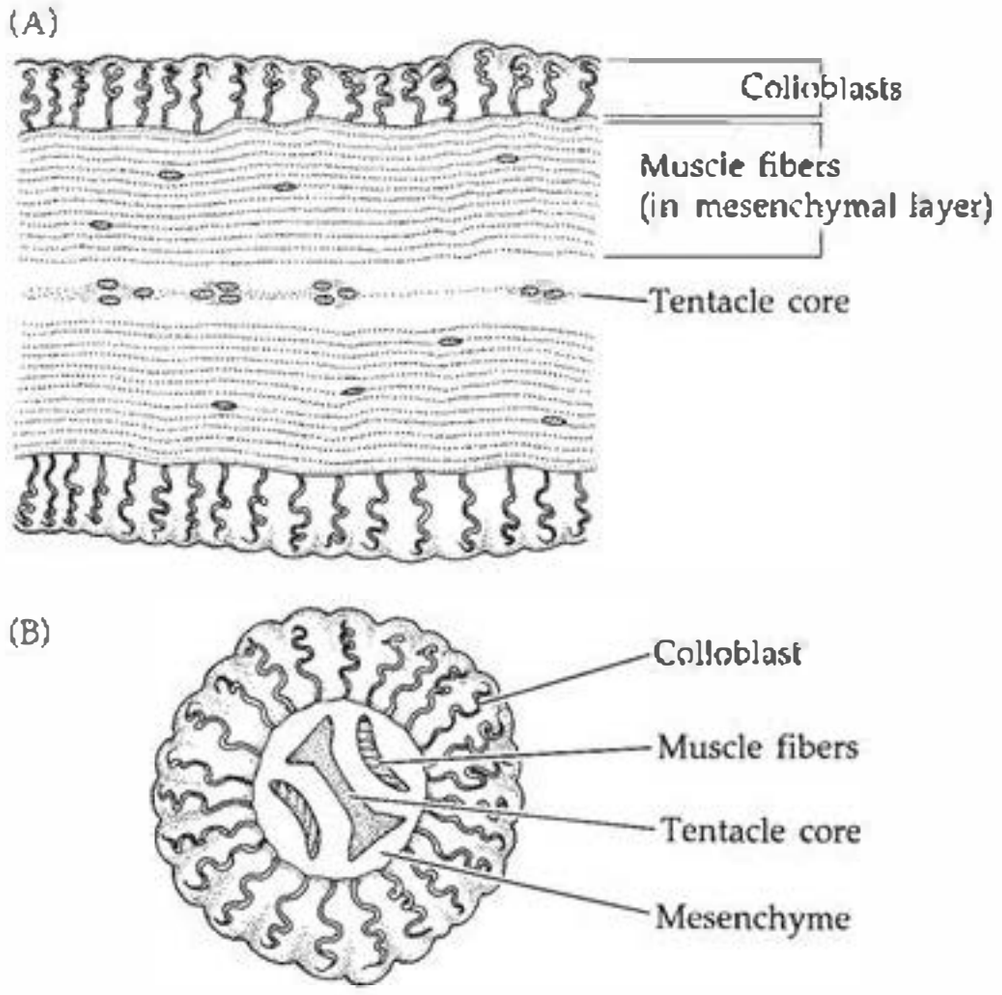
ctenophoran movement appears to be caused by the dense and highly regular packing of ciliary elements at the base of each comb row. While iridescence may serve to discourage predators or attract prey, it seems unlikely to function in social communication among ctenophores because of the simplicity of these animals' visual systems. Because of their size, ctenophore ctene plates move at low Reynolds numbers, where fluid flow is smoother but where water viscosity can impede ciliary movement. In contrast, the bodies of ctenophores move at higher Reynolds numbers, where viscosity is less important but water turbulence can impede or enhance animal movement through the medium.

As noted above, the mesenchymal musculature is used to maintain body shape and assist in feeding; it is involved in behaviors such as prey swallowing, pharyngeal contractions, and tentacle movements. Usually both longitudinal and circular muscles are present just beneath the epidermis. In the benthic and epifaunal platyctenids, stomodeal musculature facilitates a creeping locomotion. In the snakelike cestids, body muscles may generate graceful swimming undulations. Swimming in the lobate ctenophores is assisted by muscular flapping of their two oral lobes, and perhaps also by use of the four paddle-like auricles. The lobate species *Leucothea* (Figure 8.1F) can swim either by typical slow ctene propulsion or by rapid ctene propulsion; the latter is accomplished by an increased ciliary beat that produces a vortex wake, resulting in jet propulsion. Giant smooth muscle fibers—the first to be discovered in ctenophores—have been found in *Beroe*.

Feeding and Digestion

Comb jellies, so far as is known, are mostly predatory in their habits. The long tentacles of cydippids (and of the larvae of most other forms) have a muscular core with a colloblast-laden epidermal covering (Figure 8.6). The tentacles trail passively or are "fished" by various swirling movements of the body. Upon contact with zooplankton prey, the colloblasts (sometimes called lasso cells) burst and discharge a strong adhesive material. Each colloblast develops from a single cell and consists of a hemispherical mass of secretory granules attached to the muscular core of the tentacle by a spiral filament coiled around a straight filament (Figure 8.7). The straight filament is actually the highly modified nucleus of the colloblast cell. The spiral filament, which uncoils upon discharge, adheres to the prey by the sticky material produced in the secretory granules. As the tentacles accumulate prey, they are periodically wiped across the mouth by muscular contractions, occasionally combined with a coordinated somersaulting action of the animal that brings the mouth to the trailing tentacle. In members of the orders Lobata and Cestida, which bear very short tentacles, small zooplankton are trapped in mucus on the body surface and then carried to the mouth by ciliary currents (along the ciliated auricular grooves in lobate forms and ciliated oral grooves in cestids). Most of the benthic platyctenids also feed by capturing zooplankton in a somewhat similar fashion.



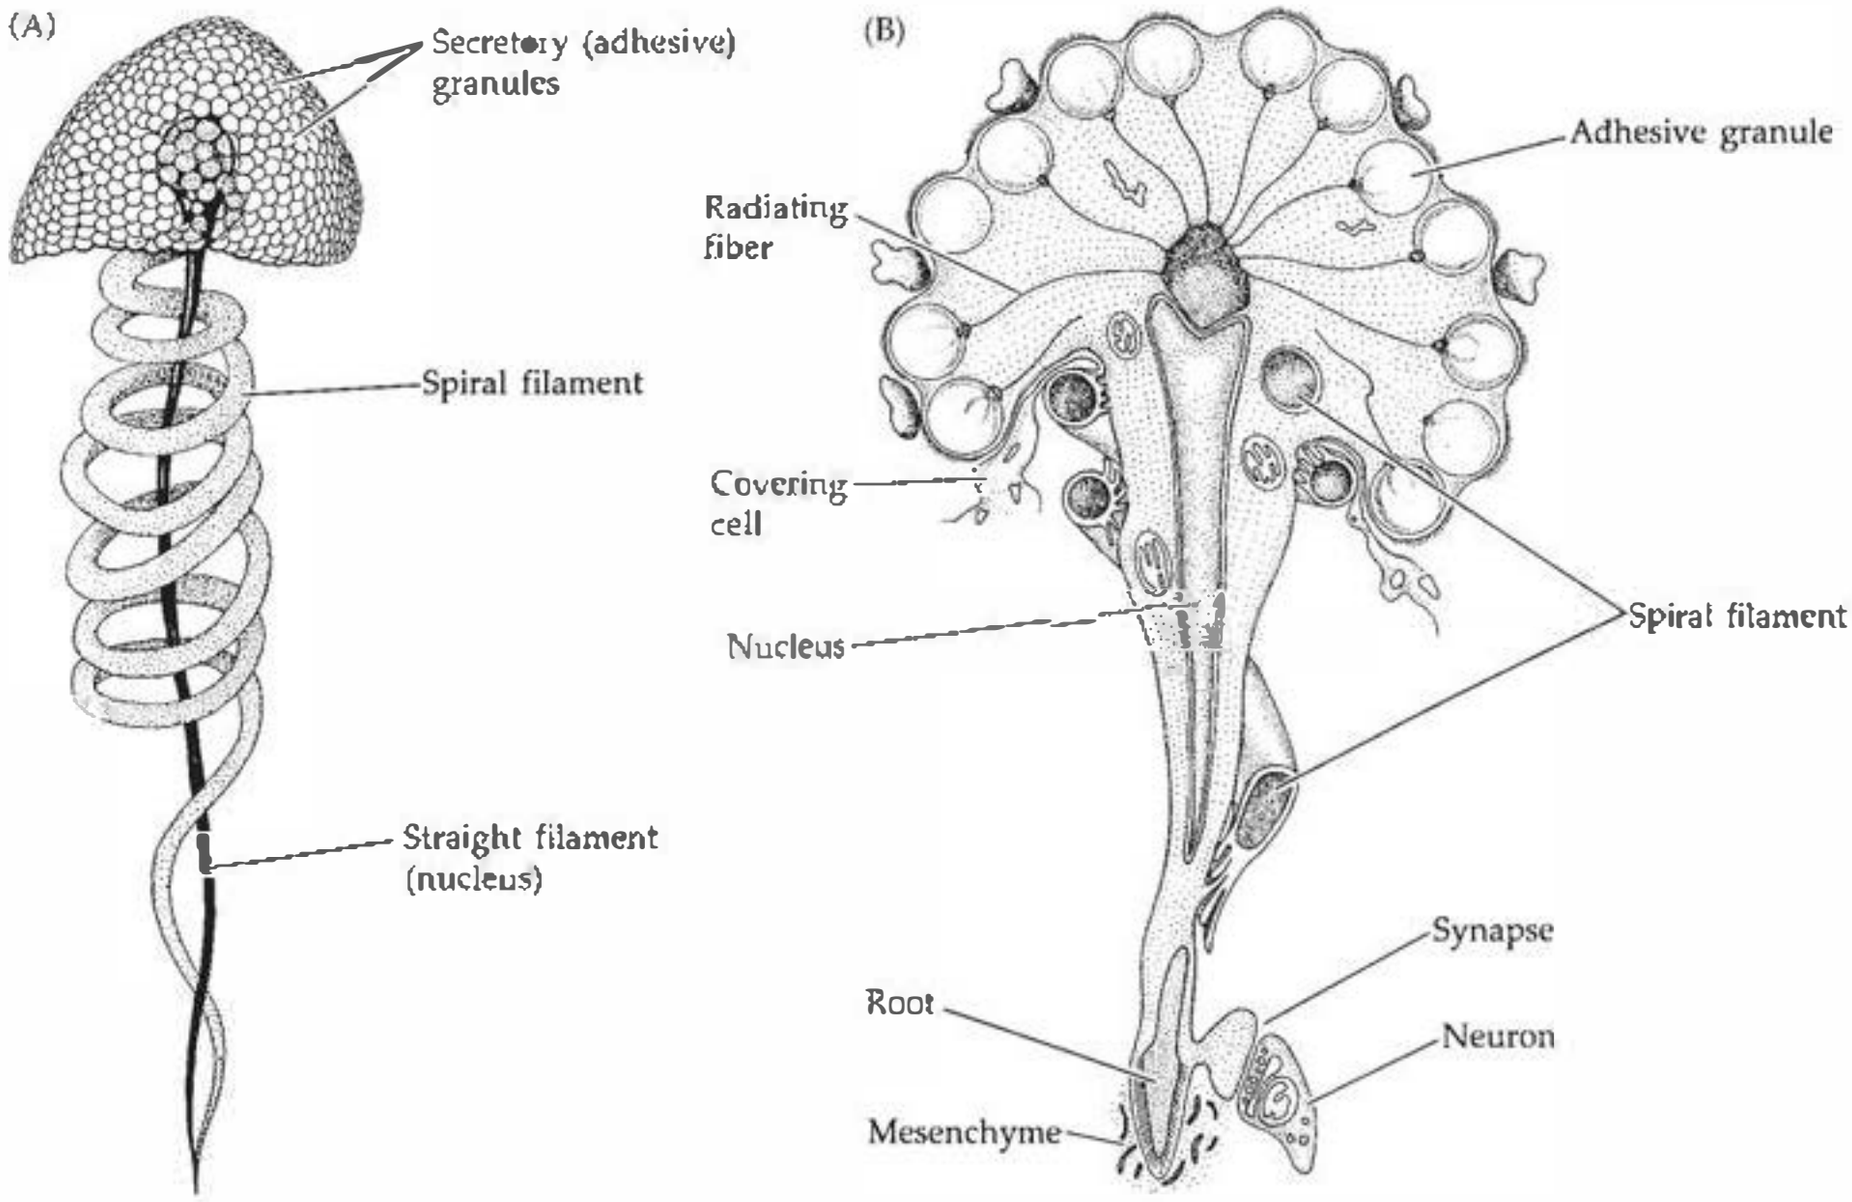


Figure 8.6 Ctenophore tentacle structure. (A) Longitudinal section of tentacle. (B) Cross section of a lateral filament (tentilla) of a tentacle.

In some areas of the world's seas, ctenophores may be the dominant macrozooplankters and planktonic predators (e.g., *Mertensia ovum* in the Arctic region). Early life stages of *Mnemiopsis leidyi* also consume significant quantities of microphytoplankton and microzooplankton, indicating a mixed diet. Stable isotope studies of the lobate ctenophore, *Bolitopsis infundibulum* indicate that these animals rely primarily on surface photosynthetic products for food, suggesting that some species may lie quite low in the food chain. These same animals also appear to supplement their diet with copepods, which may sink to waters layers near the sea floor during diapause, and where *B. infundibulum* may form large aggregations to feed on this abundant source of carbon. The tendency of ctenophores to form aggregations near food sources or at the water's surface may contribute to their patchy distribution in nature.

Some ctenophores prey on larger animals, especially gelatinous forms. The cydippid *Lampea* (formerly *Gastrodes*), for example, lives embedded in the body of pelagic tunicates of the genus *Salpa*, on which it feeds. Figure 8.8 is a series of remarkable photographs showing the cydippid ctenophore *Haeckelia* eating the tentacles of the trachyline hydromedusa, *Aegina*. After

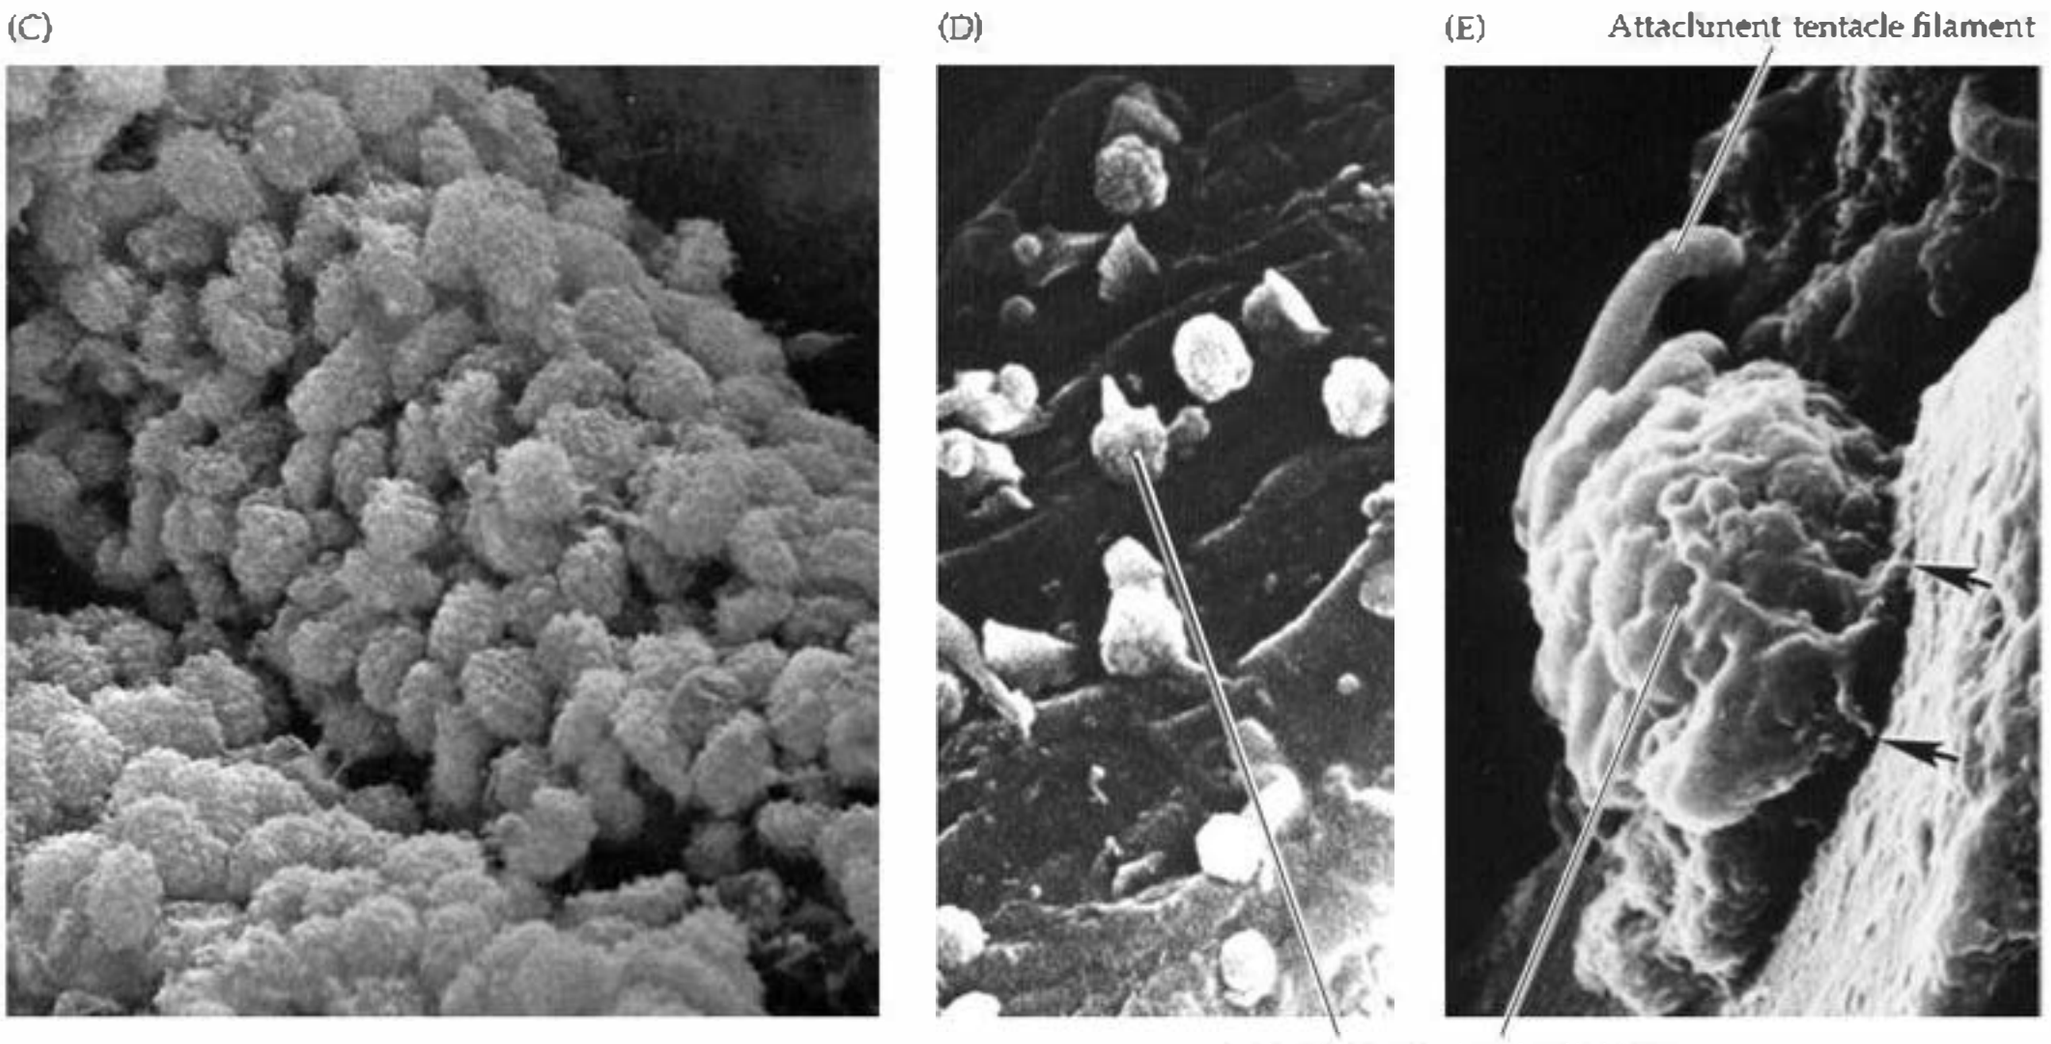

Figure 8.7 **Colloblasts** (A) The functional parts of a colloblast. (B) Longitudinal section. (C) Colloblasts on the lateral tentacle filaments (tentillae) of *Pleurobrachia* (SEM). consuming the tentacles one by one, *Haeckelia* retains the prey's unfired nematocysts, incorporates them into its epidermis, and uses them for its own defense. This phenomenon, known as **kleptocnidae**, occurs in several unrelated groups who prey on cnidarians.

Ctenophores were center stage in an ecological drama that played out in the Black Sea not long ago. In the 1980s, the predatory northwest Atlantic ctenophore *Mnemiopsis leidyi* was accidentally introduced into the Black Sea by way of ship ballast

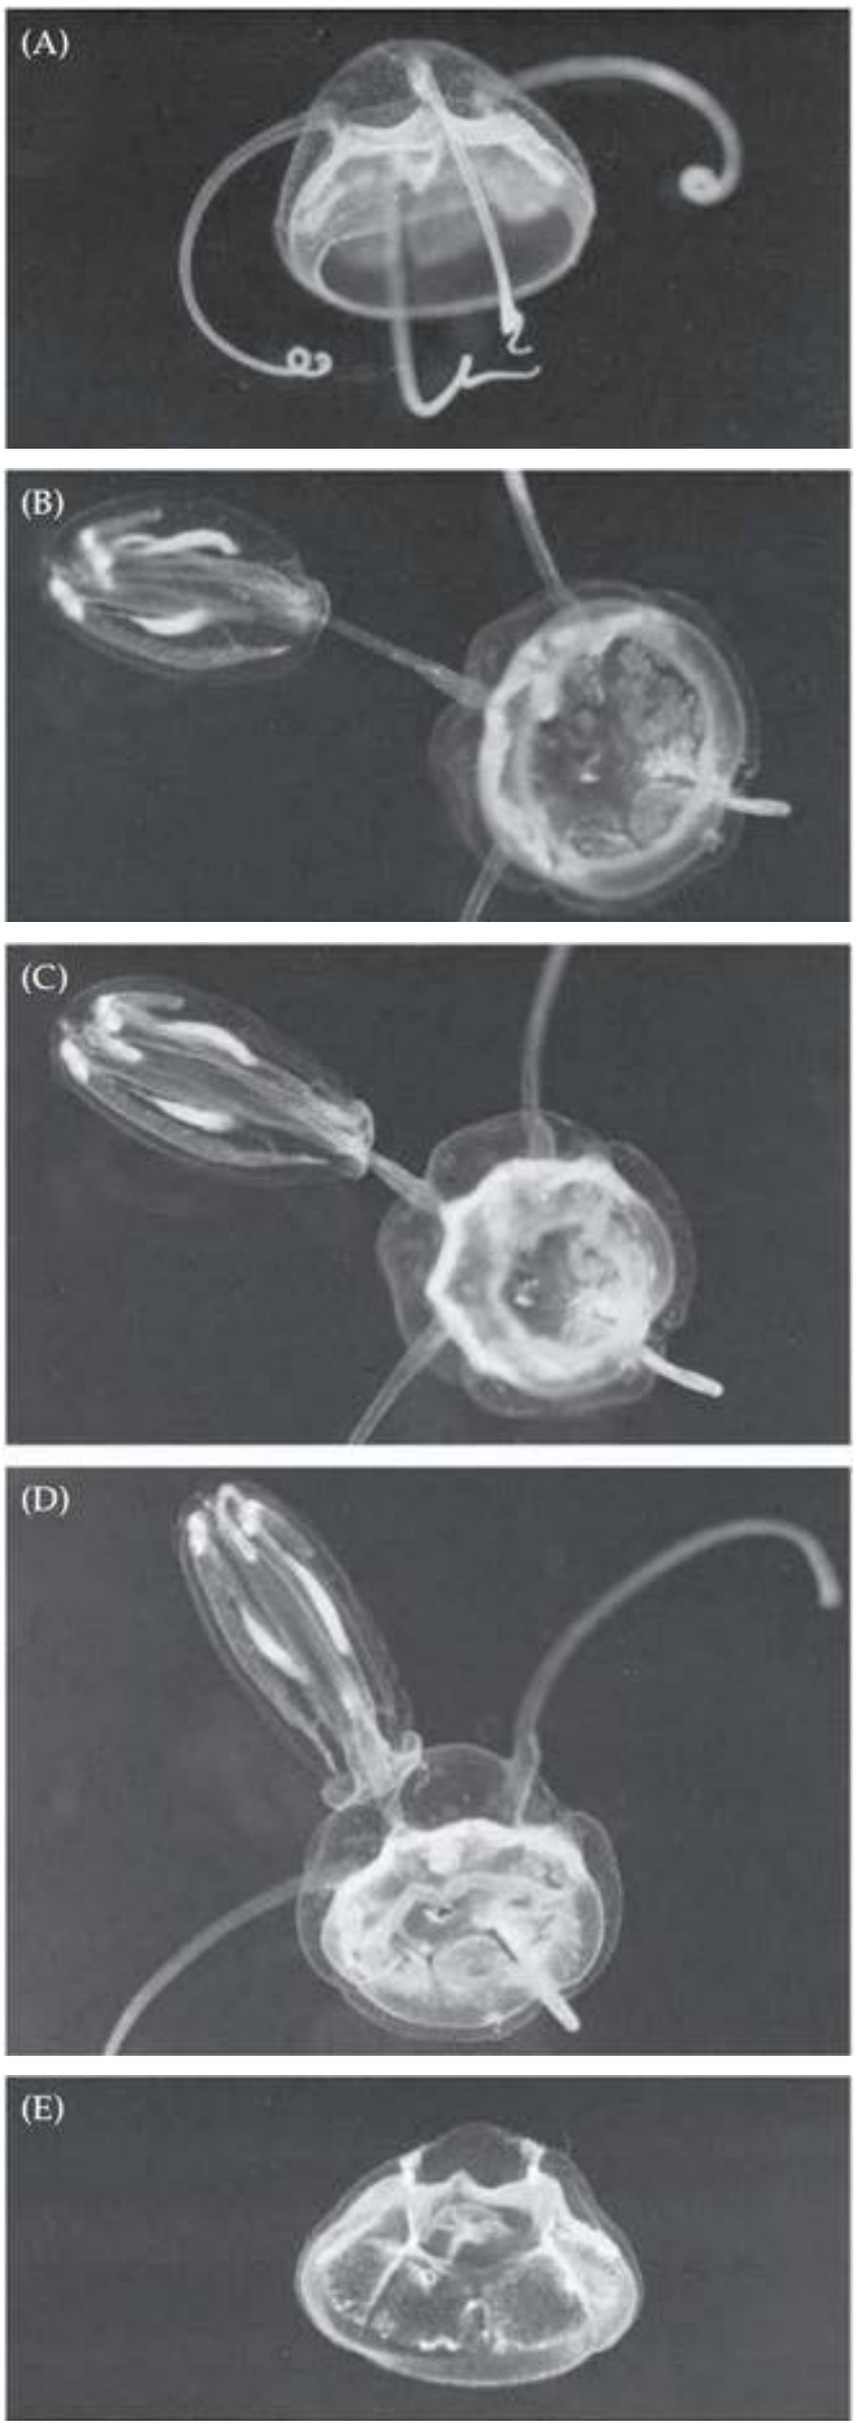

Figure 8.8 The cydippid ctenophore *Haeckelia rubra* (= *Euchlora rubra*) feeding on the trachyline hydromedusa *Aegina citrea*. (A) Intact specimen of *Aegina*, with all four tentacles present. water. The few invaders quickly underwent explosive population growth, reaching biomass levels in excess of one kilogram per cubic meter by 1989, devastating the food web of the entire Black Sea Basin and causing a collapse of the anchovy fishery (one of the favored prey of *M. leidyi*). Then, in 1997, another ctenophore, *Beroe ovata*, was accidentally introduced to the Black Sea, probably also from ballast water. *Beroe ovata* feeds almost exclusively on *Mnemiopsis*, and its introduction resulted in a precipitous decline (perhaps extirpation) of *M. leidyi* in the sea, followed at last by the disappearance of *Beroe* itself. Introduced ctenophores continue to present a threat to local fisheries in many parts of the world and their numbers are now monitored closely, particularly in the Mediterranean Sea. Most recently, *M. leidyi* has invaded the Caspian and Baltic Seas

The ctenophoran mouth opens into an elongate, highly folded, flattened, muscular, stomodeal pharynx. The epithelium of the pharynx is richly endowed with gland cells that produce the digestive juices. Large food items are tumbled within the pharynx by ciliary action. Digestion takes place extracellularly, mostly in the pharynx. The largely digested food passes via a small chamber (the **infundibulum**, funnel, or stomach) from the pharynx into a complex system of radiating gastrovascular canals (Figures 8.2 and 8.3). The details of the arrangement of the canals vary among different groups; the following description applies to the arrangement in a cydippid.

Two paragastric or pharyngeal canals recurve and lie parallel to the pharynx. Two transverse canals depart at right angles to the stomodeal plane and divide into three more branches. The middle branch of each triplet, the tentacle canal, leads to the base of the tentacle sheath. Each of the other two branches (the interradial canals) bifurcates to form a total of four adradial canals on each side of the animal. These in turn connect to the eight meridional canals, one beneath each comb row. Finally, an aboral canal passes from the infundibulum to the aboral pole, where it divides beneath the apical sense organ into four short canals, two ending blindly and two (the anal canals) opening to the outside via small anal pores. The anal pores serve as a rudimentary anus, assisting the mouth in the voiding of indigestible wastes. They may also serve as an exit for metabolic wastes

Within this very complicated gastrovascular canal system, digestion is completed, nutrients are distributed through the body, and absorption takes place Minute pores lead from the various canals into the mesenchyme (Figure 8.9). Surrounding these pores are circlets of ciliated gastrodermal cells called ceil rosettes, which appear to regulate the flow of the digestive soup and perhaps also play a role in excretion. Except for the stomodeal pharynx, the gastrovascular system is lined by a simple epithelium of endodermal origin.

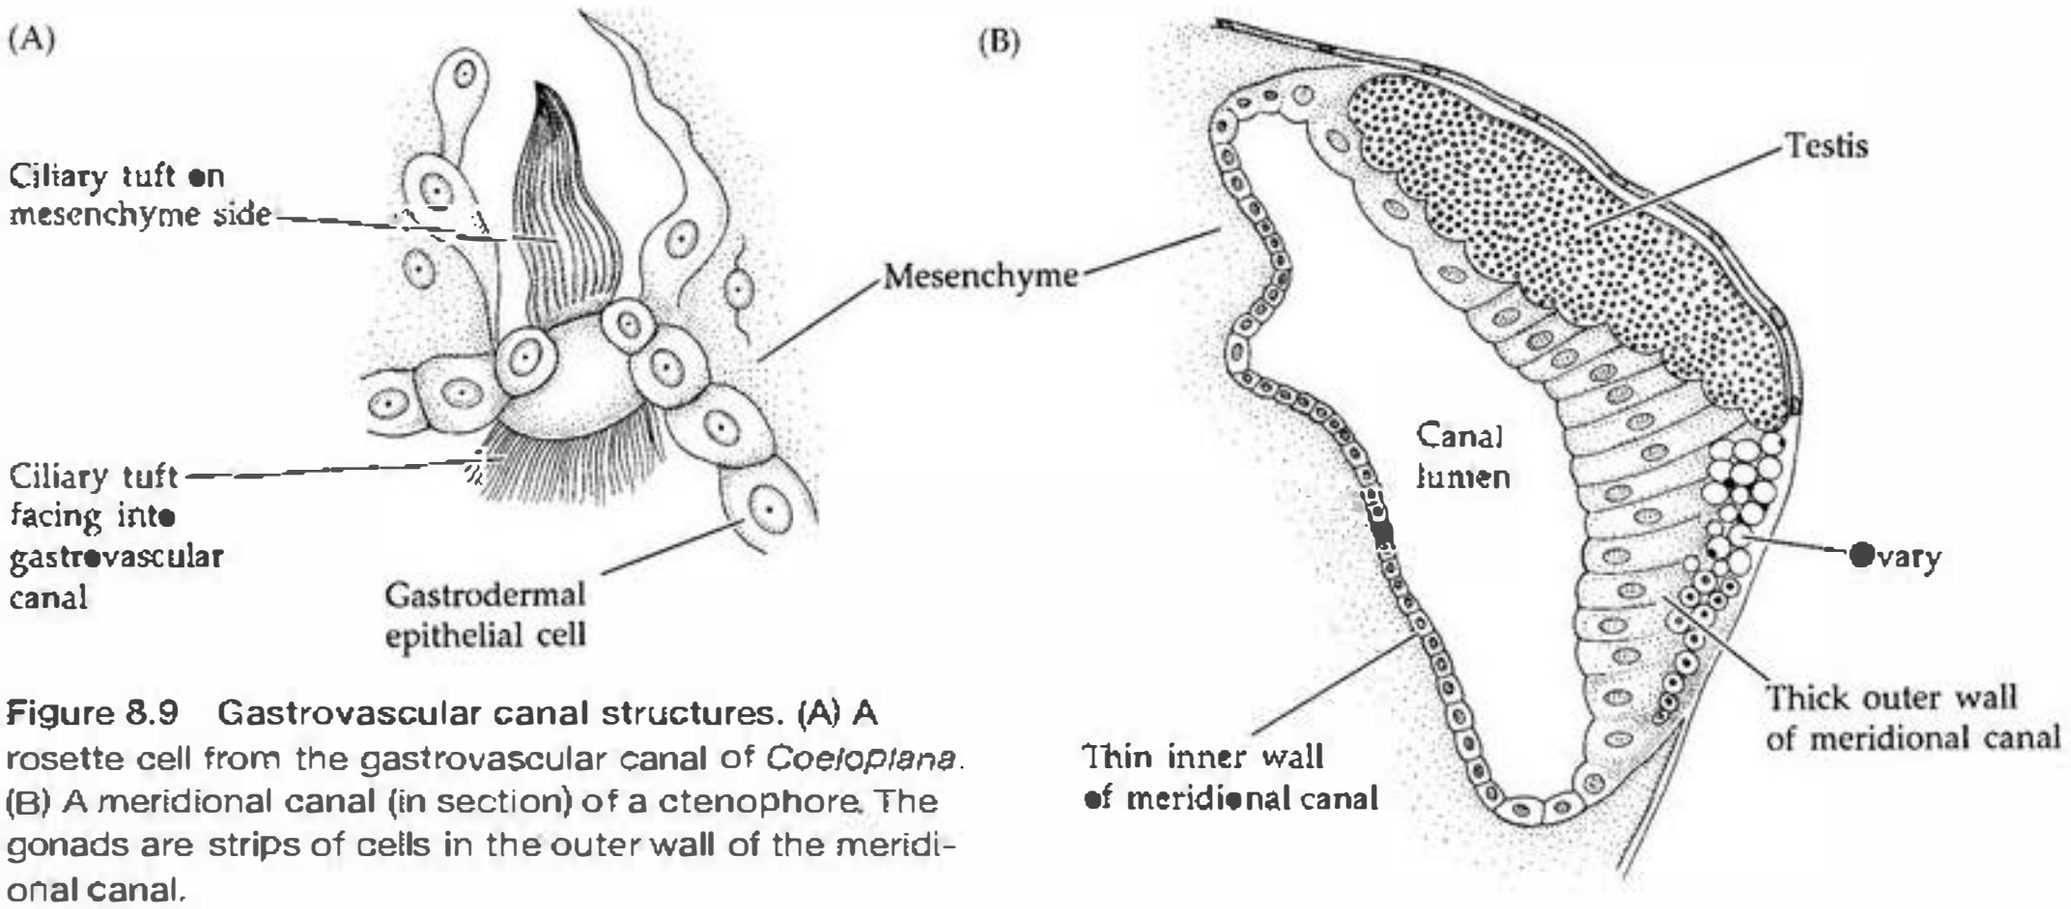

Figure 8.9 Gastrovascular canal structures. (A) A rosette cell from the gastrovascular canal of *Coeloplana*. (B) A meridional canal (in section) of a ctenophore. The gonads are strips of cells in the outer wall of the meridional canal.

Circulation, Excretion, Gas Exchange, and Osmoregulation

There is no independent circulatory system in ctenophores; as in cnidarians, the gastrovascular canal system serves in this role by distributing nutrients to most parts of the body. The gastrovascular system probably also picks up metabolic wastes from the mesenchyme for eventual expulsion out of the mouth or anal pores. The cell rosettes may also transport wastes to the gut. Gas exchange occurs across the general body surface and across the walls of the gastrovascular system. All of these activities are augmented by diffusion through the gelatinous mesenchyme. Movement of water over the body surface is enhanced by the beating of the comb plates. Thus, the extensive canal system and the ciliary bands help to overcome the problem of long diffusion distances.

Nervous System and Sense Organs

Although the nervous systems of both ctenophores and cnidarians are noncentralized nerve nets, there are certain important differences. In a ctenophore, nonpolar neurons form a diffuse subepidermal plexus. Beneath the comb rows, the neurons form elongate plexes or meshes such that they produce nervelike strands. The bases of the ctenes are thus in contact with a rich array of nerve cells. A similar concentrated plexus surrounds the mouth. However, as in cnidarians, no true ganglia occur, a condition that contrasts markedly with the presence of a centralized nervous system in bilateral Metazoa (the Bilateria).

The nerve nets of ctenophores consist of polygonal nerve cords spread under the ectodermal epithelium; these nerve nets show high levels of regional specialization and concentrations associated with the apical sensory organ/polar fields and tentacle bulbs, structures without clear homologs in any other animal group.

The apical sense organ is a statolith that functions in balance and orientation. The calcareous statolith is supported by four long tufts of cilia called balancers (Figure 8.10). The whole structure is enclosed in a transparent dome that apparently is also derived from cilia. From each balancer arises a pair of ciliated furrows (= ciliated grooves), each of which connects with one comb row. Thus, each balancer innervates the two comb rows of its particular quadrant. Tilting the animal causes the statolith to press more heavily on the downside balancers, and the resulting stimulus elicits a vigorous beating of the corresponding comb rows to right the body.

The two comb rows in each quadrant innervated by a single ciliated furrow beat synchronously. If a ciliated furrow is cut, the beating of the two corresponding comb rows becomes asynchronous. The normal direction of ciliary power strokes is toward the aboral pole, so that the animal is driven forward oral end first. The beat in each row, however, begins at the aboral end of the comb row and proceeds in metachronal waves toward the oral end (i.e., antiplectic metachrony). Stimulation of the oral end reverses the direction of both the wave and the power stroke. Removal of the apical sense organ or statolith results in an overall lack of coordination of the comb rows, and the injured ctenophore loses its ability to maintain a vertical position. The comb rows are very sensitive to contact; when a comb row is touched, many species retract it into a groove formed in the jelly-like body.

In cydippids and beroids, the stimulation for any given ctene to beat is triggered mechanically, by hydrodynamic forces arising from the movements of the preceding plate. However, in the lobate ctenophores, the ctenes are not coordinated in this mechanical fashion. In these animals a narrow tract of shorter cilia—the interplate ciliated groove—runs between successive ctenes and is responsible for coordinating their activity.

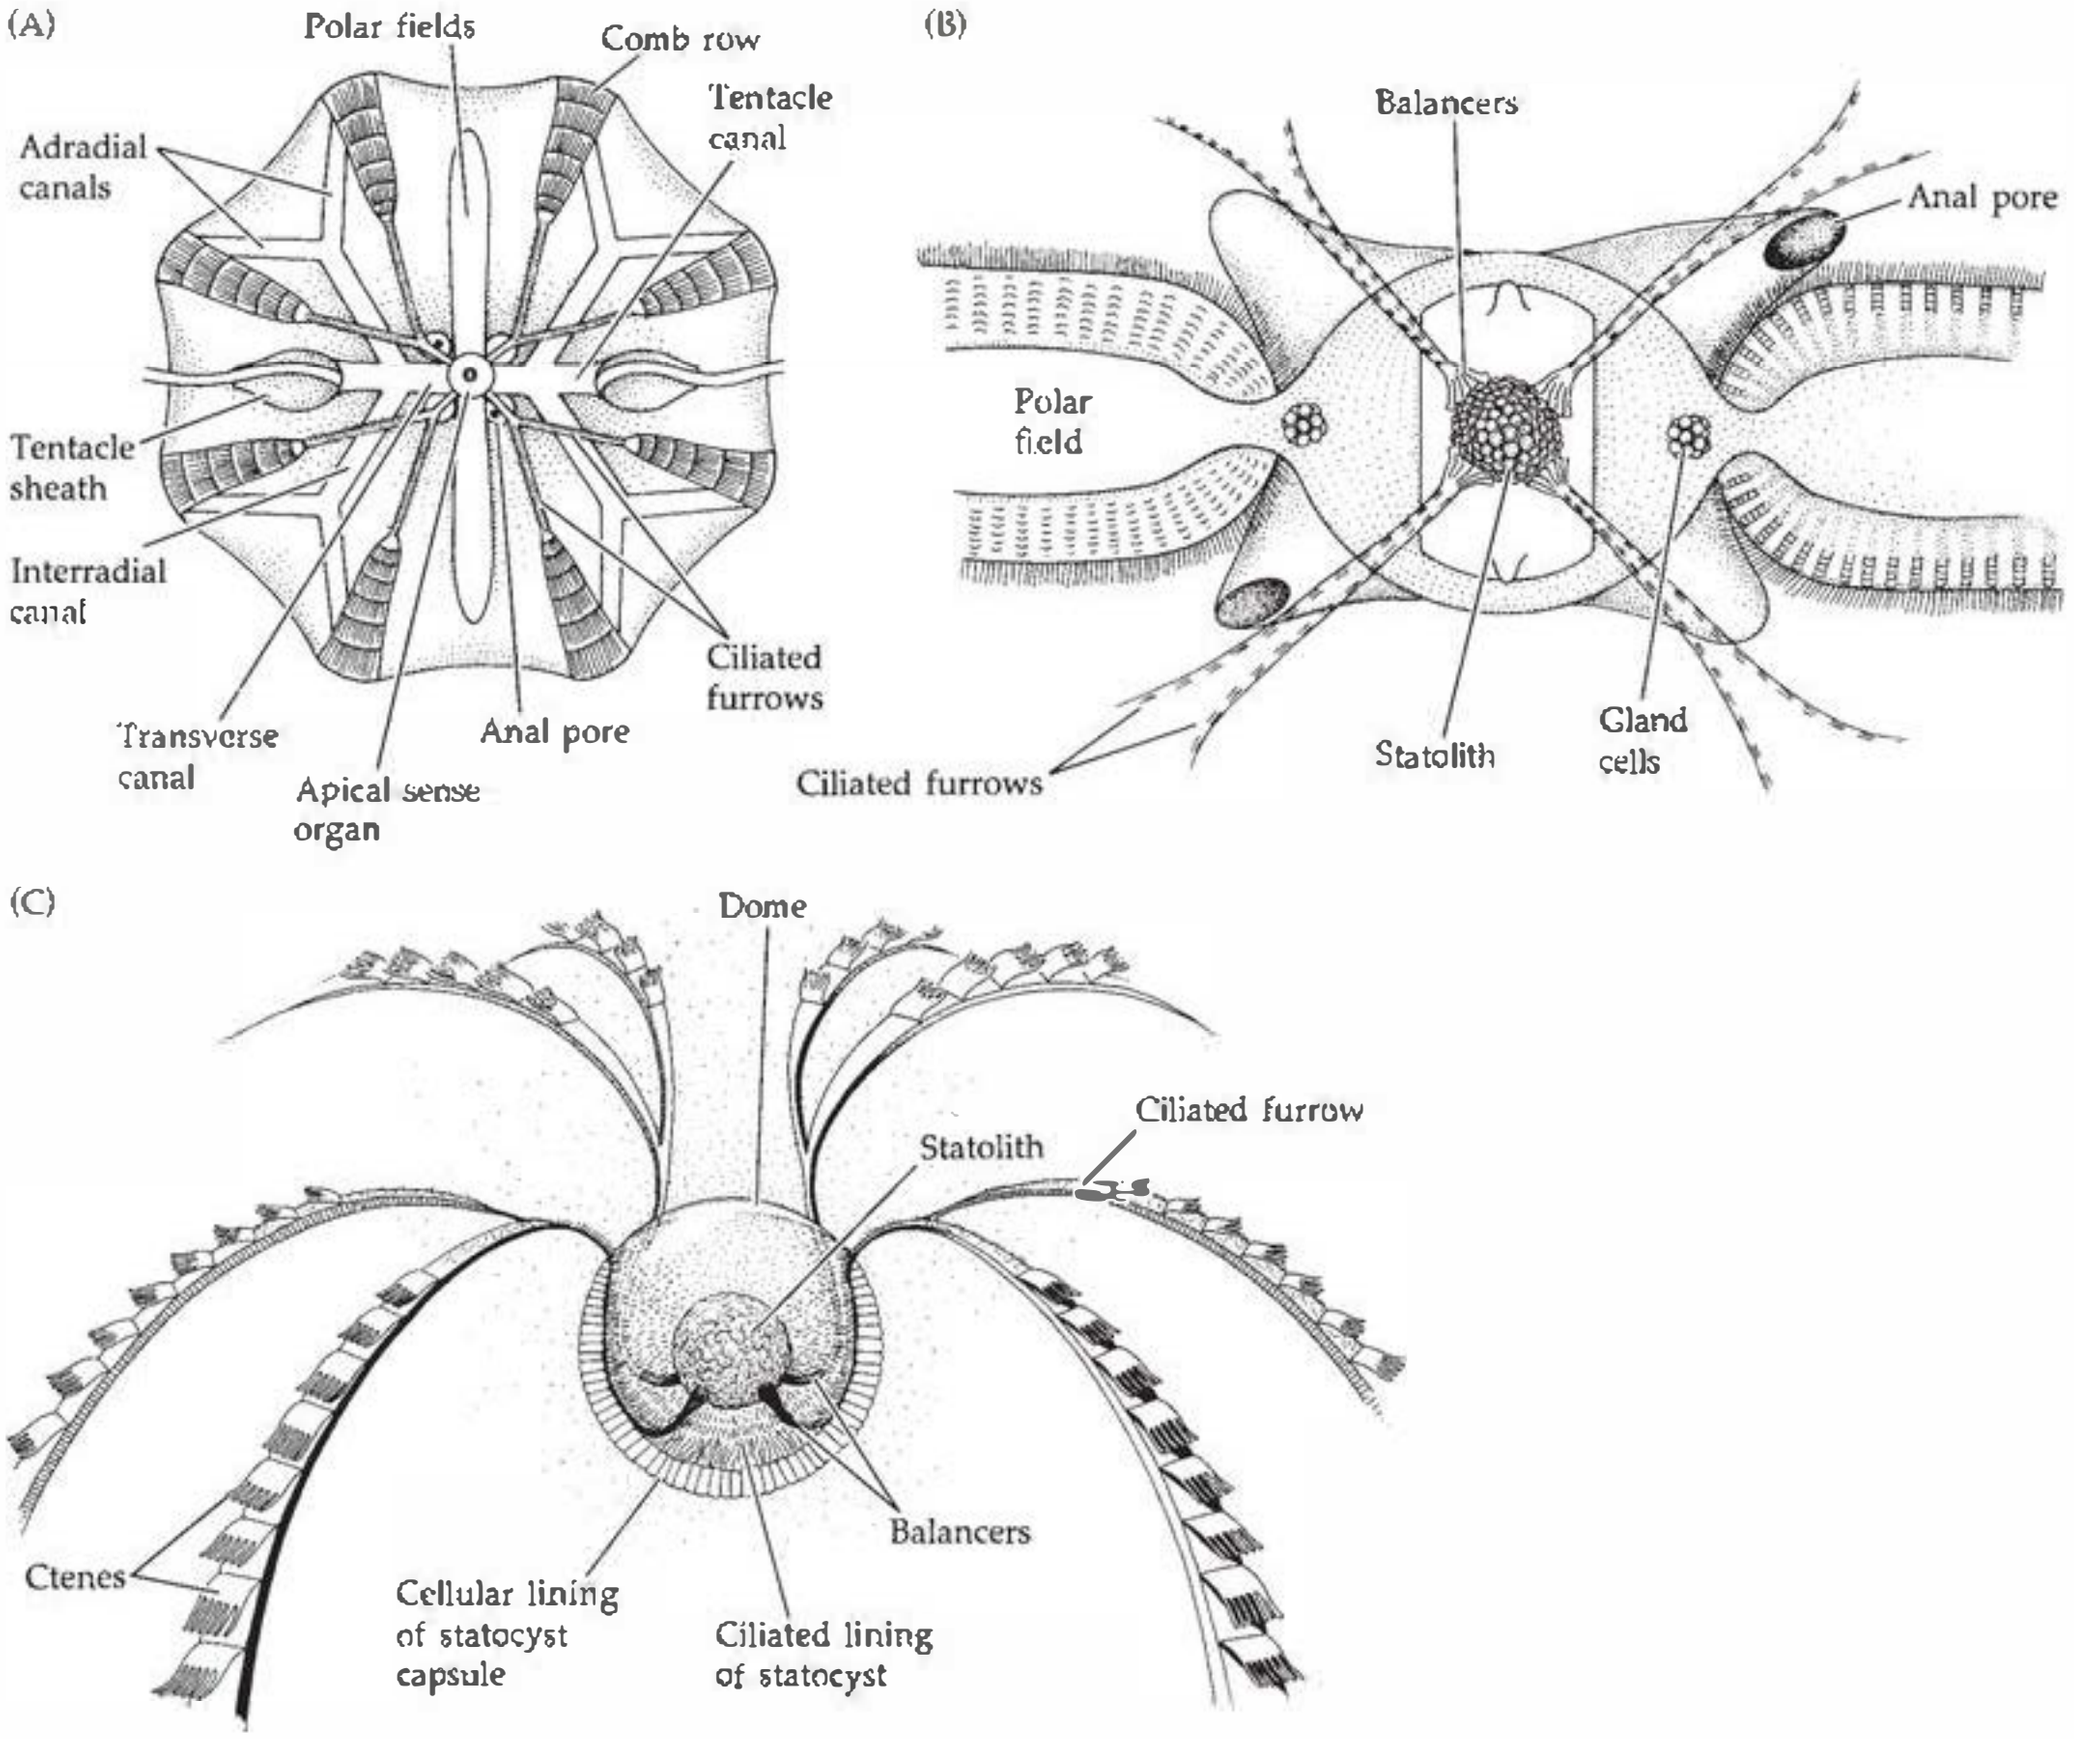

Figure 8.10 The ctenophore apical sense organ. (A) *Pleurobrachia* (aboral view). Note the relationship of the statocyst to the comb rows, the ciliated furrows, and the gastrovascular canals. (B) Apical sense organ of the cydippid *Hormiphora*. (C) Apical sense organ and its relationship to the eight comb rows.

It is not known how the cilia of the groove are coordinated or how the grooves stimulate the appropriate comb row, so these actions may also be mechanical. The interplate ciliated grooves develop only as the lobate ctenophores mature to adulthood; the free-swimming larvae resemble cydippids and lack the grooves.

In some ctenophores, two oval tracts of cilia called polar fields lie on the stomodeal plane of the aboral surface (Figure 8.10B). These structures are presumed to be sensory in function.

Reproduction and Development

Asexual reproduction and regeneration Ctenophores can regenerate virtually any lost part, including the apical sense organ. Entire quadrants and even whole halves will regenerate. Speculation that ctenophores may reproduce by fission or budding is still under investigation. Platyctenids reproduce asexually by a process that resembles pedal laceration in sea anemones; small fragments break free as the animal crawls, and each piece can regenerate into a complete adult.

Sexual reproduction and development Most ctenophores are hermaphroditic, but a few gonochoristic species are known (e.g., members of the genus *Ocyropsis*). The gonads arise on the walls of the meridional canals (Figure 8.9B). Pelagic ctenophores generally shed their gametes via the mouth into the surrounding seawater, where either self-fertilization or cross-fertilization takes place. Fertilization appears to take place within the meridional canals in *Pleurobrachia*. Special sperm ducts occur in at least some platyctenid species. The eggs are centrolecithal and formed in association with nurse cell complexes. Polyspermy is known to occur in some ctenophores. Those that free-spawn typically produce embryos that grow quickly to planktotrophic

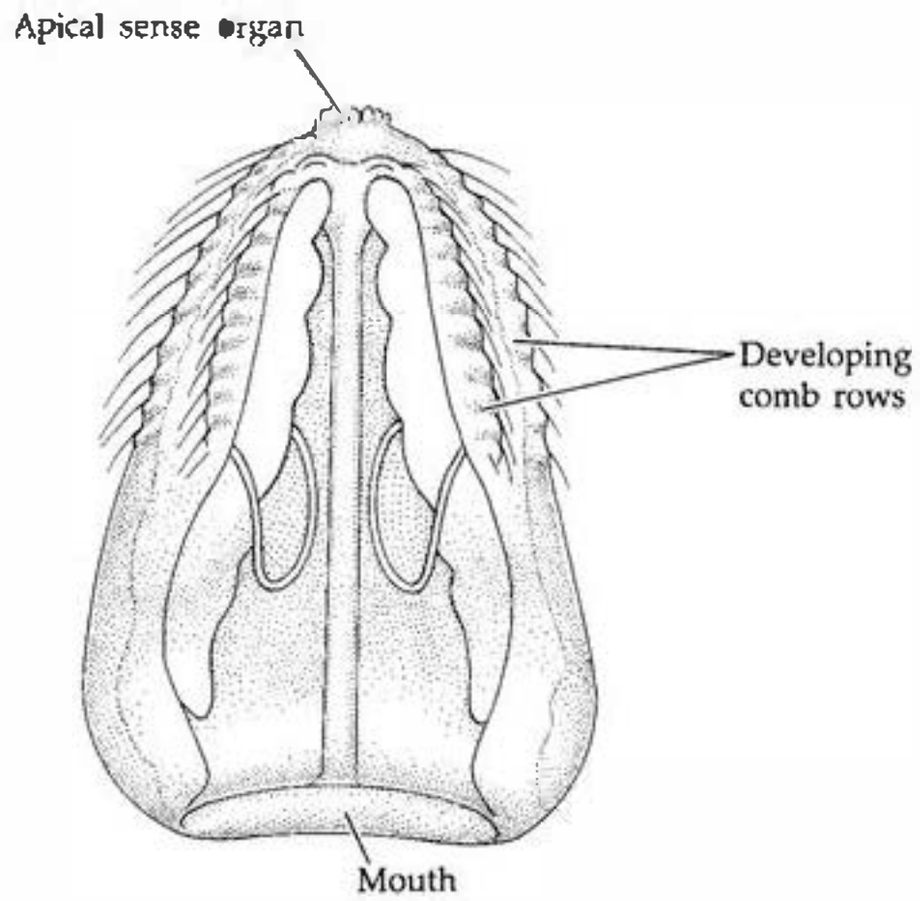

Figure 8.11 A typical young cydippid larva.

cydippid larvae (Figure 8.11), although species in the order Beroida lack this larval phase. Development is thus usually indirect, although growth to the adult is gradual rather than metamorphic. Some ctenophores are known to reproduce sexually before they have completed their larval development, a condition known as dissogeny. Precocious reproduction is known in at least two orders (Lobata: *Mnemiopsis leidyi;* Cydippida: *Pleurobrachia bachei*), and may reflect an evolutionary history favoring early reproduction, possibly because food supplies are only intermittently available, or because predation rates are high. In the benthic *Coeloplana* and *Tjalfiella*, fertilization is internal and embryos are brooded until a cydippid larva is formed and released. This mixed life history provides a means of dispersal for these benthic, sedentary animals.

Ctenophoran cleavage cannot easily be classified as either spiral or radial. During early cleavage, the first four blastomeres arise by the usual two meridional cleavages, which mark the adult planes of symmetry. The third division is also nearly vertical and results in a curved plate of eight cells (macromeres). The next division is latitudinal and unequal, giving rise to micromeres on the concave side of the macromere plate. The micromeres continue to divide and spread by epiboly over the aboral pole and eventually over the macromeres. The latter also invaginate, so the gastrula arises through a combination of epiboly and invagination. Thus, the micromeres become ectoderm and the macromeres become endoderm. Just prior to gastrulation, the macromeres divide and produce additional micromeres on the oral side of the embryo. Whereas the aboral micromeres become ectoderm, these oral micromeres are incorporated into the endoderm and, in at least some species, give rise to photoreceptor cells. There is some question about the fate of all of these oral micromeres. Metschnikoff (1885) suggested that these cells may contribute to the mesenchyme and may thus be viewed as true endomesoderm. Harbison (1985) also made a case for a triploblastic condition in ctenophores. However, as mentioned above, the recently sequenced genome of *Pleurobrachia bachei* shows no indication of developmental homology between ctenophoran mesenchyme and the mesoderm of true triploblast bilaterians.

As the micromeres cover the embryo to form the epidermis, four interradial bands of small, rapidly dividing cells become apparent. Eventually, each of these thickened ectodermal bands differentiates into two of the comb rows. The aboral ectoderm differentiates into the apical sense organ and its related parts; the oral ectoderm invaginates to form the stomodeum. The gastrovascular system develops from endodermal outgrowths and the tentacle sheaths arise as ectodermal invaginations from the points where the tentacles sprout. The embryo eventually develops into a free-swimming cydippid larva (Figure 8.11) that closely resembles adult ctenophores of the order Cydippida. Some authors have taken this as evidence that Cydippida houses the most primitive lineage of extant ctenophores.

The development of ctenophores differs markedly from that of cnidarians. In the latter group, early cleavage results in an irregular mass of cells whose fates are not clearly predictable until later development, and the mesenchyme is strictly ectodermal in origin. In the ctenophores, on the other hand, development is determinate and a very precise cleavage pattern unfolds, in which the ultimate morphology is definitely mapped. For example, if the two blastomeres of a 2-cell embryo are experimentally separated, the "half-embryos" develop into adults with exactly half the normal set of adult structures. Such results indicate that blastomere fate is highly determined, but they also suggest that inductive processes among embryonic cells and tissues are important in ctenophore embryogenesis, as is true in many bilaterian Metazoa. Additional data suggest that such processes can lead to more variation in cell fate than was previously suspected. Ctenophores lack the planula larva that characterizes cnidarians; instead, they produce a cydippid larval type having no obvious counterpart among the cnidarians. The presence of a brief "planula" stage has been reported in the development of the parasitic cydippid *Gastrodes parasiticum* (Komai 1922, 1963) that was said to burrow into the test of host salps, where it then developed into a free-swimming cydippid. This has not been confirmed by any subsequent research, and the nature of Komai's "planula" remains unresolved.

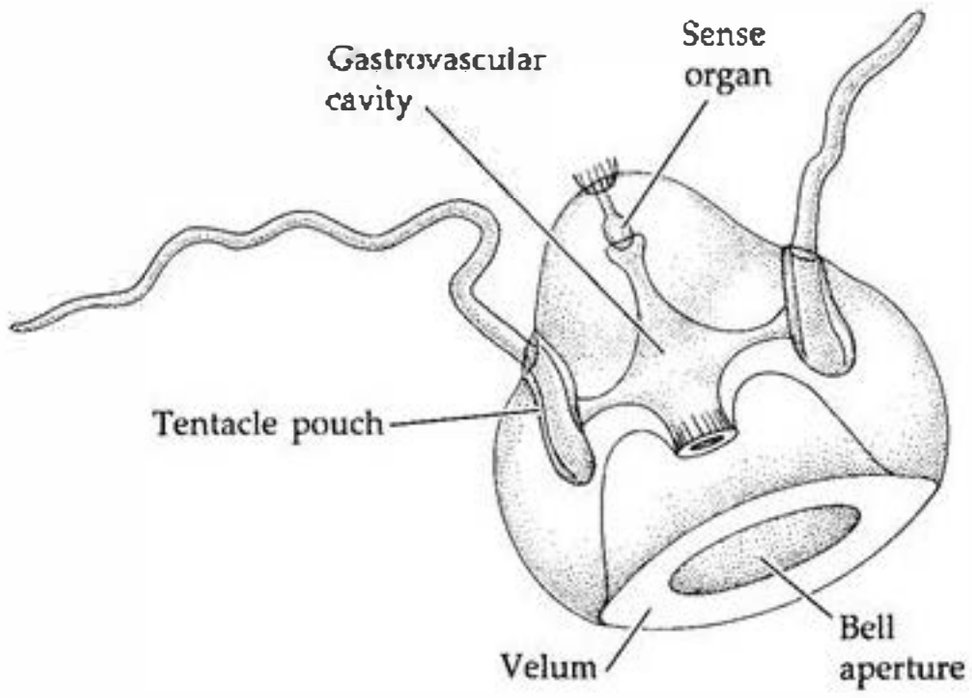

Figure 8.12 The aberrant cnidarian trachyline medusa *Hydroctena*, which superficially resembles a ctenophore in its possession of an apical sensory structure and tentacle pouches.

Ctenophoran Phylogeny

Even though the ctenophores and cnidarians are widely regarded as belonging to the same general grade of construction, it is difficult to link ctenophores to any specific cnidarian group. Although the phylogenetic relationships of the basal Metazoa (Porifera, Placozoa, Cnidaria, Ctenophora) remain enigmatic, some recent molecular phylogenies have united Cnidaria and Ctenophora as sister groups, reviving the old concept of "Coelenterata." Some zoologists have suggested that ctenophores arose from the hydrozoans, by way of an intermediate medusa possessing an aboral statocyst and two tentacle sheaths, such as is seen today in the aberrant trachyline medusa *Hydroctena* (Figure 8.12). In this medusa, the number of tentacles has been reduced to two, and these are set high on the bell, like the tentacles of trachylines in general. The tentacles also arise from deep epidermal pockets that resemble the tentacle sheaths of ctenophores. This argument is weakened by fossil evidence that Cambrian ctenophores probably lacked tentacles entirely. *Hydroctena* also has a single apical sense organ, although its construction differs from that of ctenophores. Several other trachyline medusae also have solitary aboral sense organs.

Although these similarities may suggest a relationship between ctenophores and trachyline cnidarians, and while ctenophores also show certain similarities to the scyphozoans and anthozoans, such as the stomodeum and the highly cellular mesenchyme, and the four-lobed gastrovascular cavity of the cydippid larva, as we have seen, ctenophores are really quite different from cnidarians in many fundamental ways. These differences are evident both in adult morphology and in patterns of development. Many of the similarities between ctenophores and cnidarian medusae may well be convergences reflecting adaptations to their similar lifestyles and, in fact, many gelatinous zooplankters show superficial similarities in body form and construction.

Some molecular phylogenies have placed the Ctenophora basal in the animal tree (below Porifera) as the earliest-diverging animal phylum. Perhaps supporting this hypothesis are next-generation sequencing studies that have shown the genomes of ctenophores and sponges to lack several homeobox-containing genes that are present within the genomes of placozoans, cnidarians, and bilaterians. Further, ctenophore genomes are unique in many respects. For example, they lack microRNA and microRNA-processing machinery, and their mitochondrial genomes are reduced.

The presence of mesenchymal muscle cells and gonoducts in some species, along with certain features of early cleavage, have led some zoologists to suggest a relationship between the ctenophores and the flatworms (Platyhelminthes; Chapter 10). Some researchers have viewed the ctenophores as ancestral to the flatworms; but a reverse scenario has also been suggested. The presence of benthic, crawling ctenophores (e.g., *Ctenoplana* and *Coeloplana*) has been used as evidence that ecological and anatomical intermediates between the two groups are plausible. However, the current consensus is that there is little evidence to link the ctenophores to the flatworms, and molecular phylogenetic studies do not link the two groups.

Phylogenetic relationships within the Ctenophora have been challenged by limited gene data and, in the case of the 18S rRNA gene, highly unequal substitution rates among the lineages. Within the Ctenophora, disagreement exists about whether the tentaculate or atentaculate condition is primitive, and whether the atentaculate lineage (the order Beroida) arose from somewhere among the tentaculate groups. The "atentaculate primitive" hypothesis is supported by the lack of tentacles among Cambrian forms. The modern number of 8-comb rows appears to have stabilized in fossil forms by about 400 million years ago. The enigmatic octoradiate Ediacaran *Eoandromeda* now appears likely to have been a ctenophore, whose comb rows spiraled down the length of its cone-shaped body (Figure 8.13). Limited molecular phylogenetic research to date has provided little resolution of internal ctenophoran relationships, though it suggests that the cydippid family Mertensiidae might be the sister group to all other ctenophores, and the orders Cydippida and Beroida might not be monophyletic. These studies have also supported the monophyly of the orders Lobata, Cestida, and Platyctenida.

CHAPTER 9

Introduction to the Bilateria and the Phylum Xenacoelomorpha

Triploblasty and Bilateral Symmetry Provide New Avenues for Animal Radiation

Along the evolutionary path from prokaryotes to modern animals, three key innovations led to greatly expanded biological diversification: (1) the evolution of the eukaryote condition, (2) the emergence of the Metazoa, and (3) the evolution of a third germ layer (triploblasty) and, perhaps simultaneously, bilateral symmetry. We have already discussed the origins of the Eukaryota and the Metazoa, in Chapters 1 and 6, and elsewhere. The invention of a third (middle) germ layer, the true **mesoderm**, and evolution of a bilateral body plan, opened up vast new avenues for evolutionary expansion among animals. We discussed the embryological nature of true mesoderm in Chapter 5, where we learned that the evolution of this inner body layer facilitated greater specialization in tissue formation, including highly specialized organ systems and condensed nervous systems (e.g., central nervous systems).

In addition to derivatives of ectoderm (skin and nervous system) and endoderm (gut and its derivatives), triploblastic animals have mesodermal derivatives—which include musculature, the circulatory system, the excretory system, and the somatic portions of the gonads. Bilateral symmetry gives these animals two axes of polarity (anteroposterior and dorsoventral) along a single body plane that divides the body into two symmetrically opposed parts—the left and right sides. The evolution of bilaterality also resulted in cephalization, the concentration of sensory and feeding structures at a head end. Bilaterians further evolved a **complete gut** (or through gut), with a mouth and an anus and excretory organs in the form of protonephridia and metanephridia (except in the phylum Xenacoelomorpha, likely the most primitive living bilaterians).

As noted in Chapter 1, the oldest fossils thought to be bilaterians are from the Ediacaran period—embryos found in the Doushantuo deposits of China, dating 600–580 million years ago. The most recent molecular dating studies also suggest that the origin of the Bilateria was probably in the Ediacaran, about 630–600 million years ago, although some dated trees have estimated the origin even earlier.

Classification of The Animal Kingdom (Metazoa)

Non-Bilateria*

  - SUBPHYLUM CHELICERATA

Deuterostomia
- PHYLUM ECHINODERMATA
- PHYLUM HEMICHORDATA
- PHYLUM CHORDATA

*Paraphyletic group

BOX 9A Characteristics of the Phylum Xenacoelomorpha

1. Soft-bodied, dorsoventrally flattened, acoelomate almost exclusively marine worms
2. Epidermis with unique pulsatile bodies, found in no other Metazoan phylum; cilia of epidermis with distinctive arrangement of microfilaments, with the standard 9+2 arrangement extending for most of the shaft, but microfilament doublets 4–6 fail to reach the end of the cilium (the "xenacoelomorphan cilia")
3. Midventral mouth and incomplete gut (i.e., lacking an anus)
4. Largely lacking discrete organs (e.g., no discrete circulatory system, protonephridia or nephridia, or organized gonads)
5. Cerebral ganglion with a neuropil; with anterior statocysts and a diffuse intraepithelial nervous system
6. With circular and longitudinal muscles
7. Hox and ParaHox genes present (but fewer in number than in other metazoans)
8. With direct development (no larval forms)

Monophyly of the Bilateria is strongly supported by both molecular and morphological analyses. Anatomical synapomorphies of this clade include: presence of a third germ layer (mesoderm), bilateral symmetry, cephalization, and a body with both circular and longitudinal musculature—although there are prominent reversals or losses in all of these characters.

The field of molecular phylogenetics has recently provided us with better resolution of evolutionary relationships among animals. Molecular biology has also led to the expansion of a field called evolutionary developmental biology ("EvoDevo"), which attempts to understand the evolution of the molecular underpinnings of differences in the organization of animal body plans. In large part, understanding the evolution of animal body plans is about unraveling the transition from basal Metazoa (Porifera, Placozoa, Cnidaria, Ctenophora) to the Bilateria, and their subsequent radiation. However, genomic-level research has also shown that there is no simple relationship between genomic/molecular complexity and organismal/developmental complexity, so contrary to earlier assumptions the mere presence of members of conserved gene families (e.g., "segmentation genes") in an organism's genome reveals little about the evolutionary relationships of that organism to other animals. Thus, reconstructing the phylogenetic tree of the animal kingdom using conserved genes and morphological characters is a critical step. Ultimately, phylogenetics and EvoDevo together might allow us to reconstruct the nature of the first bilaterian animal—the so called **Urbilaterian**.

The Basal Bilaterian

The notion that acoel flatworms are the most primitive living bilaterians has been around for many years. In the past, some workers have even speculated that acoels might be the most primitive living metazoans, having evolved from a ciliate protist ancestry (the "syncytial, or ciliate–acoel hypothesis"). But most biologists have favored some version of the "planuloid–acoeloid hypothesis," which postulated acoels to be the link between diploblasts (via a planula larva) and triploblasts. A third hypothesis, which gained traction for a short while, was that the simplicity of acoels was the result of *loss* of derived features from a more complex ancestor (the "archicoelomate hypothesis").

Recent molecular phylogenetic research strongly suggests that acoelomorph worms (Acoela and Nemertodermatida), perhaps along with worms of the genus *Xenoturbella*, are likely to be the oldest living bilaterian lineages, or perhaps basal deuterostomes but either way, sharing a great many characteristics in common with an ancestral bilaterian, the so-called hypothetical "Urbilaterian." Acoelomorphs are small, directdeveloping (no larval stage), unsegmented, ciliated worms. They have mesodermally-derived muscles (but no coelom, circulatory, or excretory system), multiple parallel longitudinal nerve cords and a centralized nervous system, and a single opening to the digestive cavity. Importantly, research suggests that their mouth—the single gut opening—does not derive from the blastopore (i.e., they are deuterostomous in their development). Thus, the origin of the Bilateria may have been accompanied by an embryological shift in the origin of the mouth from the blastopore (as seen in Cnidaria and Ctenophora) to elsewhere.

Many bilaterian phyla have a larval type that has been described as **primary larvae**. These are ciliated larvae with a characteristic **apical organ** a true larval organ that disappears, in part or entirely, before or at metamorphosis. The apical organ is a putative sensory structure that develops from the most apical blastomeres during embryogenesis. It does not fit the narrow definition of a ganglion, because it seems to comprise only sensory cells. However, many spiralians develop lateral (cerebral) ganglia in close apposition to the apical organ, and this compound structure was called the "apical organ" in some of the older literature. It appears the apical organ is commonly used in larval settlement, and it is lost once a larva settles (the settlement process typically uses cells around the apical pole). In spiralian protostomes, the apical organ differentiates from the most apical cells (the $1a^1$-$1d^1$ cells in spiral-cleavage terminology). It is highly variable, and

aspects of it are sometimes retained in the adult central nervous system. In the pilidium larva of nemerteans the apical organ is shed at metamorphosis together with the whole larval body, which in some cases is ingested by the emerging juvenile worm.

Deuterostomes are more difficult to interpret, and only in echinoderm and enteropneust (i.e., Ambulacraria) larvae are apical organs clearly present. Apical organs occur in cnidarian larvae, but not in Porifera, thus it has been proposed that the primary larva/apical organ could be a synapomorphy that defines a clade called Neuralia (i.e., Cnidara + Bilateria). In Cnidaria the apical organ consists of a group of monociliated nerve cells; upon settlement, the nervous system becomes reorganized and the larval nerve net is lost, with development of a new adult nerve net. Recent gene expression studies have demonstrated that the apical pole of cnidarians and the apical pole of bilaterians are probably homologous. Apical organs are apparently absent in Ecdysozoa and Chordata (except, perhaps, in the nonfeeding amphioxus larva).

Protostomes and Deuterostomes

Early in the evolution of bilaterians there was a split into two major lineages, which have long been called Protostomia and Deuterostomia. These groups were named over 100 years ago, and they were long defined on the basis of embryological principles. In protostomes the blastopore (the position in the embryo that typically gives rise to endodermal tissues) was said to give rise to the mouth ("protostome" = mouth first). Typically in deuterostomes, the blastopore gave rise to the adult anus, the mouth thus forming secondarily at a different location ("deuterostome" = secondary mouth). In both lineages, the blastopore sits at the vegetal pole of the embryo when gastrulation begins.

As molecular phylogenetic discoveries have reshuffled the animal phyla among the protostome and deuterostome lineages, a new view of embryological patterns has emerged. In the Deuterostomia (now defined as the phyla Echinodermata, Hemichordata, and Chordata), the blastopore *does* consistently give rise to the anus, and the mouth forms secondarily. But among the Protostomia, gastrulation is now known to be much more variable. In fact, we have learned that in protostomes, while the anus usually does form secondarily, the blastopore does not always give rise to the mouth, especially among animals in the large clade known as Spiralia (annelids, molluscs, nemerteans, and others). Even within the clade Ecdysozoa we now know deuterostomy can occur. For example, both nematomorphans and priapulans have deuterostomous development, with the blastopore giving rise to the anus (at the vegetal pole) and the mouth arising at the animal pole. Gene expression studies have shown that, in *Priapulus caudatus*, typical metazoan foregut and hindgut gene expressions accompany this development, and the hindgut/posterior markers *brachyury* (*bra*) and *caudal* (*cdx*) are expressed as the anus emerges from the blastopore. Continuing developmental work on crustaceans is revealing that most species probably also express a form of deuterostomy. And in Chaetognatha gastrulation occurs by invagination of the presumptive endoderm, leaving no blastocoel; the blastopore marks the eventual posterior end of the animal, and both mouth and anus form secondarily, thus also a deuterostome-like development. In fact, evidence is accumulating that mouth formation from oral ectoderm (in the animal hemisphere), typical of deuterostomy, may be ancestral in both protostomes and deuterostomes, and perhaps in Bilateria itself.

So we see that, although the names Protostomia and Deuterostomia are still used for the two main clades of Bilateria, the names themselves are no longer perfectly descriptive—they are legacy names. It has been suggested that new names should be coined for these two large clades, but as yet there has been no agreement on what these names might be. The largest animal phyla belong to Protostomia: Arthropoda (over a million described living species) and Mollusca (nearly 80,000 described living species)—as do the smallest animal phyla (Micrognathozoa and Placozoa, one described species each; Cycliophora, two described species), although several undescribed species are known to exist in these small phyla.

Today, the groups Protostomia and Deuterostomia constitute clades based mostly on molecular phylogenetic evidence, and morphological and developmental synapomorphies defining these two clades remain ambiguous. A probable synapomorphy of the Protostomia, as it is now constituted, is a central nervous system with a dorsal cerebral ganglion that usually has circumesophageal connectives to a pair of ventral nerve cords. Probable synapomorphies of the Deuterostomia are a trimeric body coelom condition and pharyngeal gill slits, at least primitively (trimery is lacking in the phylum Chordata, gill slits are absent in extant echinoderms but may have been present in some extinct, basal echinoderms). Although still somewhat controversial, the position of the phylum Xenacoelomorpha (acoels, nemertodermatids, and *Xenoturbella*) appears to be basal within Bilateria, this group not aligning strongly with either protostomes or deuterostomes (Box 9A).

The Protostomia contains 24 phyla, five of which still remain enigmatic in terms of their phylogenetic alignment: Chaetognatha, Platyhelminthes, Gastrotricha, Rhombozoa, and Orthonectida. Some molecular evidence suggests all of these but Chaetognatha probably belong in the clade known as Spiralia, and in fact Platyhelminthes and Rhombozoa do seem to show spiral cleavage (and some evidence suggests

Chaetognatha might also have spiral cleavage). Recent studies have suggested that Chaetognatha may be the sister group to Spiralia. Gastrotrichs have a unique, but non-radial embryogenesis, and the embryology of Orthonectida, Cycliophora, and Micrognathozoa is not yet known. Bryozoa and Brachiopoda clearly do not have spiral cleavage. Thus, we do not yet know if spiral cleavage is a synapomorphy of the clade that bears its name—i.e., "Spiralia" is another legacy name. It may eventually be shown that all of these phyla comprise a single clade and are descendants of a spirally cleaving ancestor, making this cleavage pattern a valid synapomorphy for the group known as Spiralia. If spiral cleavage does prove to be a synapomorphy for Spiralia, its absence in some phyla would be viewed as the product of secondary modifications to the embryological process. Recall that in spiral cleavage, the 4d cell (also known as the mesentoblast) gives rise to most of the mesoderm, called endomesoderm. Most spiralians also generate some mesoderm from micromeres of the second or third quartet that are primarily responsible for ectoderm formation (thus it is called ectomesoderm); this commonly gives rise to larval musculature.

Some spirally cleaving animals have a unique larval type, called the trochophore larva (e.g., Mollusca, Annelida, Nemertea, and possibly some others), and the clade name "Trochozoa" has been proposed for those phyla, although this clade gets very mixed support in molecular trees and might be paraphyletic. In addition, recent phylogenomic work suggests that these "trochophore phyla" may comprise a sister group to the Lophophorata (Phoronida, Bryozoa, Brachiopoda), and perhaps also including Entoprocta, as a larger grouping known as the Lophotrochozoa. Although DNA sequence data support the clade Spiralia, no unambiguous morphological synapomorphies that might define it have been identified. The phylogenetic relationships of the spiralian phyla remain to be sorted out, and so far their deep ancestry has defied clear resolution. However, two clades within Spiralia do seem to be well supported, and we treat these as chapters in this book; these are the clades Gnathifera (phyla Gnathostomulida, Micrognathozoa, Rotifera) and Lophophorata (phyla Phoronida, Bryozoa, Brachiopoda).

The other main protostome clade, Ecdysozoa, contains 8 phyla (and about 80% of animal species diversity) that all molt their cuticle at least once during their life history. The Ecdysozoa comprise three well-supported clades: Panarthropoda (Tardigrada, Onychophora, Arthropoda), Nematoida (Nematoda, Nematomorpha), and Scalidophora (Priapula, Kinorhyncha, Loricifera), the latter supported mostly by morphological data. The phylogenetic relationships of these three clades have not yet been determined, so they appear as an unresolved trichotomy in our tree of the Metazoa (Chapter 28). Morphological evidence suggests that Nematoida and Scalidophora are sister groups, and they share a number of morphological similarities (e.g., a circumoral collar shaped brain composed of a ring neuropil with anterior and posterior concentrations of cell bodies). However, these morphological similarities might be plesiomorphic within Ecdysozoa, and most molecular analyses place Nematoida as a sister group to Panarthropoda. The internal relationships of the scalidophoran phyla also remain unclear. The most recent work on Panarthropoda suggests Onychophora may be the sister group to Arthropoda, and Tardigrada the sister group to those. Unlike the Spiralia, the Ecdysozoa can be defined by unambiguous morphological synapomorphies, including their threelayered cuticle that can be molted, a process regulated by ecdysteroid hormones in those groups where this is known. The cuticle consists of a proteinaceous exocuticle and an endocuticle with chitin or collagen, with the epicuticle forming from the apical zone of the epidermal microvilli. Ecdysozoans also lack external epithelial cilia, lack a primary larva or ciliated larva, and none of them has spiral cleavage. This clade was discovered in one of the first, pioneering studies using molecular sequence data (Aguinaldo et al. 1997).

The other great bilaterian clade, Deuterostomia, is quite small, comprising fewer than 100,000 living species in only three phyla: Echinodermata, Hemichordata, and Chordata. Although only a "sidebranch" in the tree of life, we tend to give this clade exaggerated importance because, of course, it is the lineage to which we humans (and other vertebrates) belong. As noted above, this clade was originally defined largely on the basis of deuterostomous embryology. However, we now know that deuterostomous development occurs throughout its sister lineage, the Protostomia, leaving us with few definitive morphological or developmental features defining the Deuterostomia. However, as noted above, a trimeric body coelom and pharyngeal gill slits, at least primitively, may eventually be proven to be synapomorphies for the Deuterostomia. Deuterostomes also appear to possess a unique developmental gene, called *Nodal*.

Within the deuterostome clade, recent morphological and molecular work (and also Hox gene motifs) suggests that echinoderms and hemichordates are sister groups, constituting a clade called Ambulacraria, and this is the sister group to the phylum Chordata. If this assessment is correct, it means the features shared between chordates and hemichordates (long thought to comprise a sister group), such as gill slits, may have indeed been ancestral within Deuterostomia, but lost in the echinoderm line (and also in some hemichordate lineages), as suggested by the putative presence of gill slits in some extinct echinoderms. Gill slits in Deuterostomia have been shown to be homologous based on their gene expression patterns. Several

deuterostome animals with gill slits are known from the fossil record, although it is not yet certain whether these belong to basal urochordates, to basal echinoderms, or to their own extinct lineages. Another feature shared between the Hemichordata and Chordata is the stomochord/notochord, long viewed as homologues. It is now thought that these structures might have had much earlier origins and may or may not be homologous, or that a group of vacuolated cells in ancestral Deuterostomia gave rise to these structures independently in hemichordates and chordates. Within Chordata, Urochordata is the sister group to Vertebrata (a clade known as Olfactores), and Cephalochordata is the sister group to those. There is some evidence that a fourth group, the genus *Xenoturbella* (or even the whole clade Xenacoelomorpha) might be near the base of the deuterostome line, but opposing evidence suggests *Xenoturbella* is more likely allied with the Acoelomorpha as an ancestral bilaterian clade, the view we follow in this book.

Deuterostomia is an ancient lineage, and dated phylogenetic trees (using fossils to date branching points) suggest the ancestral line existed well into the Precambrian. The oldest definitive fossil of Deuterostomia is a 530 millionyear old creature called *Yunnanozoon*, from the lower Cambrian Chengjiang biota of Yunnan Province, China, although the affinities of yunnanozoans are still uncertain.

The classification of Metazoa used in this book is shown in the box at the start of Chapters 6 through 27. You will notice that phyla are listed under clade names (most of which lack formal nomenclatural ranking). You will also notice that within these clades, there is often little phylogenetic structure indicated. This is because much of the branching pattern of the tree of life still remains to be discovered. Genomic data are still lacking for many groups, and in other cases data are available for only one or two species. Expanded taxonomic sampling, additional genomic data sets, and new analysis techniques should resolve the remaining questions of animal phylogeny over the coming decade.

Phylum Xenacoelomorpha

The acoels and the nemertodermatids have had a long journey. They were initially viewed as the most primitive living platyhelminths (true flatworms), due to their simple anatomy, and in fact, were thought by many to be the most primitive living Bilateria because most workers placed the phylum Platyhelminthes at the base of the bilaterian tree. As ultrastructural work revealed increasing complexity, opinion shifted, and from the 1960s to the turn of the century these worms, together known as the Acoelomorpha, were widely regarded not as primitive, but as secondarily reduced platyhelminths. However, as multigene phylogenetic analyses have begun to explore these small soft bodied worms, it has become evident that they are indeed primitive bilaterians (perhaps diverging even before the protostome-deuterostome split), and not members of the phylum Platyhelminthes at all. Thus, the pendulum has swung 180 degrees, as is known to happen in phylogenetics. A growing knowledge base and new technologies can lead to major shifts in our understanding of life. In addition, molecular phylogenetics has shown a close relationship between the acoel and nemertodermatid worms, which is further supported by their unique ciliary rootlet system, perhaps the early cleavage pattern (i.e., the horizontal orientation of the second, asymmetric cleavage plane), and several other features described below.

Even more recently, another genus of small marine worms, *Xenoturbella*, was found to be allied closely with the Acoelomorpha, and a new phylum name was created to house these three worm groups—Xenacoelomorpha. The phylum currently contains about 400 species, two in the subphylum Xenoturbellida and 398 in the subphylum Acoelomorpha (mostly in the class Acoela). All described species are small, flattened, marine worms with an incomplete digestive system (i.e., lacking an anus) and lacking discrete excretory systems (however, there is an undescribed xenoturbellid species reported to be several centimeters in length).

DNA sequence analyses have suggested that Acoelomorpha are basal bilaterians and are likely the sister group of Xenoturbellida. Analyses have been divided on whether Xenoturbellida are deuterostomes or basal bilaterians, but the latter idea seems to have stronger support. However, the high evolutionary rate of analyzed genes in Acoelomorpha might be creating long branch attraction problems and further studies are needed. Thus, although we recognize the phylum Xenacoelomorpha, and treat Acoelomorpha and Xenoturbellida as subphyla, it is possible that these two groups will eventually again be separated, with Acoelomorpha being placed at the base of the Bilateria, and Xenoturbellida within the Deuterostomia. We discuss each of the three curious worm groups (Acoela, Nemertodermatida, Xenoturbellida) separately below.

In addition to the molecular phylogenetic data that support an Acoela–Nemertodermatida sister group relationship, both groups have unique epidermal bodies that represent degenerating ciliated cells, the pulsatile bodies (and a type of pulsatile body also occurs in the xenoturbellids). These epidermal bodies are unknown from any other metazoan phylum. In Acoela, the cilia are retained in vacuoles prior to digestion, whereas in nemertodermatids the cilia appear to be lost before resorption begins. The musculature of acoels and

nemertodermatids is also strikingly similar, yet different in some key aspects; acoels have a grid of orthogonal musculature with mainly ventral diagonal musculature, and a muscular posterior pharynx in what may be basal species. More derived acoels have more complex layers of diagonal muscles. Nemertodermatids seem to have an orthogonal grid and well-developed diagonal muscles throughout the body, but no evidence of a muscular pharynx. These anatomical features are described below.

In addition to pulsatile bodies, both Acoela and Nemertodermatida (and *Xenoturbella*) lack discrete excretory systems, the presence of which unites all other Bilateria, and their cerebral ganglion has a neuropil (i.e., it can be considered a true brain, but see below). Furthermore, they share a unique pattern of neurotransmitter activity, body-wall musculature, and mode of embryonic development. Hox and ParaHox genes are present in both groups, although these are not strictly similar. Both taxa appear to have the beginning of the extended central Hox set.

Although initially considered to be a turbellarian flatworm, the unusual anatomy of *Xenoturbella bocki* quickly distinguished it from platyhelminths, as well as from the Acoelomorpha. Phylogenetic (and even some morphological) studies initially linked *Xenoturbella* to deuterostomes. Sequences of Hox genes in *X. bocki* also suggested it could be a basal deuterostome with a reduced Hox gene complement. Additional work using the entire mitochondrial genome of *Xenoturbella* showed links with deuterostomes. However, the lack of typical deuterostome characteristics suggested that *Xenoturbella* might belong at the very base of the deuterostome tree. Other phylogenetic analyses, including nuclear genes from *X. bocki*, also suggested that *Xenoturbella* might be closely tied to the clade known as Ambulacraria (Echinodermata and Hemichordata). If these relationships are correct, developmental evidence of structures common to other Ambulacraria should exist, including gill slits, endostyle, and enterocoelic coelom formation. However, such evidence has not been found (although studies have been frustrated by the fact that *Xenoturbella* ova are very yolky, which obscures observation of early cleavage).

By 2009, large scale molecular phylogenetic studies had begun to move *Xenoturbella* even further down the animal tree, suggesting it is sister to the Acoelomorpha (Acoela + Nemertodermatida), at the base of the Bilateria. The anatomical data seemed to agree with this linking, and it was eventually suggested that the three groups together warranted phylum status, the Xenacoelomorpha. Acoels have only three Hox genes (one each of the anterior, central, and posterior groups). Nemertodermatids have only two (a central and a posterior group). *Xenoturbella* has one anterior, two (or three) central, and one posterior gene. Platyhelminths, on the other hand, have an almost complete Hox cluster. The most recent phylogenetic studies on Acoelomorpha and *Xenoturbella* are still conflicting, plagued by longbranch attraction and small taxon sampling issues. Although we accept the phylum Xenacoelomorpha in this edition of *Invertebrates*, we recognize that the relationships of these three worm taxa are still subject to modification.

CLASSIFICATION OF PHYLUM XENACOELOMORPHA

Generally small, flattened or cylindrical, acoelomate marine worms with anterior statocysts, diffuse intraepithelial nervous system, midventral mouth, incomplete gut (i.e., lacking an anus), unique pulsatile bodies (unknown from any other Bilateria), and largely lacking discrete organs (e.g., without a discrete circulatory system, nephridia, or organized gonads). Cilia of epidermal cells with distinctive arrangement of microfilaments wherein the standard 9+2 arrangement extends for most of the ciliary shaft, but toward the end, microfilament doublets 4 through 7 end, leaving doublets 1–3 and 8–9, which continue to the end of the cilium. These xenacoelomorphan cilia are not known in any other animal phylum (although very similar cilia have been described from the pharynx of some enteropneust hemichordates). With both circular and longitudinal muscles. With direct development and no distinct larval forms. Two subphyla, Acoelomorpha and Xenoturbellida.

SUBPHYLUM ACOELOMORPHA The union of Acoela and Nemertodermatida as sister taxa is based on molecular phylogenetic evidence, as well as anatomical data. Both groups: lack discrete excretory systems (present in all other Bilateria), have cerebral ganglia with a neuropil, share a unique pattern of neurotransmitter activity and unique body-wall musculature, and go through a distinctive mode of embryonic development. Hox and ParaHox genes are present in both groups, although these are not strictly similar.

CLASS ACOELA Acoels lack a permanent digestive cavity. The pharynx, when present, is simple, leading to a solid syncytial or cellular endodermal mass. With a unique anterior statocyst containing one statolith, and biflagellate sperm with 2 flagella whose axonemes are incorporated into the sperm cell; endolecithal ova; without epithelial basal lamina, or discrete excretory or circulatory systems. Small (1–5 mm) worms, common in marine and brackish water sediments; a few are planktonic or symbiotic. (e.g., *Actinoposthia, Amphiscolops, Antigonaria Conaperta, Convoluta, Convolutriloba, Daku, Diopisthoporus Eumecynostomum, Haplogonaria, Hofstenia, Isodiametra, Myopea, Oligochaerus* [with freshwater species], *Paratomella, Philactinoposthia, Polychoerus, Praesagittifera, Proporus Solenofilomorpha, Symsagittifera, Waminoa*)

CLASS NEMERTODERMATIDA Interstitial or endosymbiotic marine worms possessing a ciliated, glandular epiderms and an anterior statocyst generally containing two

statoliths; a proboscis with extensible filaments is present in some species; mouth may be present or absent; pharynx never present; gut cavity with small and relatively occluded, but with true epithelium and gland cells; unflagellate sperm; with endolecithal ova; with limited basal lamina beneath the epidermis. One genus (*Meara*) contains species that are symbionts in sea cucumbers. (e.g., *Ascoparia, Flagellophora, Meara, Nemertinoides Nemertoderma, Sterreria*)

SUBPHYLUM XENOTURBELLIDA Two described species, *Xenoturbella bocki* and *X. westbladi* (but others are known to exist, and the species-level differences between the two described species have been questioned). Despite its simple body plan, *X. bocki* is a relatively large worm, reaching 4 cm in length, and some undescribed species may exceed that size. Xenoturbellids have a humpike structure in the anterior third of the body but lack other structural organs (other than a statocyst) and possess only a diffuse nervous system. These worms live in holes on sandy coastlines or deeper offshore muds and are specialized to eat molluscs.

Class Acoela

Acoels are mostly minute, marine or brackish water, sediment- or surface-dwelling worms. They range in size from less than a millimeter to about a centimeter in length. Those inhabiting interstitial habitats are generally long and slender, whereas those inhabiting surfaces tend to be more disc shaped, broad, and flat. Swimming species are cylindrical with tapered ends, or occasionally enrolled sides. Epiphytic species are usually cone shaped with ventrally enrolled sides that may give the appearance of trailing "fins." A few species of acoels have also been found in the gut of echinoderms, in fresh water, and in hydrothermal vents. (Figures 9.1A–H)

Acoela lack a distinct internal body cavity they are acoelomate (as are the other members of the phylum Xenacoelomorpha). Acoels also lack a structural gut, and this was actually the basis of the name Acoela. Instead, they possess a multinucleated mass (a syncytium) that phagocytizes ingested food particles (Figure 9.2). Larger species often supplement their nutritional requirements with endosymbiotic algae, which can contribute to the bright coloration seen in many (Figure 9.3A). Acoels living in the guts of other animals often have symbiotic bacteria inhabiting their epidermis.

Acoels possess both circular and longitudinal muscles. Their nervous system consists of an array of paired longitudinal nerve cords with a concentration of anterior sensory cells and a cerebral commissure (the "brain") (Figure 9.4). The anterior statocyst with a single statolith is distinctive in acoels and (along with simple, light sensitive eyes in a few species) appears to assist in maintaining the animal's orientation (Figure 9.1A–H). They lack sclerotized structures other than those associated with genitalia, although some species manufacture crystalline spicules in the parenchyma. They also possess aberrant, complex, biflagellate sperm that vary in the structure of the usual 9+2 arrangement of microtubules possessed by many metazoans. Acoels have direct development and exhibit no distinct larval forms.

Acoels were first described at the turn of the nineteenth century from northeast Atlantic coastlines. These and other early descriptions placed the Acoela within the turbellarian Platyhelminthes, and distinguished major subtaxa on the basis of the female reproductive system. Later revisions in the middle of the twentieth century established over 20 families, and most of the nearly 400 described species were based primarily on details of male copulatory structures. Similarities in internal anatomy, epidermal ciliation, and the appearance of epidermal "pulsatile bodies" led to combining Acoela with another turbellarian group, Nemertodermatida, as the Acoelomorpha.

The lack of hard anatomical features in these worms led workers to studies of microscopic ultrastructure using scanning and transmission electron microscopy, including investigations of muscle fiber orientation and structure (which distinguished several major lineages), sperm morphology, and spermatogenesis (which identified biflagellate sperm and unusual patterns of microtubules within sperm acrosomes), as well as neuroanatomy. Studies increased in number near the end of the twentieth century as the diversity of habitats investigated increased, including anoxic sulfide sands. 18S and 28S rRNA, mitochondrial DNA, and myosin heavy chain type II nucleotide sequences have all placed Acoelomorpha outside of the Platyhelminthes. Further systematic refinements within major acoel clades (notably the polyphyletic family Convolutidae), and developmental analyses, have corroborated genetic results that place acoels outside the Platyhelminthes. Much taxonomic revision is still underway, and about 9 to 20 families are currently recognized, depending on whose schema is followed.

Both molecular phylogenetics and EvoDevo research provide evidence that acoels likely lie at the base of the bilaterian tree. For example, the pattern of expression of *ClEvx* (a gene responsible for sensory specificity brain neurons) anterior and posterior to the statocyst in hatchling acoels is more similar to that found in cnidarians than it is to more derived bilaterians. Other studies indicate that *brachyury* (*bra*) and *goosecoid* (*gsc*), genes associated with the formation of the acoel mouth, are also expressed during mouth development in protostomes as well as deuterostomes, suggesting that acoel and bilaterian mouths are homologous. Studies of neural development and structure in the acoel *Symsagittifera* show that genes associated with brainlike structures are present, suggesting that such genetic machinery was in place in the Urbilaterian ancestor (if indeed acoels represent such an ancestor). The overall primitiveness of Acoela appears to also be reflected in their lack of a clearly differentiated gut or

excretory system, unencapsulated gonads, absence of ciliary or rhabdomeric eyes, lack of a basal lamina under the epidermis, and absence of a larval stage.

The Acoel Body Plan

Body Wall and External Appearance

Most acoels are tiny, just a few millimeters long. The smallest species tend to be interstitial, feeding on bacteria and organic particulates available on the surfaces or between the spaces of the sediments they inhabit. Infaunal species tend to be more elongate (Figure 9.1A,B,F,H). Larger species usually inhabit the surfaces of rocks, large algae, or cnidarians (Figure 9.1C–E,G). These more rapidly moving species are often predatory, gliding quickly on their ciliated surfaces and capturing prey with a raptorial "hood" that consists of lateral extensions of the body.

Large-bodied species, reaching lengths of 4–5 m, in some families (e.g., Convolutidae) have anterior ocelli (Figure 9.1G), whereas small-bodied species tend to lack these. Larger-bodied species also often have photosynthetic endosymbionts under their epidermis (Figures 9.1E and 9.3A–E). Endosymbiotic algae are contained within the bodies of many large species of acoels, and this association probably evolved more than once—both zoochlorellae and zooxanthellae have been identified among the various species. Algae are usually obtained during feeding by juvenile worms, but in some species can also be transmitted within oocytes by parents to their offspring (vertical transmission). In *Heterochaerus langerhansi*, the dinoflagellate *Amphidinium klebsii* resides below the epidermis and has been shown, using radioactively labeled carbon and nitrogen, to receive these substances from its host in the forms of CO_2 from respiration and excreted ammonia from protein metabolism. The rate of transfer is light dependent.

It has been suggested that acoel body pigmentation may have several contexts. One might be to provide protection from UV radiation for their symbiotic photosynthetic protists. A second context might be to provide cryptic coloration, either to make acoels inconspicuous to visual predators, or possibly to make them less visible to prey. *Hofstenia* species, also known as "panther worms," are highly polymorphic in dorsal pigmentation, with diverse patterns of dappling and striping of brown, yellow, and white colorations (Figure 9.1C).

The acoel body is completely covered with cilia, which may or may not also line the mouth and entrances to reproductive structures. The epithelium lacks a basal lamina (extracellular matrix, or ECM). Early researchers identified pulsatile bodies embedded within the epidermis of acoels (and nemertodermatids), which later proved to be clumps of ciliated cells in the process of being resorbed and replaced by the epidermis.

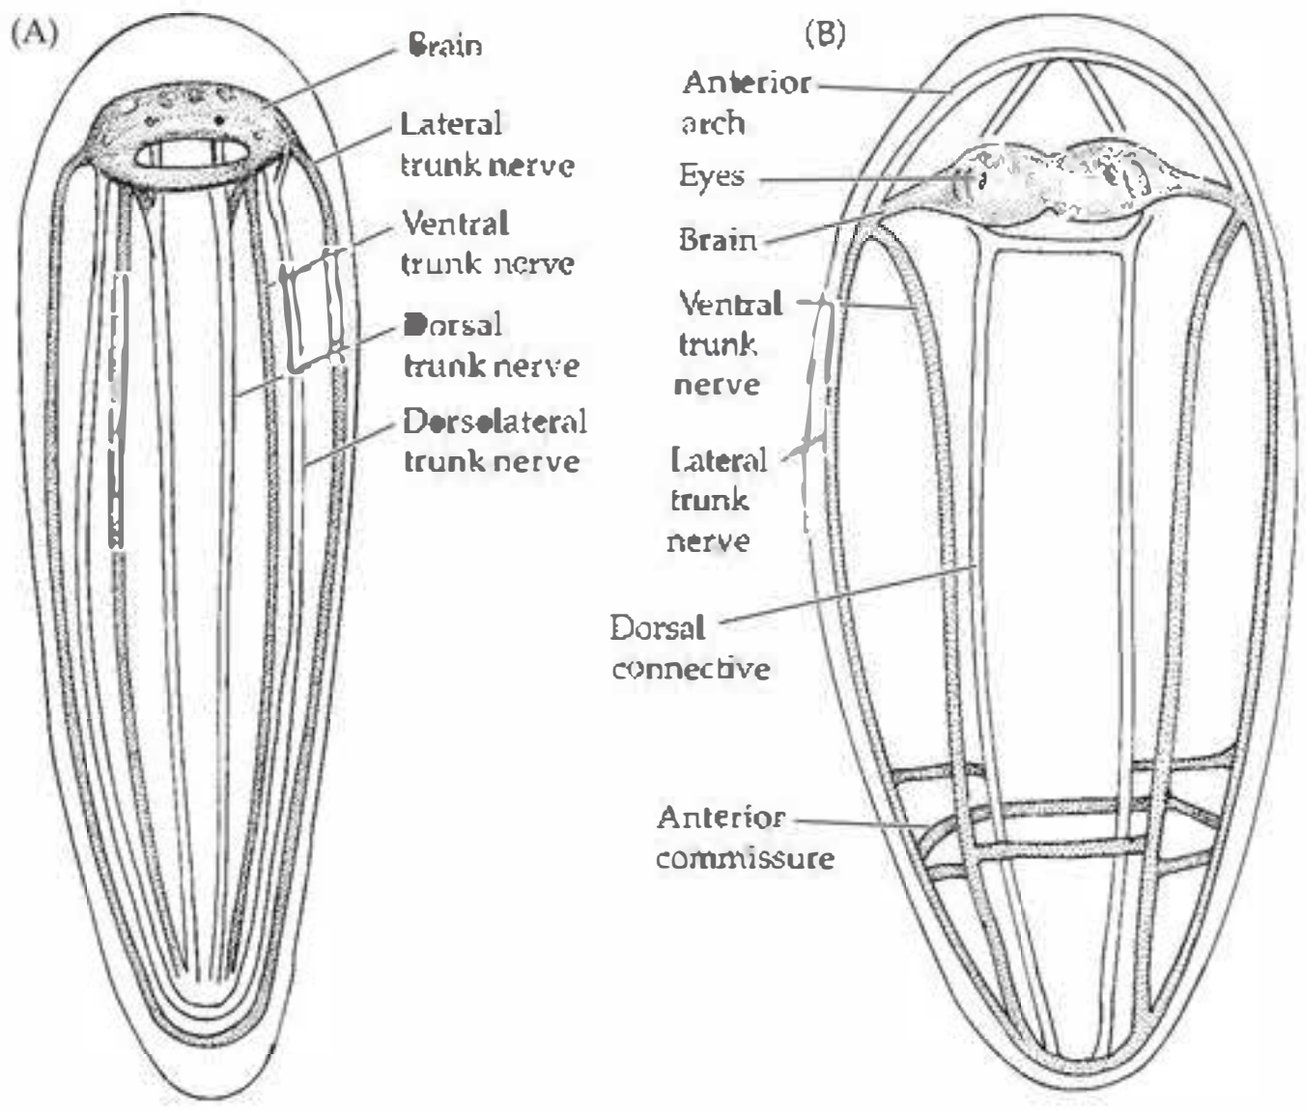

Figure 9.4 Comparison of the central nervous systems of (A) an acoel (*Actinoposthia beklemishevi*) and (B) a freeliving flatworm (*Gievzstoria expedita*).

Mucus-producing frontal organs, that superficially resemble those of flatworms but are probably not homologous in structure, occur in most families. The ciliated epidermis of acoels also bears **rhabdoid glands** distributed over the body. The **rhabdoids** themselves are composed of mucopolysaccharides and are chemically as well as structurally distinct from the rhabdites of freeliving flatworms, although their role in producing mucus to assist ciliary gliding appears to be similar. Most members of the family Sagittiferidae also have **sagittocysts** (Figure 9.5), complex needle-shaped secretory products (5–50 µm long) that are ejected with force in prey capture or for defense, and probably also to assist in sperm transfer during copulation (perhaps by perforating the partner's epidermis). Each sagittocyst arises from a **sagittocyte**, which is surrounded by tightly spiraled muscle filaments that expel the sagittocyst upon contraction (Figure 9.6).

Inset shows higher magnification of the muscle mantle; arrows indicate the location of desmosomes linking the mantle layers. (B) Close-up of the cut surface of a sagittocyst within the muscle mantle.

The position of the mouth in acoels is highly variable. In families thought to be primitive, the mouth opens at the posterior end of the animal and leads to a distinct pharynx (Figure 9.1A). Other families have anteroterminal mouths, although most acoel mouths open midventrally (Figures 9.2 and 9.7B). Both a circulatory system and an excretory system, even in the form of protonephridia, are lacking in the Acoela. Male and female reproductive organs are visible through the body wall of smaller acoels (Figures 9.1A,F,H). In larger species they may protrude from the body surface (Figures 9.7D, 9.12B).

Body Musculature, Support, and Movement

The mesodermally derived musculature of acoels provides the primary means of support, whereas the body cilia (assisted by body muscles) provide for their gliding movement. The shape of the cilia is distinctive, having a marked shelf at the tip where doublets 4–7 terminate. The rootlet system that connects the cilia is also unique. Two lateral rootlets project from each cilium and connect to the tips of the adjacent cilia. From a caudal rootlet, two bundles of fibers project to join the kneelike bend of those same adjacent rootlets. Epidermal cilia of acoels beat in a coordinated fashion to create metachronal waves that move from anterior to posterior.

Abundant dorsoventral muscles serve to flatten the body, and muscles in the body wall generate bending, shortening, and lengthening movements (Figures 9.7A–E and 9.8A–G). The body wall musculature includes circular, diagonal, longitudinal, crossover,

spiral, and even U-shaped muscles Species lacking a pharynx appear to have specialized, complicated ventral musculature to compensate for the lack of a muscu lar food moving structure and this allows body movements to force food through the mouth.

Nutrition, Excretion, and Gas Exchange

As juveniles, most acoels appear to feed on protists, including unicellular algae such as diatoms. Smaller species may continue this diet throughout their lives, whereas larger species (e g., *Convoluta convoluta*) are often predaceous, hunting minute crustaceans but also feeding on larval molluscs and other worms. Smaller protists are captured as acoels glide over them with the syncytial gut extruded through the mouth such that it engulfs food with "amoeboid" like movements. Larger prey are grasped with the anterior margin of the body and entrapped with mucus before being pressed toward the mouth. Swimming prey may also be rapidly captured and ingested, whereas dead material seems to be act vely avoided.

Some acoels possess a pharynx, in some cases known as a pharynx simplex (Figure 9.1A), and this structure is variable among the families In some cases the pharynx is a flexible, tube shaped structure that can be everted from the mouth. The pharynx is anchored by musculature attaching to circular muscles within the body wall. In the larger, predaceous species, there is no oral sphincter but several layers of circular muscles interspersed with oblique and longitudinal muscles extend throughout the protrusible structure, which is attached to the body wall by densely packed muscles (Figure 9.7B,C). In cases where no distinct pharynx exists, mus cle fibers encircle the mouth to form a sphincter.

Ingested prey is enclosed within vacuoles that drift within the digestive syncytium, and food is completely

absorbed within 18 to 24 hours. The exoskeletons of hard-bodied prey such as crustaceans are voided through the mouth. Fat globules and occasional glycogen vacuoles stored within cells appear to be the primary forms of food reserve A number of acoel species associate with corals (including *Waminoa* and several species of *Convolutriloba*). These associations appear to primarily benefit the acoels who likely feed on mucus produced by these cnidarians (Figure 9.1E). It has been suggested that the syncytial digestive system of acoels might be an extreme state of the condition seen in nemertodermatids, which have a small, relatively occluded gut lumen (and a remnant of a gut lumen is evident in the acoel *Paratomella rubra*).

The small size of acoels is sufficient to allow them to eliminate waste nitrogen and carbon dioxide, as well as obtain oxygen from the surrounding water, without a need for specific excretory or circulatory systems. Food vacuoles evidently serve to move materials from the digestive syncytium to other cells within the body.

Nervous Systems and Sense Organs

The central nervous system of acoels usually includes an anteriorly located cluster of large commissures and a few cell bodies that form a paired ganglia system with what some workers consider to be a minute neuropil (though it is quite rudimentary compared to other metazoans). Arising from this are three to five pairs of longitudinal nerve cords connected by an irregular network of transverse fibers (Figure 9.9). Typically there are single or paired dorsal nerve cords, and paired lateral and ventral cords. Peripheral neurons connect to epidermal sensory cells and to anterior light-sensitive cells that serve as simple eyes. There is no indication that the eyes have ciliary or rhabdomeric elements, and they are probably simple pigment cells with refractive inclusions and up to three nerve cells to relay the stimulus. This organization contrasts markedly with that of platyhelminths, where the brain consists of a comparatively dense ganglionic mass, the nervous system is primarily developed ventrally, and the nerve cords form an orthogonal nervous system composed of eight orthogons largely developed laterally and ventrally (Figure 9.4). Although organized as a bilobed structure, the acoel "brain" lacks the dense ganglionic cell mass (neuropil) seen in the Platyhelminthes.

The acoel statocyst is a fluid-filled, proteinaceous spherical capsule, 10–30 μm in diameter, surrounding a single retractile statolith (Figure 9.1A–H). The statolith appears to be a single spherical cell. The capsule enclosing the statolith comprises two unciliated cells. Behavioral observations indicate that acoels are capable of precise geotactic orientation, suggesting that movements of the statolith within the statocyst are detectable by the animal. Three pairs of muscle fibers insert into the membrane of the statocyst, evidently

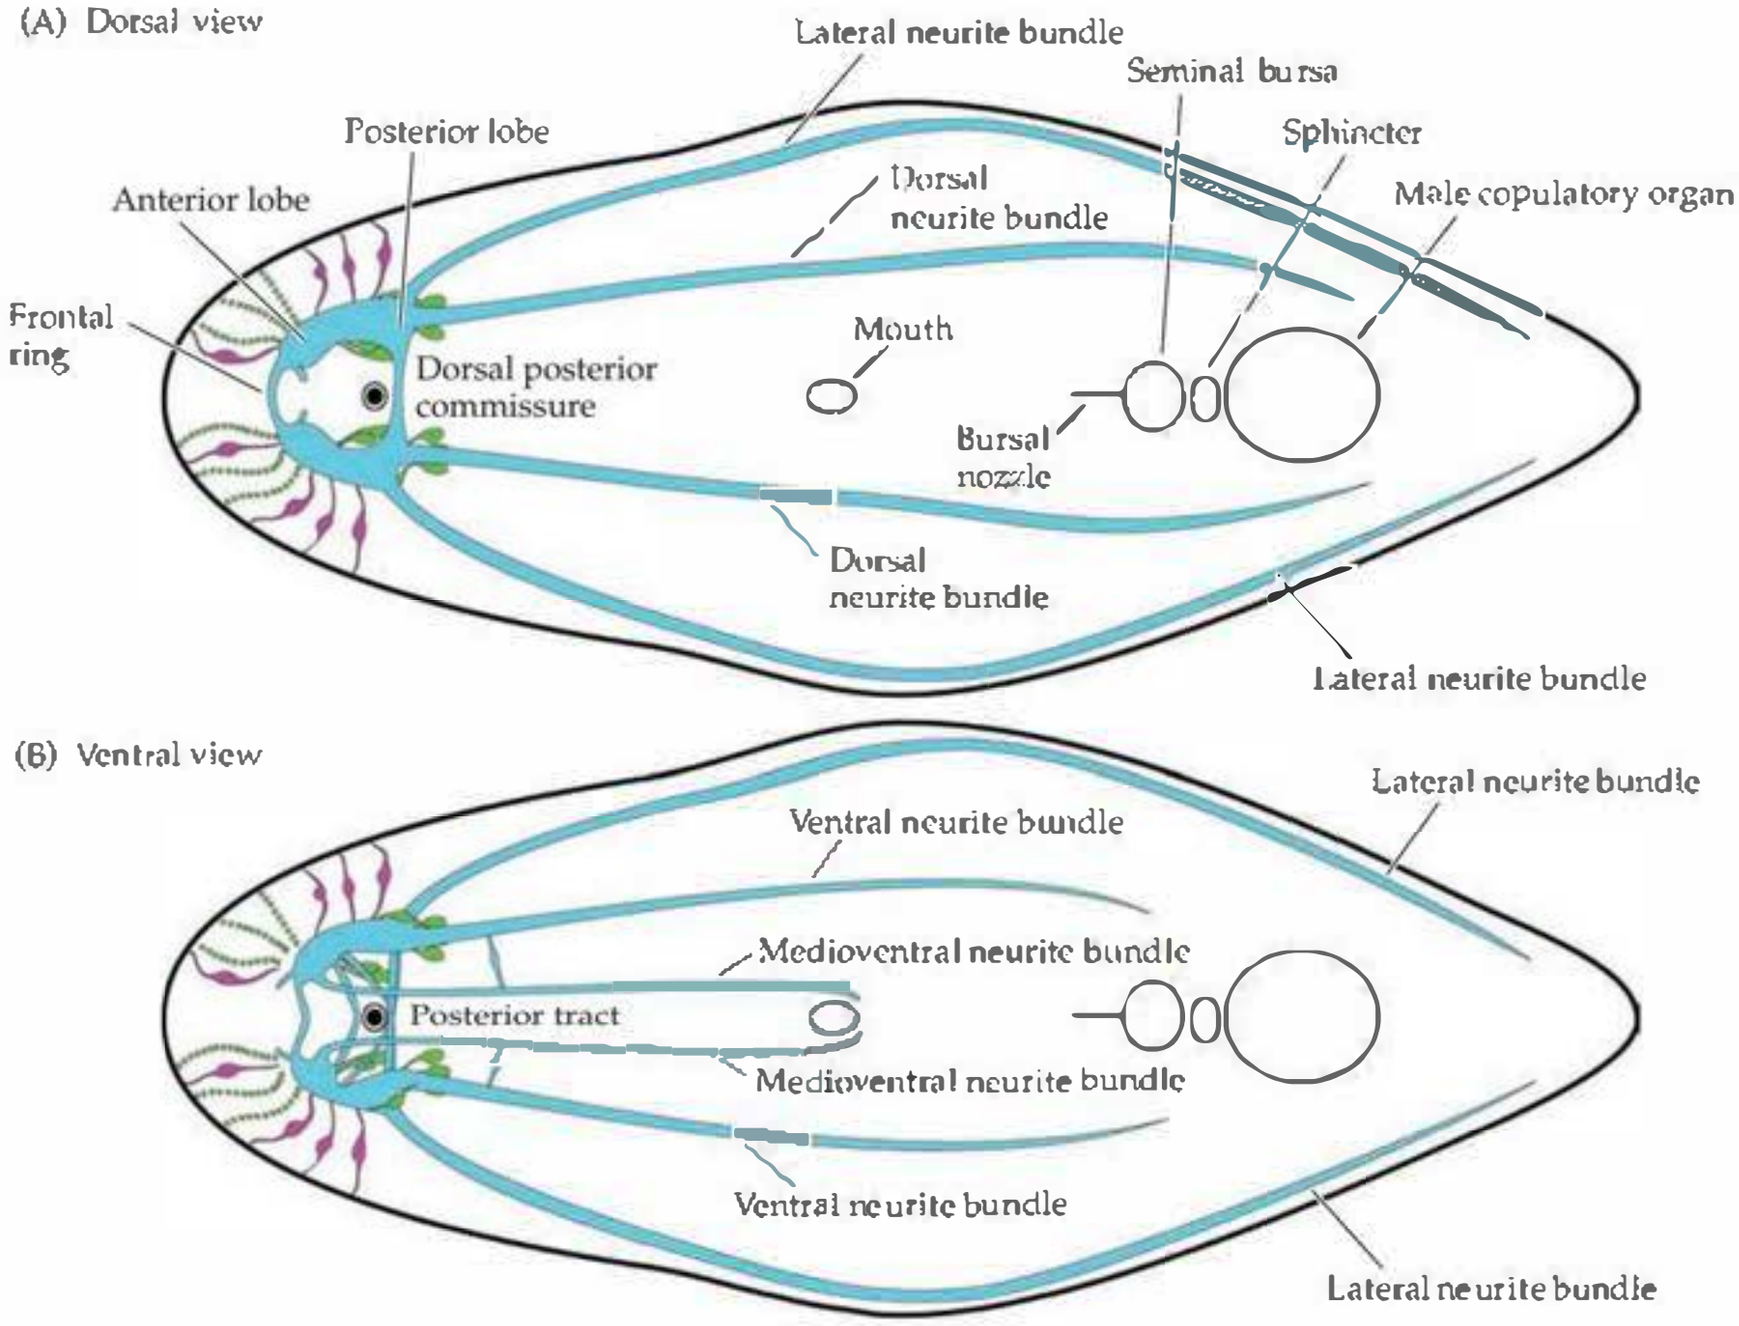

Figure 9.9 Diagram of the nervous system of *Isodiametra pulchra* (Acoela) revealed using nervous tissue-specific staining (green and magenta colors denote separate types of neural tissue in the bilobed acoel brain; cyan color is the central nervous system).

assisting in maintaining its position. While the cerebral commissure is closely associated with the statocyst, specific innervation of the structure is difficult to clearly identify, although a small nerve cushion created by two nerve bundles insert on the capsule and a cell body located at the ventral pole may be responsible for detecting deformation of statocyst fluid. Alternatively, positional information may be conveyed by the stretching of muscle fibers surrounding the statocyst. While statocysts appear in other metazoans, including cnidarians, ctenophores, platyhelminths, annelids, and others, statolith movement within the statocyst in these taxa is generally detected by cilia along the internal surface of the statocyst. The lack of these modifications within the Acoela appears to be unique.

Reproduction and Development

Acoels are capable of both sexual and asexual reproduction, and have considerable ability to regenerate cells through the actions of multipotent, mesodermally derived, neoblastlike cells. These structures were originally described in the Platyhelminthes, but analogous (or homologous) cells appear in the Acoela as well. These cells replace damaged or missing body components and appear to have few limitations in how they are able to repair or replace tissues, particularly epidermal cells.

Three distinct forms of asexual reproduction have been documented within the Acoela: transverse fission, longitudinal fission, and budding (Figure 9.10). Although

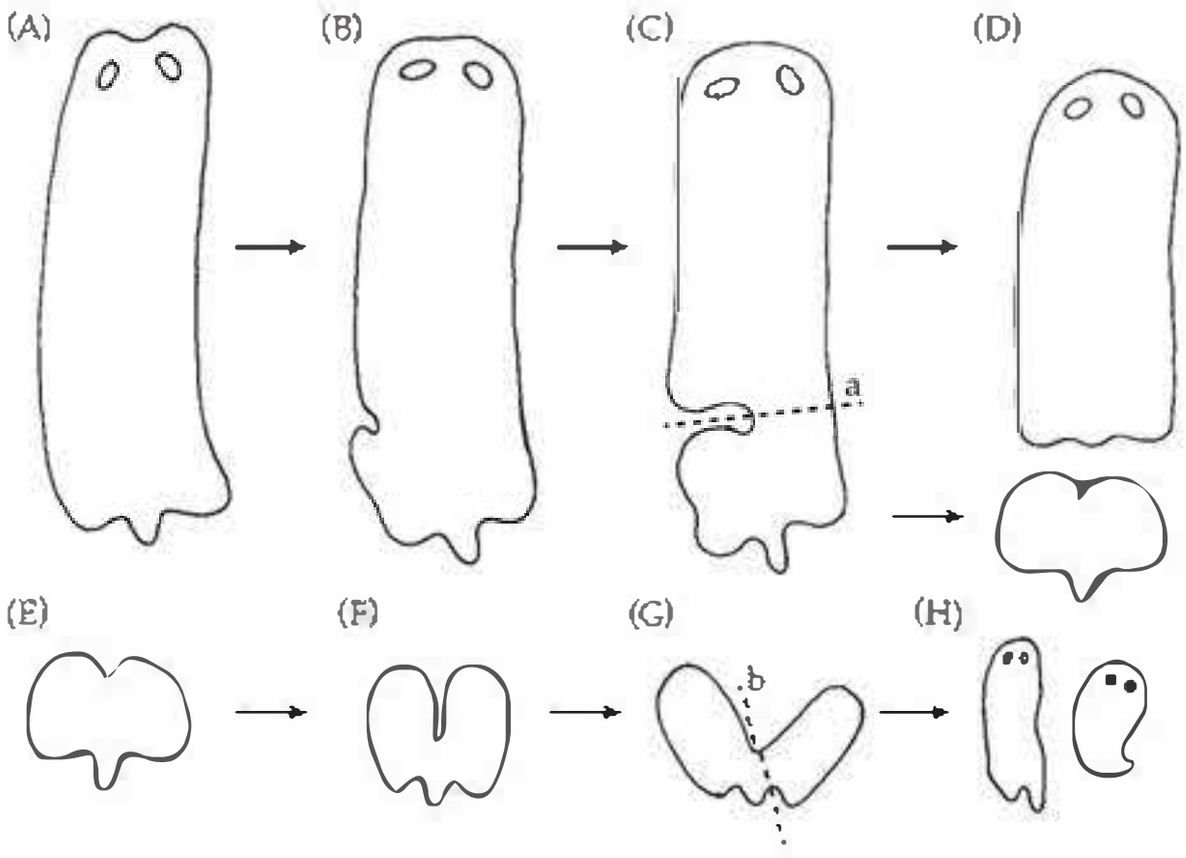

Figure 9.10 Modes of asexual reproduction in *Convoluta longifissura* (Acoela). (A) Intact animal. (B–D) Transverse fission; lower element of (D) shows "butterfly" stage preceding transversion fission (E–H).

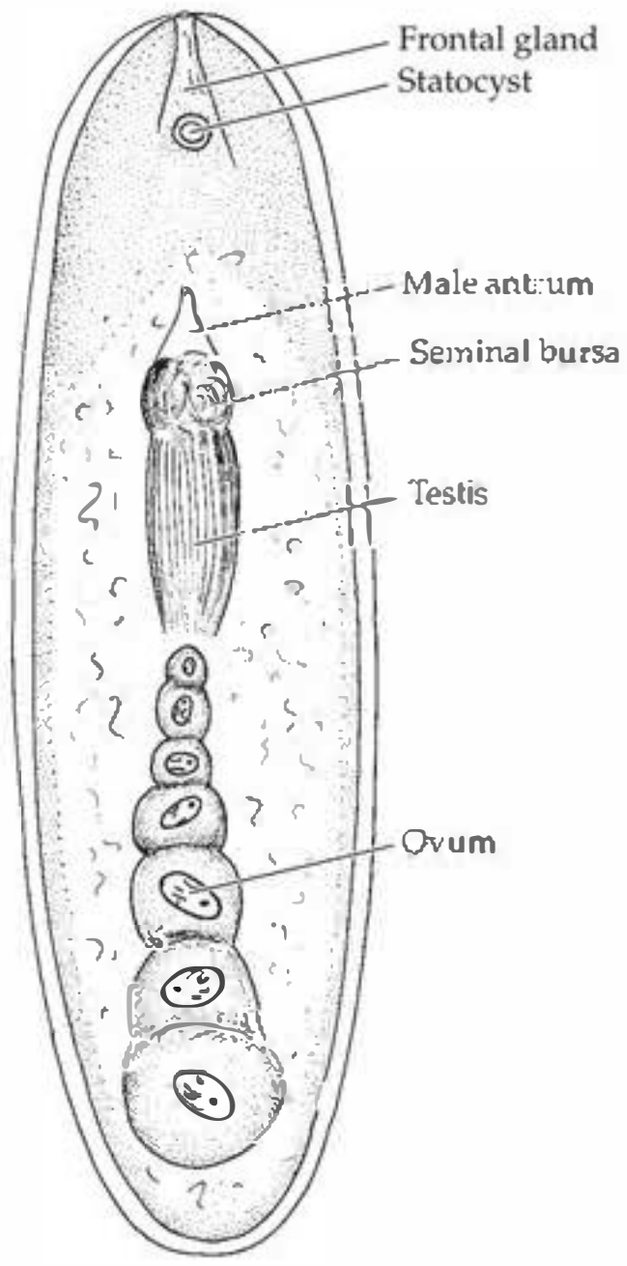

Figure 9.11 Internal organization of *Antigonaria arenaria* (Acoela).

capable of asexual reproduction, and while often found in large local abundances, acoels are not known to markedly increase their numbers asexually under natural conditions (as seen in many other asexual organisms), except perhaps in the family Paratomellidae.

Most acoels are simultaneous hermaphrodites (Figure 9.11), although some (e.g., all members of the family Solenofilomorphidae) are protandrous. Ovaries and testes may be paired or unpaired, with testes usually dorsal and ovaries more ventral (Figure 9.12A). In some species a single mixed gonad exists. In no cases are the gonads saccate—that is, the germ cells are not lined or discretely separated from the surrounding parenchyma.

Genitalia are usually visible near the posterior end of the animal. The penis is a muscular and glandular, or needle-like structure, often with multiple stylet-like elements (Figure 9.12B). Male intromittent organs, regardless of form, can be retracted into a seminal vesicle. During copulation the penis is everted through the gonopore that typically lies in a distinct antrum, or vestibule on the body surface. A separate female gonopore exists in some species. In others, the female pore connects directly to the male pore. In still others, no external female opening exists and insemination is hypodermic. Most, but not all acoels have the vagina positioned anterior to the penis.

A seminal bursa may exist that appears to receive sperm from mating partners either during copulation or after hypodermic insemination, and a sclerotized bursal or vaginal nozzle or sphincter regulates the

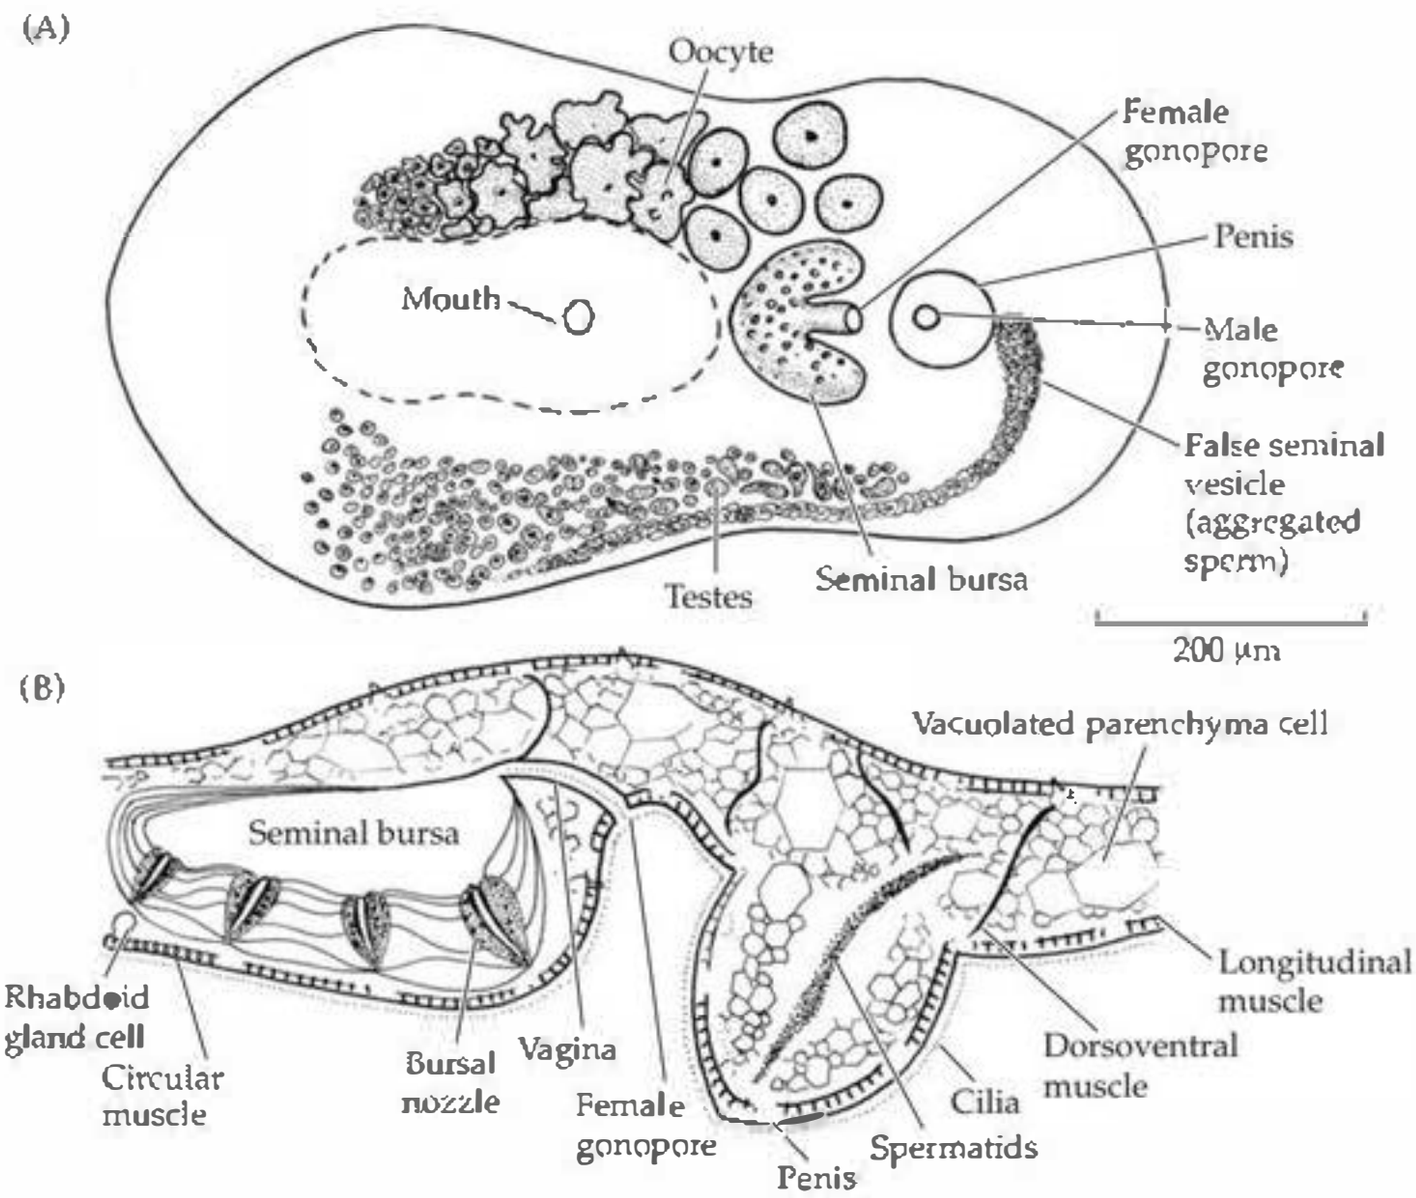

Figure 9.12 Acoela. Reproductive anatomy of *Polychoerus gordoni*. (A) Dorsal view; note in this species as in other Convolutidae, male and female gonads are paired, but are shown singly here. (B) Sagittal view of female and male reproductive anatomy.

passage of sperm to eggs. These are among the few sclerotized structures in these soft-bodied worms, and they were considered important in early taxonomic treatments of Acoela. Like many persistent terms in invertebrate zoology, the name "nozzle" was coined by Libbie Hyman who thought these structures resembled the nozzle of a hose. In certain Convolutidae, multiple bursal nozzles may exist in the same individual (Figure 9.12B). While highly variable in form, seminal bursae and their associated structures appear to be homologous among all acoels.

Copulatory behavior was observed by Hyman to occur during daylight hours when high densities of individuals are maintained in aquaria or other confined spaces. Individuals approach one another and exchange quick touches or "nips" of the anterior ends. Larger individuals appear to initiate copulation, which proceeds after both individuals roll into a ball, and then unroll with their genitalia firmly engaged. Individuals mutually insert their penes into their partner's female gonopore and direct sperm and seminal fluid into the female bursa.

Acoel sperm are distinctively biflagellate, with the two axonemes of the flagella incorporated into the cell body (a condition also seen in Platyhelminthes). Several well-defined patterns exist in acoel sperm morphology, and these seem to be phylogenetically informative. Combined studies of 18S rRNA sequence data and sperm morphology have revealed remarkable concordance between these two sources of data. Seminal bursae and bursal nozzle complexity also appears to correlate with variation in sperm morphology.

Oocytes in the gonads of acoels give rise to endolecithal eggs. Fertilization is always internal, and zygotes are released either through the mouth, via the female gonopore, or through a rupture created in the epidermis by the growing embryos. Zygotes may be brooded or protected by encapsulation, but are usually deposited singly and undergo direct development. Eggs appear to be laid primarily at night, in flat gelatinous masses

Embryonic development is direct, and the cleavage pattern of acoels appears to be a unique "spiral duet" cleavage program that is different from any other metazoan (although this has been questioned). Nemertodermatids, while exhibiting duet cleavage in the 4 cell stage, do not exhibit this spiral duet pattern, and their cleavage pattern is distinct from the Spiralia. It has been suggested that the acoel spiral duet-cleavage pattern might have evolved from an ancestral spiral quartet cleavage typical of the Spiralia. As in spiral quartet cleavage, the first horizontal cleavage is unequal and so produces micromeres, but it occurs at the two-cell stage instead of the four-cell stage, so the micromeres appear as duets instead of quartets. One is tempted to call this "bilateral cleavage," rather than spiral cleavage, and it is quite different from that of all other spiral-cleaving Metazoa. So far as is known, acoel embryos generate only endomesoderm, whereas most spiral cleaving animals tend to also produce some ectomesoderm. Internal tissues arise either by delamination or by immigration of cells that form the ectoderm and mesoderm. By the time gastrulation is complete, the embryo has a layered appearance, with an outer epidermal primordium, and a middle layer of progenitor cells of muscles and neurons, while the innermost cells are those that will develop into the digestive syncytium. Endomesoderm forms from both of the third duet macromeres at the vegetal pole, whereas the mouth forms anteriorly as 1a micromere descendants expand around the posterior pole. An anus never forms

Class Nemertodermatida

Nemertodermatida comprise a few dozen species of marine worms described from several locations around the world, including the Swedish coast (their original discovery site), the Mediterranean, Adriatic, North and Caribbean Seas, and the east coast of North America. Like acoels, nemertodermatids were once classified in the phylum Platyhelminthes. Nearly all known species are free-living, usually in fine sand, mud or gravel; however, species in the genus *Meara* are symbionts in

the foreguts of holothurian echinoderms (sea cucumbers). Nemertodermatids range in length from a few millimeters to nearly a centimeter. They can be leaf shaped or narrow and elongated, and they may creep over the substratum or swim with serpentine movements. Their bodies are densely covered with locomotory cilia, and as a group they are easily recognized by an anterior statocyst containing two statoliths in separate chambers (Figure 9.13A,B)—although a few reports of one to four statoliths also exist in the literature. Some species possess an eversible proboscis associated with feeding (oddly, some of these species lack a distinct mouth) with numerous branches that extend anteriorly "like a witch's broom" (Figure 9.14).

The epidermal cells of nemertodermatids lack a true basal lamina but are connected to underlying muscle cells and to each other via a narrow extracellular matrix. Septate junctions between epidermal cells are lacking. As in the acoels, old or damaged ciliated epidermal cells are withdrawn into the body and resorbed, creating temporary structures called pulsatile bodies (Figure 9.15). Also as in acoels, species inhabiting the guts of other animals often have symbiotic bacteria inhabiting their epidermis (Figure 9.16). The form of the mouth and gut vary among species from temporary structures to a porelike opening and a narrow intestinal lumen, although a complete gut is lacking (there is no anus, nor is there a discrete pharynx). They lack discrete circulatory or excretory structures. Asexual reproduction has not been reported. Male sexual structures may consist of a simple, ciliated invagination of the epidermis or an eversible penis; seminal vesicles may be present. Where these structures are lacking, sperm appear to simply be ejected from the

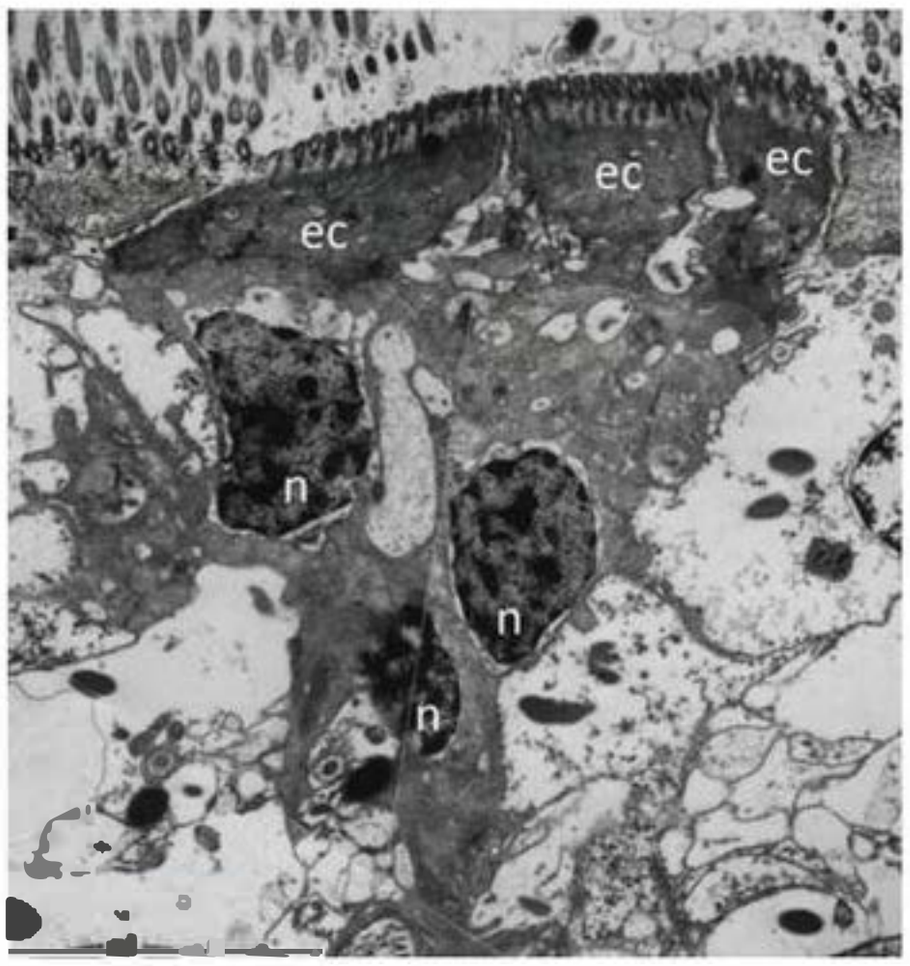

Figure 9.15 TEM micrograph showing a cross section the epidermis of the nemertodermatid, *Meara stichopi*. Three ciliated epidermal cells (ec), presumably worn or damaged and bearing only the dark stubs of locomotory cilia, are being compacted and withdrawn into the integument to be dissolved; the three dark structures are the epidermal cell nuclei (n).

male antrum. The female gonopore with an associated bursa is located dorsally in most species. Mature eggs are released through the mouth. Duet cleavage and direct development are similar to that observed in acoels (Figure 9 20).

The first described nemertodermatids was classified within the acoel Platyhelminthes by Otto Steinböck in 1930. Long before similar hyperbolic statements by now-deposed dictators, Steinböck, a colorful individual known to express himself in doublespaced capital letters with exclaination marks for emphasis, announced his discovery as "the mother of all turbellarians," possessing a "novel, two-stoned statocyst, an unusually thick and gland-rich epidermis, a peripheral nervous system, and a mixed, lacunar gonad without accessory organs." Going Steinböck one better, in 1940 Tor Karling removed the Nemertodermatida from the Acoela and other than-turbellarians altogether because of their wellformed intestinal lumen, a structure lacking in acoels. The Acoela and Nemertodermatida were combined as sister taxa within the Platyhelminthes in 1985 with Ulrich Ehlers' recognition of the taxon Acoelomorpha, primarily based on ciliary structures. Additional work on Nemertodermatida has proceeded slowly because specimens are difficult to come by and because many characters can be highly variable within populations.

The relationship of *Meara stichopi* to its echinoderm hosts is poorly understood, but does not appear to be parasitic—hosts do not appear to be harmed by the presence of the worms. In fact, the relationship could be mutualistic, as nematodes have been found within the guts of endosymbiotic *Meara*. Symbiotic species of both *Meara* and *Nemertoderma* are known to possess elongated, y-shaped symbiotic bacteria (Figure 9.16). In *Meara*, these symbionts are found primarily on the ventral side of the host's body. The y shape of the bacteria has been suggested to represent the mode of asexual reproduction because appendages are found only on certain bacterial cells. Ultrastructural studies indicate that bacteria occur only on the outside surface of their worm hosts, suggesting that the association between bacteria and host does not represent infection.

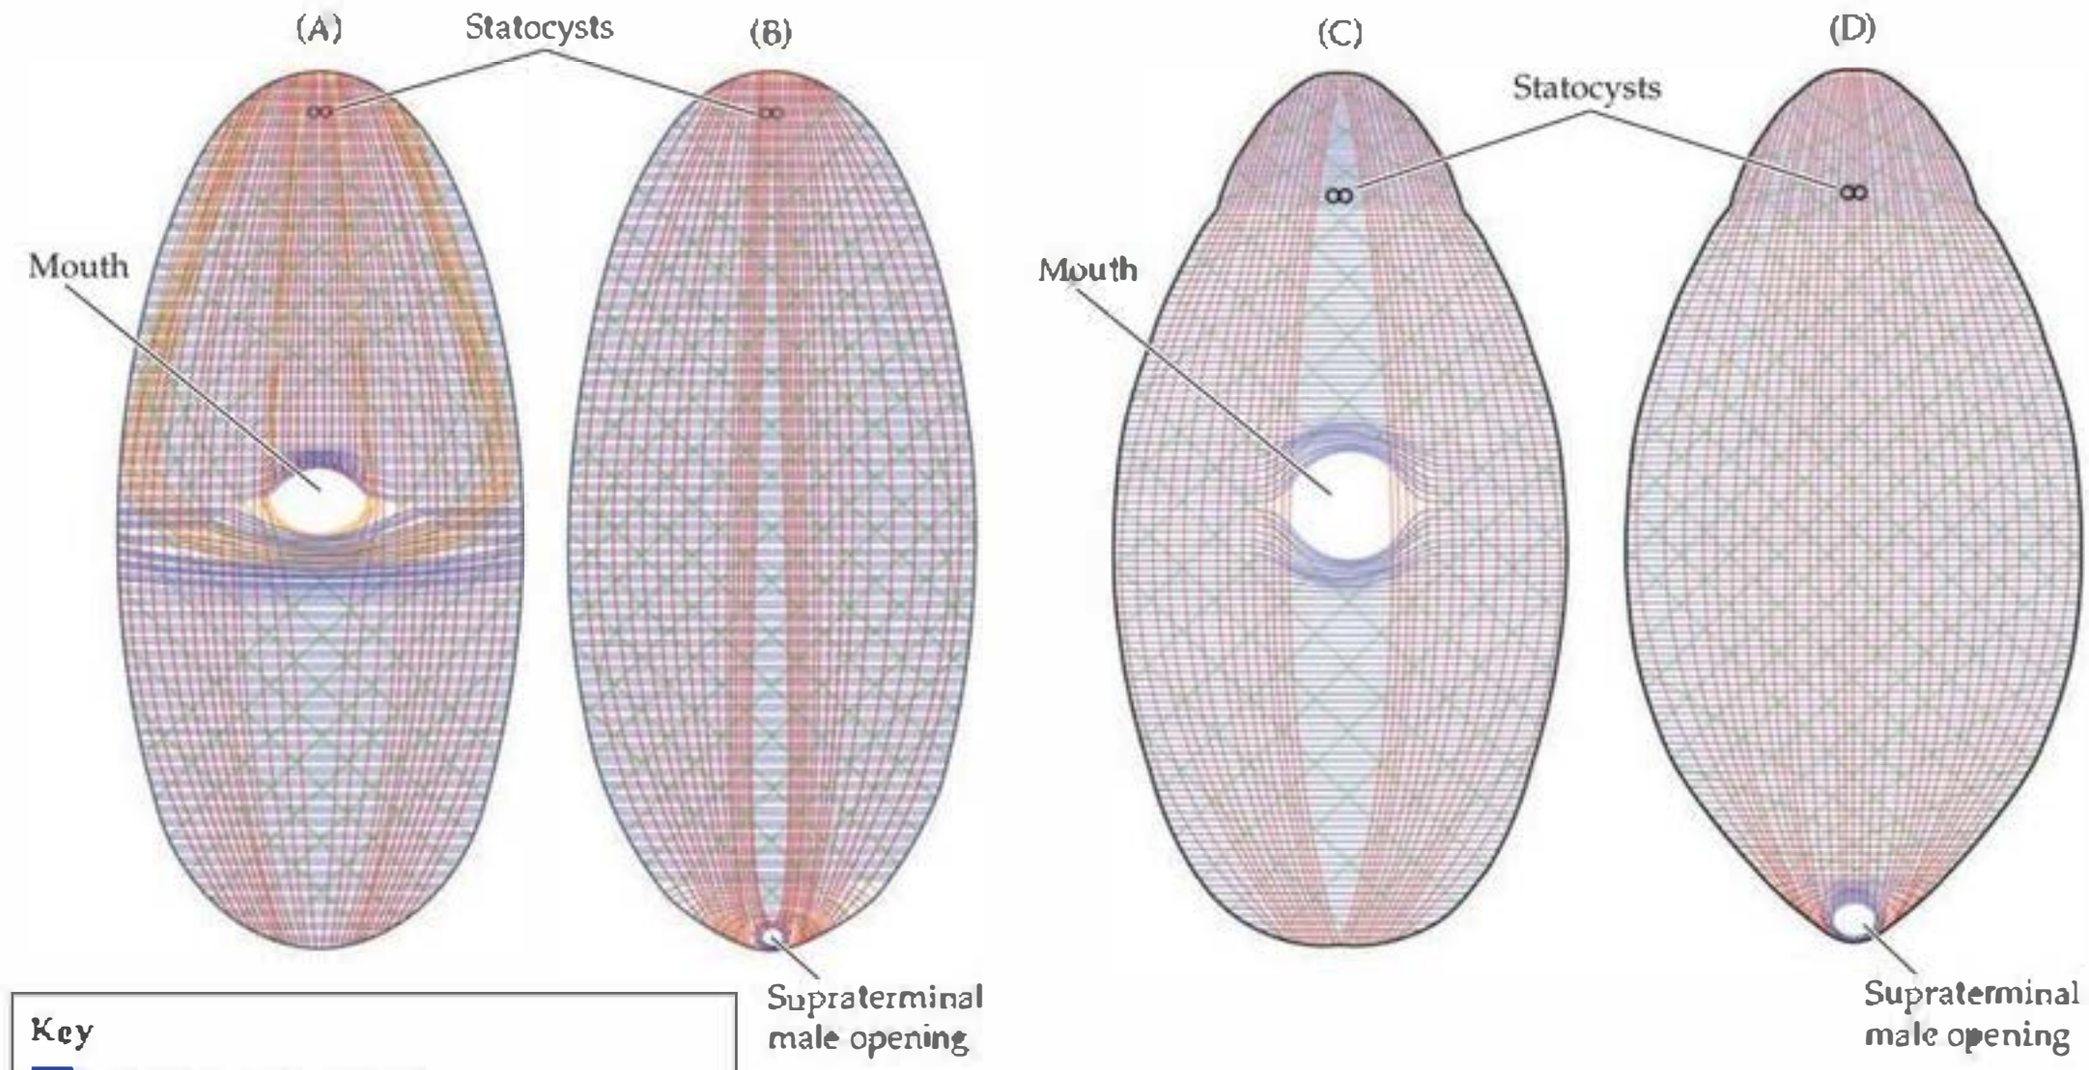
The Nemertodermatid Body Plan

General Body Structure

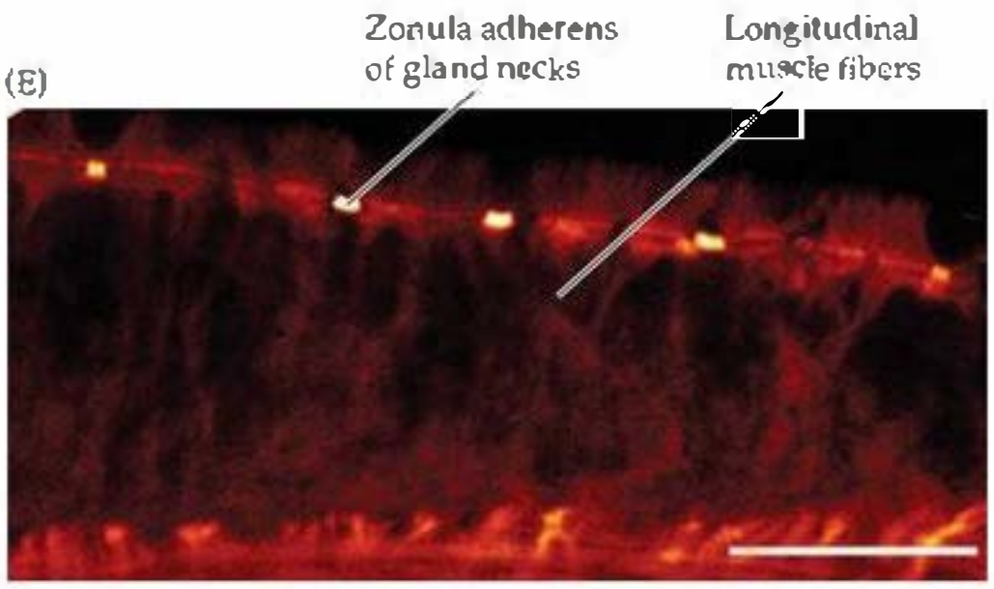
In general, nemertodermatids are small. The endosymbiotic *Meara stichopi* is usually less than 2 mm in length, free-living *Nemertoderma* average about 3 mm in length, and a few "giant" nemertodermatids grow to nearly one centimeter in length. Most individuals are colorless to yellow or red, but pigmentation can be variable within populations.

The epidermis of most species appears to contain numerous bottle-shaped mucous glands. Overall, the epidermis resembles that of nemertean worms, which led to the namesake "Nemertodermatid." In the genus *Nemertoderma*, these glands are more abundant at the apical pole, forming an anterior gland complex with separated, outwardly directed gland openings or necks. However, these openings are not grouped together in a regular way at an apical pore and thus do not form a "frontal organ" as has been described in Platyhelminthes. Nevertheless, the structures are sufficiently similar to that of turbellarians that earlier authors considered them to be homologous with the frontal organ structures of flatworms.

Cell and Tissue Organization



The epidermis of nemertodermatids is entirely ciliated. The cells are connected by an intracellular terminal web—a stratified structure composed of a closely woven inner layer of intensely staining fibrils overlain with more loosely packed fibrils, which bulges at the cell borders. Epidermal cells are joined apically by belt-like adherens junctions (belt-desmosomes) called zonula adherens. Interspersed among the cells are the necks of various glands and sensory receptors, particularly in the anterior region of the animal. The necks of glands appear to have associated muscular rings that may regulate the flow of gland contents (Figure 9.17E).



The ciliary rootlet structure is similar in Acoela and Nemertodermatida, one of the primary reasons workers grouped these two taxa together (as the Acoelomorpha). The rootlets of nemertodermatids include a rostrallyoriented rootlet and a caudally-oriented rootlet. In their original description, *Meara stichopi* was reported to possess "restitution cells," that appeared to contain ciliary structures in the process of being resorbed. Indeed, these cells represent structures similar to the pulsatile bodies reported in acoels, wherein worn cells are encapsulated and transported to the digestive tract for resorption (Figure 9.15). However, this feature is distinct in the nemertodermatids because the cilia detach from their basal apparatus before encapsulation, eliminating their ability to pulsate, causing some researchers to refer to them as "degenerating epidermal bodies."

Support and Movement

As in the acoels, body wall musculature of nemertodermatids has been extensively investigated using phalloidinstaining procedures.[1] Like most acoels, body musculature in nemertodermatids consists of outer circular and inner longitudinal muscle layers. Diagonal musculature typically is also present and varies among species, with fibers forming connec-

[1]Phalloidin is a naturally occurring toxin in the death cap mushroom (*Amanita phalloides*). Its toxicity is due to its ability to stabilize actin filaments within cells, and this attribute has led to it being widely used (fluorescently labeled) in research to visualize filamentous actin, such as muscle fibers

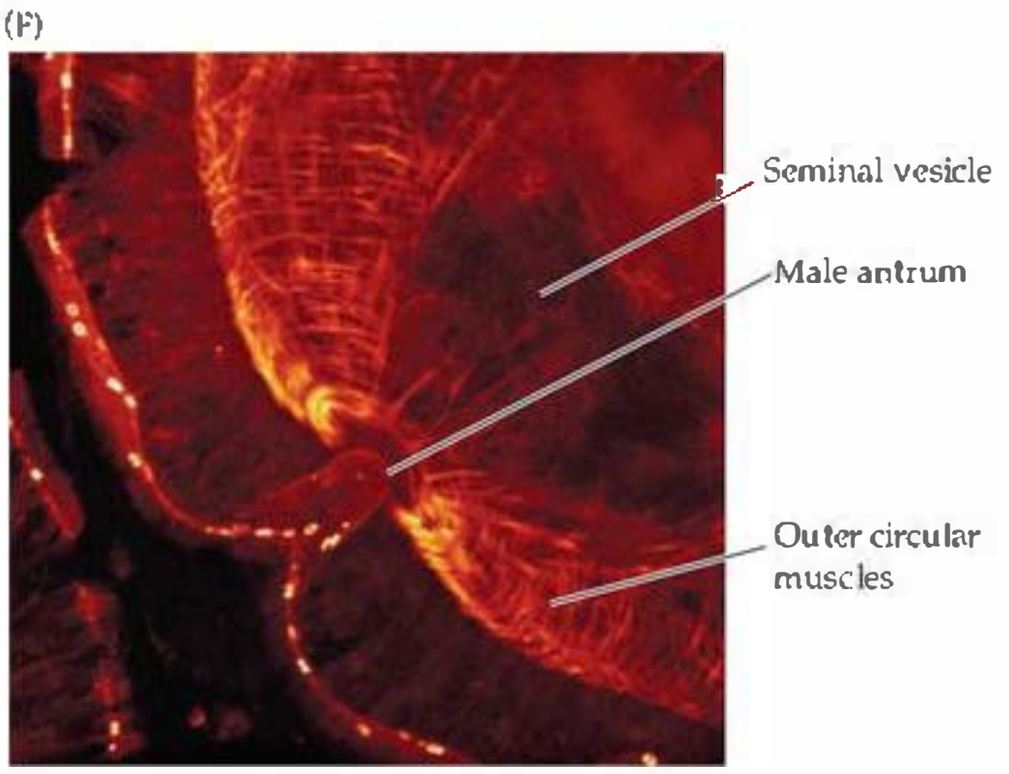


Figure 9.17 Schematic diagrams (A–D) and phalloidin-enhanced micrographs (E,F) of nemertodermatid musculature. (A) Ventral and (B) dorsal views of *Meara stichopi* (graphic showing muscle patterns). (C) Ventral and (D) dorsal views of *Nemertoderma westbladi* (graphic showing muscle patterns). Outer circular muscles (blue); inner longitudinal muscles (in red); diagonal muscles (in green); U-shaped muscles surrounding the mouth (in orange) on ventral side. (E) Lateral view of epidermis in *Nemertoderma westbladi*, showing longitudinal muscle fibers beneath circular ones in central space. Above this are two thin stained layers, the lower layer corresponding to the intracellular web, the upper layer corresponding to microvilli of the epidermal surface. The zonula adherens of the gland necks appear as brightly stained areas at this level. (F) Posterior body region of *Nemertoderma westbladi*, with invagination of body wall to form the male antrum; finer musculature of the seminal vesicle is visible in open space.

tions between layers in some (e.g., *M. stichopi*; Figure 9.17A,B) and forming distinct layers in others (e.g., *N. westbladi*; Figure 9.17C,D). Musculature surrounding the mouth also varies, being best developed in species with a permanent mouth. Musculature is also well developed around permanent genital openings (e.g., *M. stichopi*), but less so in species with transient genital orifices (e.g., *N. westbladi*).

The opening of the male gonopore and its associated antrum appear as an invagination of the entire body wall, and musculature associated with the seminal vesicle consists of a thin layer, present only in individuals with mature male organs (Figure 9.17F). Parenchymal muscles may also be present in individuals in all life stages, forming a three-dimensional network throughout parenchymal tissue. The statocyst is

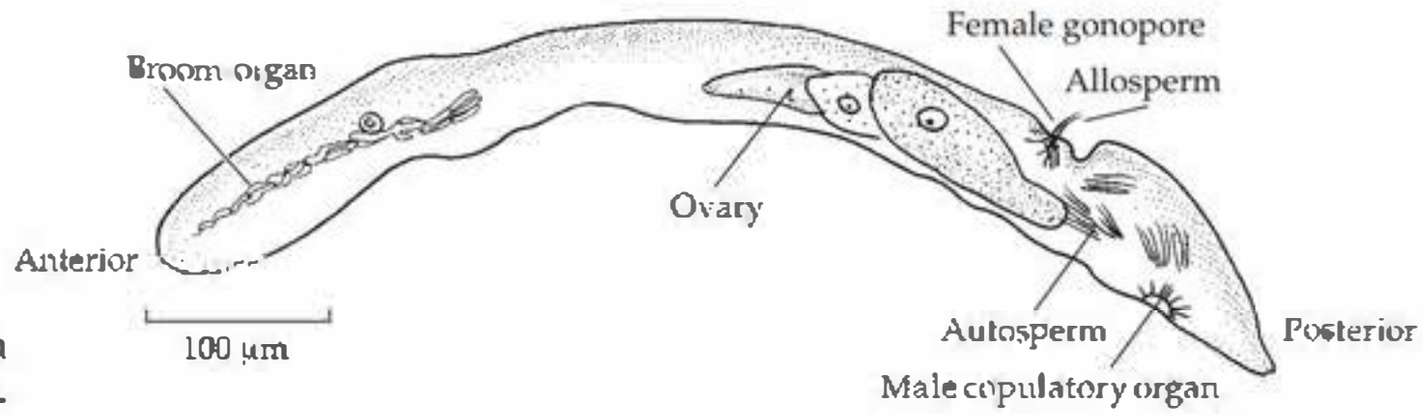

Figure 9.18 Nemertodermatida. Diagram of *Ascoparia* sp., showing location of dorsal female gonopore and subterminal male copulatory organ.

supported by muscles that attach dorsoposteriorly and anterolaterally to other body wall musculature. Nemertodermatids move by creeping on their ciliated surfaces or, in more elongated species, by undulating their bodies in a serpentine way.

Nutrition, Excretion, Gas Exchange

The gut of nemertodermatids has only a single opening, like that of cnidarians and other Xenacoelomorphs. However, unlike acoels, the nemertodermatid gut is not syncytial and instead contains a well-defined intestinal lumen. In some species, a cone of gut tissue has been reported to protrude and retract like a tongue to collect food particles. However, no known nemertodermatid possesses a structure recognizable as a muscular pharynx. Other species appear to lack a mouth altogether. In such species (e.g., *Flagellophora*), an anterior broom organ is reported although this structure does not seem to be directly connected to the gut. Instead it seems to consist of a bundle of up to 30 glands whose necks are protrusible through a canal at the anterior end of the body (Figure 9.14B). When opened, the broom organ appears to possess distal ends that are slightly swollen and possibly adhesive. Some researchers suggest that the lack of a mouth may represent an ancestral condition and that the mouth of nemertodermatids is a transient structure that appears during a limited part of postembryonic life, with the duration of persistence dependent upon the species.

Meara stichopi inhabits the foregut of the holothurian *Parastichopus tremulus*, a species common on Scandinavian coastlines, and appears to feed on detritus as well as upon nematodes within the guts of its host. Free-living species have been found with comparatively large turbellarians and nematodes within their guts.

As in acoels, the small body sizes of nemertodermatids allow them to eliminate waste nitrogen and carbon dioxide, as well as obtain oxygen from the surrounding water, without a need for discrete excretory or circulatory systems.

Nervous System

The nervous system of nemertodermatids is still poorly understood. Immunoreactivity studies to the neurotransmitter serotonin (5-hydroxytrypamine; 5-HT), and the regulatory neuropeptide FMRFamide, have shown considerable variation in responses in the species examined. In *Meara stichopi*, 5-HT reactivity reveals a subepidermal nerve net and two, loosely organized longitudinal nerve bundles along the length of the animal. In *Nemertoderma westbladi*, 5-HT reactivity shows a two-ringed, anterior commissure, with the rings converging near the statocyst, and connected by thin fibers. Two lateral fibers extend longitudinally from the commissure, as does a delicate curtain of evenly spaced finer longitudinal fibers that become indistinct caudally. FMRFamide immunoreactivity follows the same pattern as 5-HT reactivity in *M. stichopi* and *N. westbladi*. These results suggest that the nemertodermatid nervous system is distinct from the bi-lobed ganglionic brain and orthogon peripheral nervous systems of Platyhelminthes (i.e., paired longitudinal ventral nerve cords connected by a regular pattern of transverse commissures). Nemertodermatid central nervous systems are also distinct from the commissural brains of acoels (i.e., symmetrical commissural fibers with few cell bodies and 3–5 pairs of radially arranged longitudinal nerve cords, irregularly connected with transverse fibers).

Reproduction and Development

The reproductive anatomy and natural history of nemertodermatids is not well studied, and only a few species have been examined in this regard. The male gonopores in nemertodermatids appear to open dorsally (or supraterminally) and are associated with a muscular male antrum. In fully mature specimens, a muscular seminal vesicle and often a male copulatory organ may also evert either posteriorly or slightly dorsally (Figure 9.18). Female genitalia, if present, are located dorsally. *Flagellophora* seem to have a deep, well-defined invagination that may represent a female gonopore (Figure 9.14).

In *Meara stichopi*, follicular testes occupy most of the preoral part of the body. The ovary occupies the postoral part of the body and often contains one or more large ova within the posterior body region. The male intromittent organ opens terminally to slightly supraterminally in this species.

In general, Nemertodermatida have a 9+2 arrangement of microtubules in their uniflagellate sperm, a condition distinct from the variable microtubule arrangement and biflagellate condition of acoel sperm. Many field-collected nemertodermatids contain two types of sperm. **Autosperm** (sperm produced by the individual in which they are found) in *M. stichopi* are filiform, about 45–60 µm long, and under phase contrast microscopy show indistinct divisions of individual

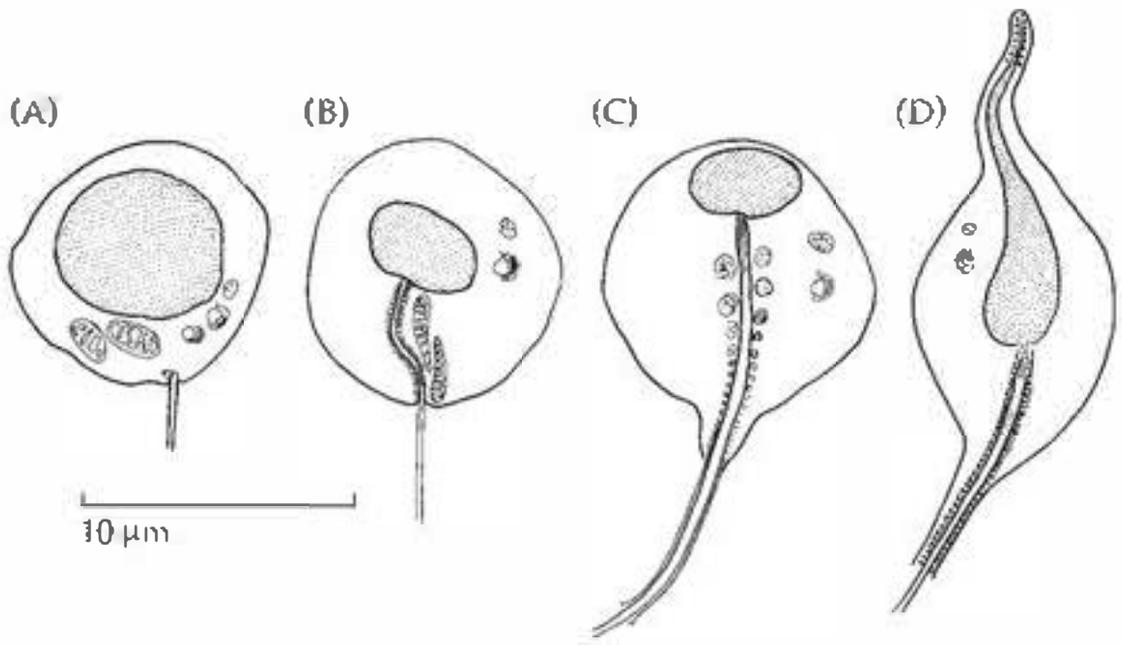

Figure 9.19 Nemertodermatida. Stages in spermatogenesis in *Meara stichopi*. (A) In early stages of spermatogenesis, the nucleus is large, with heterogeneous electron density; two mitochondria are visible. A single flagellum begins to form from a basal body situated near the cell membrane. (B) The nucleus shrinks and becomes homogenous in density. The mitochondria begin to elongate, and the basal body and associated fibers move into the cytoplasm toward a depression forming in the nucleus. Microtubules coil around the flagellar channel. (C) The mitochondria coil around the flagellar channel and a sheath grows from the cell to surround the proximal flagellum. (D) The cell and nucleus elongate to form the head of the spermatozoon. The mitochondria form tighter whorls and wander into the length of the flagellar sheath.

sperm into head, middle piece, and tail, as is typical of more derived spermatozoan forms within Metazoa (Figure 9.19). Some sperm appear to be coiled, corkscrew-fashion, over half of their length and are non-motile within the animal producing them. Allosperm (sperm not produced by the individual in which they are found) are distinctive because they tend to be uncoiled and motile within the bodies of recipient individuals.

The pioneering investigator of acoels and nemertodermatids (what is now called Acoelomorpha), Einar Westblad, noticed that development of female reproductive structures seemed to precede that of male structures indicating that some nemertodermatids are protogynous. On the other hand, other authors have noted that "male maturity seems to precede female maturity," or they have specifically stated that individuals are protandrous. In *N. westbladi*, individuals were found to have matured as males, females, and hermaphrodites, with no clear evidence of either protandry or protogyny. Mature females contained a single large egg but also contained up to 10 ova, and allosperm were found in only a few individuals. In *Ascoparia neglecta*, an elongate species with no actual mouth in mature individuals, although male and female pores are visible, and individuals possess a male copulatory organ, allosperm appear to be contained in vacuoles near the vagina.

Many species appear to lack female genitalia, yet are found to contain autosperm that is clearly contained within male reproductive structures, as well as allosperm that appear to have been introduced to the individual housing it. Individuals bearing allosperm appear to include mature as well as immature individuals raising the possibility of sperm storage and sperm competition among individuals. Taken together, there appears to be great diversity in reproductive life history among nemertodermatids. Adults in some species appear to be smaller than juveniles suggesting that maturing individuals may cease to feed and complete their life history using stored food reserves or other resources.

Copulation has not been observed in any nemertodermatids. However, earlier workers suggested that worms may simply press their posterior ends together long enough for spermatids to get through the epithelium of the recipient worm. Since male structures are located subterminally, this behavior would have to occur with the recipient positioned somewhat dorsally, or an individual transferring sperm would have to undergo dorsiflexion to accomplish impregnation. In species lacking female structures, insemination appears to be hypodermic. Oviposition is accomplished by flexing the body into a dorsi-convex shape followed by protrusion of the circumoral area of the body to force individual eggs out of the mouth.

Development in nemertodermatids is similar to that of the Acoela. The first cleavage division is holoblastic (Figure 9.20). The second division results in the formation of micromeres and macromeres. In later 4-cell stages, the micromeres shift slightly clockwise (dexiotropic), resembling spiral cleavage, but this shift does not occur until well after the division has taken place. Nemertodermatids do not have the unique

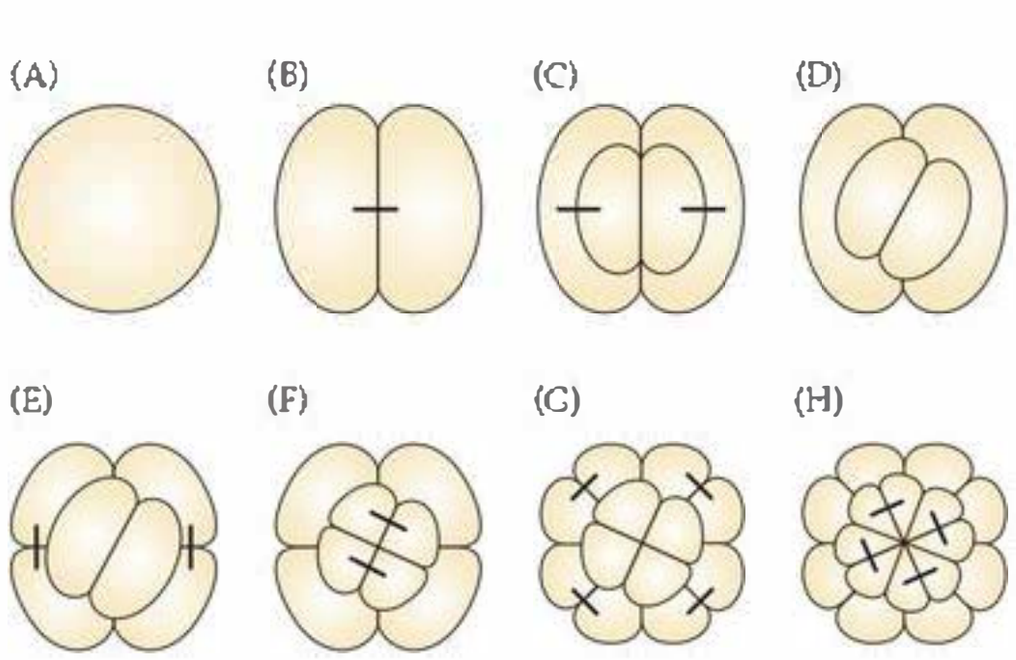

Figure 9.20 Diagram of duet cleavage in Nemertodermatida (*Nemertoderma westbladi*), viewed from the animal pole. Lines indicate cleaved relationships among cells. (A) Uncleaved zygote. (B) 2-cell stage. (C) Early 4-cell stage with micromeres oriented radially. (D) Late 4-cell stage with micromeres shifted. (E) 6-cell stage. (G) 12-cell stage with 8 macromeres and 4 micromeres. (H) 16-cell stage with 8 macromeres and 8 micromeres.

spiral duet-cleavage program seen in Acoela. Instead, cleavage starts out radial, but then takes place in a duet pattern, the micromeres shifting clockwise to produce a spiral-like pattern. The 4-cell divisions involve both macromeres, resulting a 6-cell embryo, followed by another division by the micromeres to yield an 8-celled embryo. This alternating pattern is followed until the 16-cell stage, similar to what is known in acoels as "duet cleavage," although in acoels, the first division involves a counterclockwise (levotropic) shift of the micromeres rather than the clockwise shift documented for *N. westbladi*. Nevertheless, the form of duet cleavage is similar in both taxa, suggesting to some researchers that this trait is ancestral in the Acoelomorpha.

Postembryonic development in *N. westbladi* appears to follow three life history phases. Hatchlings are nearly round; only slightly longer than wide (250 × 200 μm). These individuals grow into juveniles, which are bottle shaped and may reach nearly 1mm in length, but possess no discernable sexual structures. Mature specimens may be variable in size (averaging 450 μm in length), and possess a slightly more elongated shape as well as visible male copulatory organs and a small pointed tip at the posterior end formed by the male gonopore.

Subphylum Xenoturbellida

The free-living marine creatures known as xenoturbellids comprise just two described species, *Xenoturbella bocki* (Figure 9.21 and chapter opener photo) and *X. westbladi*, although several undescribed species are known to exist. They are delicate, ciliated worms with a very simple body plan, and are recognizable by their body furrows, the horizontal furrows (= side or anterolateral furrows), and a ring furrow (= equilateral furrow), the latter nearly crossing the animal's midline (Figure 9.22A). The furrows contain what has been interpreted as high concentrations of sensory cells, so they are presumed to be sensory structures. Like acoels and nemertodermatids, xenoturbellids possess a diffuse, basi- or intraepithelial nervous system, they use a statocyst for orientation, have circular and longitudinal muscles, and a mid-ventral mouth. Also like acoelomorphs, *Xenoturbella* lack a complete gut, organized gonads, excretory structures, coelomic cavities, or a well-developed brain.

However, unlike acoelomorphs, xenoturbellids possess simple spermatozoa, similar to those seen in externally fertilizing species. Also, muscle layers are connected by extensive interdigitations among the layers of cells as well as longitudinal muscles that are exceptionally robust. Their nervous system, while diffuse, is concentrated along its sensory furrows. Xenoturbellids also are generally larger in size, reaching up to 4 cm in length.

Sixten Bock (1884–1946), the great Swedish platyhelminth specialist, was collecting along the Swedish

Figure 9.21 ***Xenoturbella bocki.*** Live specimen, from 80 m depth, off the west coast of Sweden.

coast near The Sven Lovén Centre for Marine Sciences (then known as the Kristineberg Marine Station) in 1915 when he came across an odd-looking "flatworm." Bock never got around to identifying the creature, but Einar Westblad, another great platyhelminth specialist did, initially considered it an archoophoran turbellarian, along with similar specimens he had collected near Scotland and Norway. Eventually, in 1949, Westblad described the original specimens as *Xenoturbella bocki*, after its collector. The creatures caused immediate controversy because of their distinctive appearance. In 1999 the second species was described, and named after Westblad as *Xenoturbella westbladi*. By this time people were beginning to wonder about how unique these two "flatworms" were. The name *Xenoturbella* means "strange turbellarian" because, while they

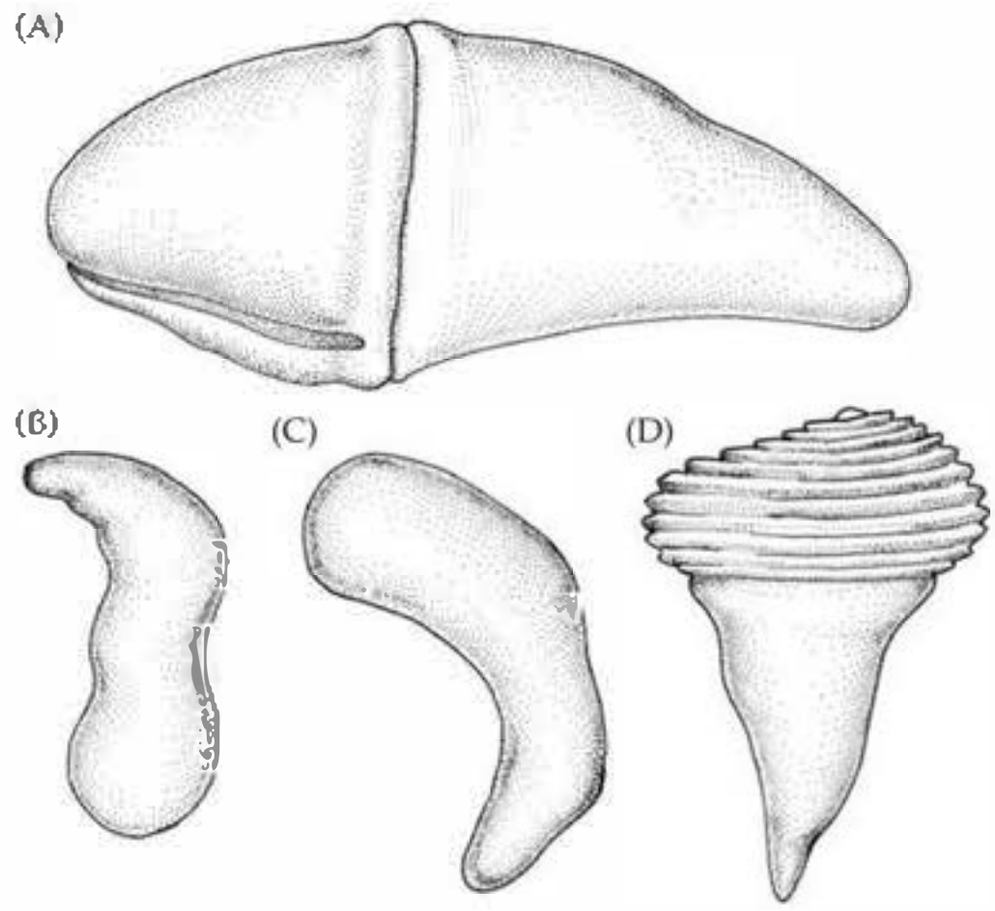

Figure 9.22 Line drawings of ***Xenoturbella bocki*** from live specimens. (A) Dorsolateral view showing the horizontal and ring furrows. resembled acoelomorphs overall, their epidermis was reminiscent of hemichordates, and their statocyst seemed similar to that of certain holothurians.

As morphological evidence accumulated on *Xenoturbella*, their relationship to flatworms began to be doubted, and by the late 1950s most researchers agreed that *Xenoturbella* was not a flatworm, but there was little consensus about what these animals actually were. Opinions on their identity ranged from considering them "among the coelenterates" to placing them as a sister taxon to the enteropneusts.

Then, in the late 1990s, analysis of ribosomal RNA on what appeared to be developing oocytes and embryos in some specimens led to the conclusion that *Xenoturbella* was in fact a highly degenerate mollusc, possibly some form of shell-less bivalve. However, subsequent investigations showed that these samples had been contaminated with gut contents containing mollusc DNA. Subsequent DNA studies suggested *Xenoturbella* might be a highly degenerate deuterostome, near the base of the deuterostome line or perhaps closely related to echinoderms and hemichordates (the clade known as Ambulacraria). Continued molecular phylogenetic studies have suggested that *Xenoturbella* is closely tied to acoels and nemertodermatids, and thus the new phylum name Xenacoelomorpha was created to house these three odd, primitive worms. While we accept this classification for this book, it is clear that the final resolution of *Xenoturbella* phylogenetic relationships is yet to be settled.

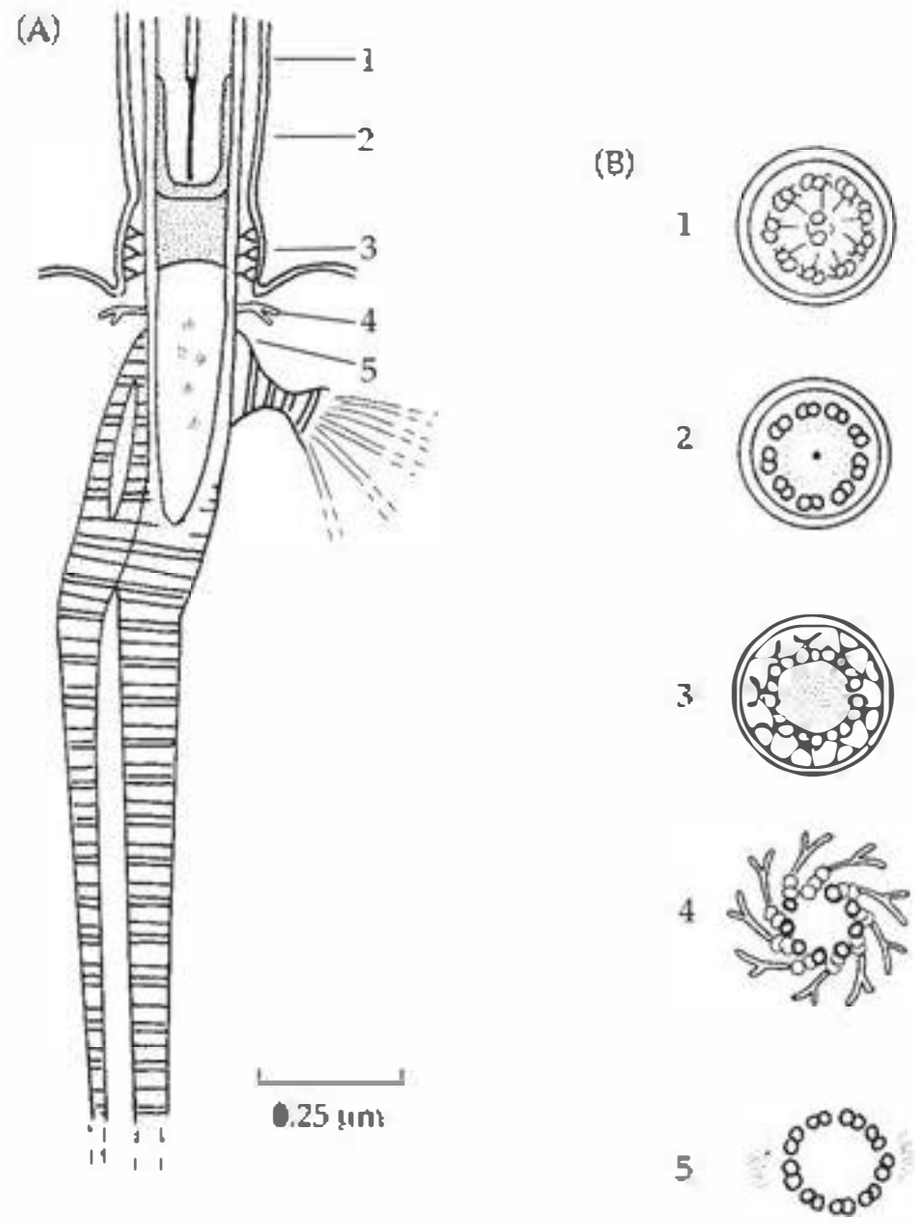

Figure 9.23 Diagram of the basal part of the cilium, basal body, and ciliary rootlets of *Xenoturbella bocki*. (A) Longitudinal median section of basal part of cilium. The Xenoturbellid Body Plan

General Body Structure

Most specimens of *Xenoturbella* are ovoid in shape, with a flattened ventrum and a length of 4 cm or less. These worms can be quite active and capable of considerable changes in shape (Figure 9.22B–D). The anterior region of most individuals is slightly lighter in color, and the horizontal furrows extend posteriorly, on either side, from the head end. Approximately midway down the body, these furrows nearly intersect with a ring furrow. The nervous system appears to be concentrated in these areas, suggesting a sensory function to these structures.

The epidermis of *X. bocki* consists of a layer of tall columnar cells with nuclei situated basally. These cells are densely ciliated, and are interspersed with unciliated or monociliated gland cells and ciliary receptors, the latter being most numerous in the horizontal furrows. The cilia themselves are attached to epidermal cells by several structures (Figure 9.23A). Each cilium ends in a basal body whose protruding basal foot has microtubules that extend into the epidermal cell. Two ciliary rootlets project from the basal body deeper into the epidermal cell; the thinner one, located on the same side of the cilium as the basal foot, projects straight into the cell, whereas the thicker rootlet has a knee-like bend. The cilia each have a distinctive arrangement of microfilaments in which the standard 9+2 arrangement extends for most of the ciliary shaft length, but near the end microfilament doublets 4–7 abruptly end, leaving only doublets 1–3 and 8–9 to continue on to the end of the cilium (Figure 9.23B). This "shelf" arrangement of microtubules is also present in Nemertodermatida and Acoela but is unknown in other known metazoan taxa (Figure 9.24).

The basal region of the epidermis houses the cell processes of the multiciliary cells, supporting cells, and a prominent intraepidermal nerve layer. The cell membrane of adjacent epidermal cells intermingle with each other, but tight couplings between the membranes of adjacent extensions do not appear to exist. However, where the cytoplasmic protrusions are shorter, they show a regular arrangement as if the two cells were held together by a zipper, but tight junctions,

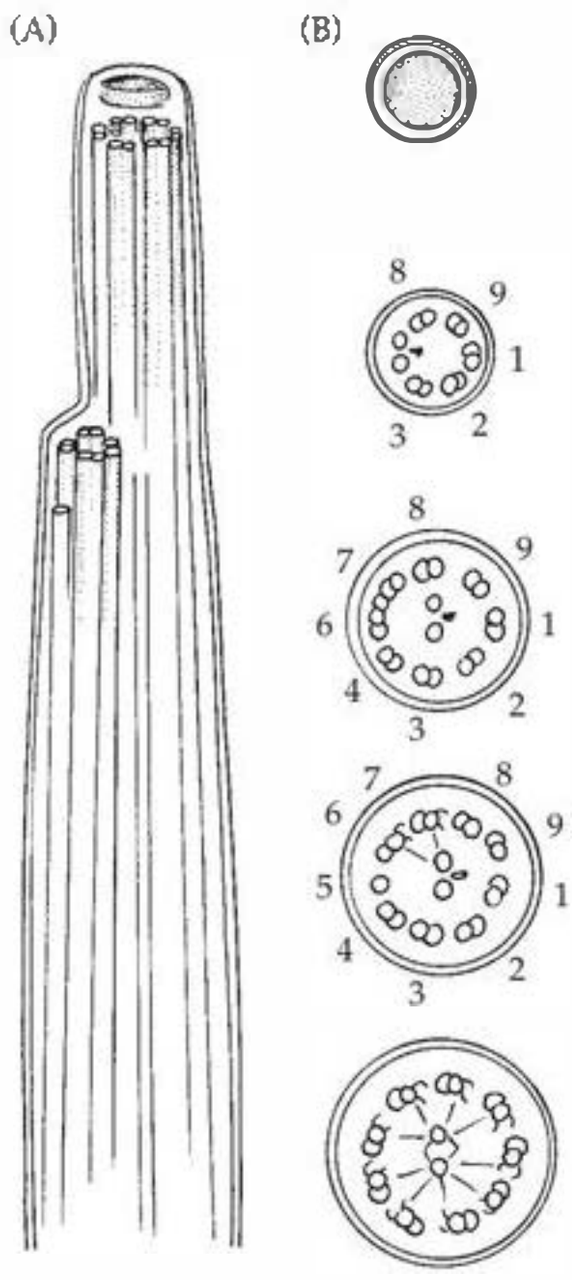

Figure 9.24 Diagram of the configuration of axonemal fibers within the distal shafts of epidermal cilia in *Xenoturbella bocki*. (A) Lateral view of the distal shaft showing the "shelf" located approximately 1.5 μm from the cilium tip. (B) Transverse sections of the cilium along its length; a 9+2 arrangement of axonemal fibers begins at the cilium base but microtubule doublets 4–7 end at the shelf.

desmosomes or gap junctions between cells have yet to be identified.

A number of workers have noted the similarities in both ciliary roots and ciliary tips in *Xenoturbella*, acoels, and nemertodermatids. Like these other groups, *Xenoturbella* is capable of withdrawing and resorbing worn out epithelial cells, yet there are differences in the character of this process. Whereas nemertodermatids do not withdraw still-motile ciliary cells, the withdrawn epidermal cells in *Xenoturbella* assume an orientation perpendicular to that of the other cells and retain some motility.

Support and Movement

Xenoturbella possess a highly muscular body wall (Figure 9.25A). An outer circular muscle layer surrounds a well-developed inner layer of longitudinal muscles, and with radial musculature extending from the gastrodermis to the outer circular layer of muscle cells (Figure 9.25B). The longitudinal layer of muscles is substantial, and individual muscle cells consists of a number of isolated fibers that when viewed in cross-section resemble a monolayered rosette.

No specialized parenchyma cells exist between the epidermis and the gastrodermis. However, all muscle cells tend to have numerous and well-defined cytoplasmic extensions with extensive mutual interdigitation. Tight attachment of adjacent cell membranes does not appear to exist, but connections resembling the zonula adherens in acoels and nemertodermatids are present, as is a fibrous subepidermal layer up to 5 μm thick. The extensive connections between muscle cells observed in *Xenoturbella* has been said to be reminiscent of hemichordates.

Xenoturbella inhabit marine mud bottoms at 20–120 m depth and move by ciliary gliding, without requiring modification of the body profile. The ventral surface is richly supplied with epidermal glands and moving animals leave behind a trail of mucus. While capable of considerable variation in body configuration due to powerful circular and longitudinal muscles, in most circumstances animals do not require such gymnastics in their basic activities.

Nutrition, Excretion, and Gas Exchange

Feeding by *X. bocki* occurs when individuals open their simple mouth and protrude their unciliated foregut. Extrusion of this structure appears to take place as a result of contractions of the surrounding body wall musculature, with relaxation of these muscles resulting in foregut retraction. The gut is cellular, but unciliated. Considerable attention has focused on the gut contents of *Xenoturbella*. Examination of mitochondrial DNA (cytochrome *c* oxidase subunit I sequence data) in the gut contents of *Xenoturbella* suggests that they feed primarily on bivalve prey, possibly in the form of eggs and benthic larvae. Such specificity suggests that these worms may be specialized predators, a hypothesis supported by the results of stable isotope studies indicating high ratios of N_{15} to N_{14} (3.42) characteristic of most predators. Two species of endosymbiotic bacteria have been described from the gut of *X. bocki*. Researchers have suggested that these bacteria might assist in nitrogen detoxification (given excretory organs are lacking) or might supply growth factors or chemical defenses to their hosts. Discrete excretory structures have not been described for *Xenoturbella*.

Nervous System and Sense Organs

The nervous system of *Xenoturbella* is a diffuse intraepithelial net without much of an anterior concentration and most researchers are reluctant to call this a brain. This arrangement is similar to that seen in some acoels and nemertodermatids, although the latter do have a small anterior concentration of neurons (larger than that of xenoturbellids). The sensory furrows of xenoturbellids appear to have slightly greater concentrations

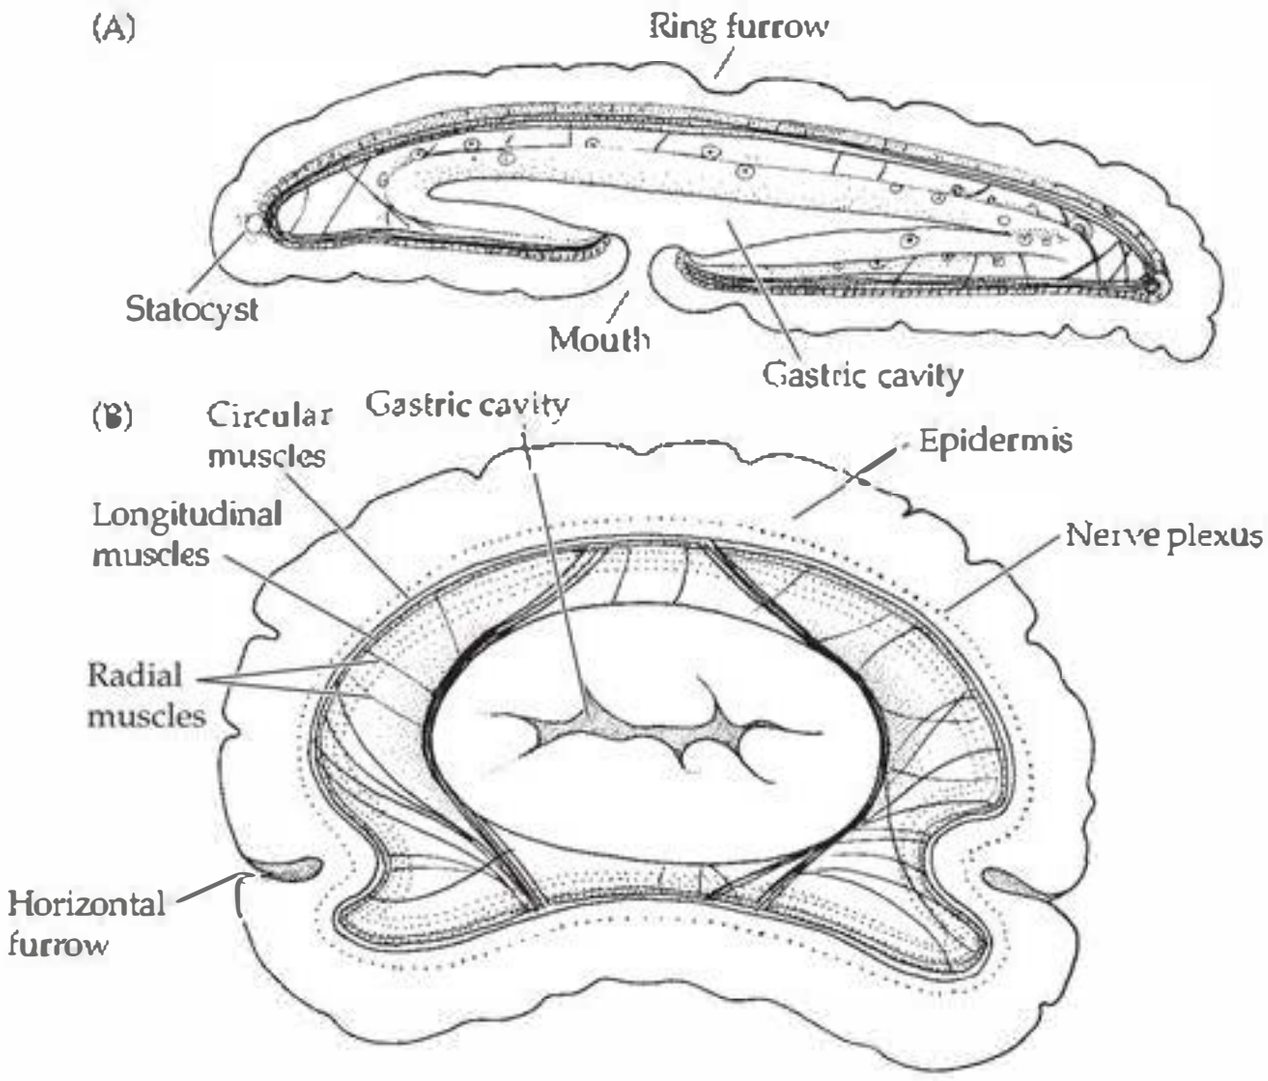

Figure 9.25 Internal morphology of *Xenoturbella bocki*. (A) Transverse section anterior to the mouth showing the gastric cavity. (B) Schematic diagram of longitudinal section anterior to mouth showing orientation of circular, longitudinal and radial muscles. Scale bars = 0.1 cm.

of neurons than other parts of their bodies. Like acoelomorphs, *Xenoturbella* have an anterior statocyst (Figure 9.25B), but the arrangement of muscles and neurons associated with this structure differs in that it appears to be embedded within the nerve net rather than specifically supplied with connecting commissures.

Reproduction and Development

Xenoturbellids are simultaneous hermaphrodites producing relatively large diameter, yolky eggs. Neither well-developed ovaries nor testes have been observed in adult individuals. In particular, male gonads appear to consist simply of a layer of male sex cells surrounding the gut. Sperm develop in clumps and appear to be of a "primitive" type, usually associated with external fertilization, wherein spermatids possess a small conical acrosome and a single flagellum. There are no copulatory organs and gametes appear to be spawned either through the gut or mouth opening. Although *Xenoturbella* has been said to have direct development, as in acoelomorphs, recent work has suggested the "hatching stage" might be called a larva; these are elongate/ovoid, swimming with a rotating motion with uniform ciliation, and have an apical tuft of cilia that are 20–30 μm in length. No mouth or blastopore has been seen in the larva.

CHAPTER 10

Phylum Platyhelminthes

The Flatworms

The phylum Platyhelminthes (Greek *platy*, "flat"; *helminth*, "worm") includes about 26,500 extant species of free-living and parasitic worms; more than 100,000 undescribed species have been estimated to exist. Platyhelminths are triploblastic, nonsegmented, bilateral, acoelomate, soft-bodied, dorsoventrally flattened worms (Box 10A). They display a variety of body forms (Figure 10.1A–N) and inhabit a wide range of environments. About 75% of all described species are parasitic, mostly belonging to the infraclasses Monogenea and Trematoda (the flukes) and Cestoda (the tapeworms). Most of the free-living forms live in marine and freshwater benthic habitats and comprise a diverse group formerly known as "turbellarians"; a few are terrestrial and some are symbiotic in or on other invertebrates. Free-living marine flatworms are often some of the most colorful and graceful creatures found in shallow tropical waters and tide pools. As their name suggests, most flatworms are strikingly flattened dorsoventrally, although the body shape varies from broadly oval to elongate and ribbon-like; a few bear short tentacles at the anterior end or have other elaborations of the body surface. The free-living forms range from less than 1 mm to about 30 cm long; although most familiar species are 1–4 cm long, the vast majority of free-living flatworms are "microturbellarians." The largest of all platyhelminths are certain tapeworms that attain lengths of several meters (a tapeworm that infests blue whales grows to 10 m in length!).

The combined features of the platyhelminths represent a suite of attributes marking major advancements in the evolution of the Metazoa (Box 10A). Combined with a third germ layer (mesoderm), bilateral symmetry, and cephalization are some sophisticated organs and organ systems and a trend toward centralization of the nervous system. The solid (acoelomate) body plan usually includes a relatively dense mesenchyme (often called "parenchyme") between the gut and the body wall. The mesenchyme is not homogeneous, but comprises a multitude of differentiated cell types and small gaps or **lacunae**. Within the mesenchyme of most flatworms are discrete excretory–osmoregulatory structures, the protonephridia,

which are found in many invertebrate taxa, especially among protostomes. Most flatworms possess complex reproductive systems and an incomplete yet complex gut with a single opening serving for both ingestion and egestion. The mouth leads to a pharynx of varying complexity and then to a blind intestine. The gut is entirely lacking in tapeworms, as well as in a few other symbiotic species.

Taxonomic History and Classification

In his first edition of *Systema Naturae* (1735), Linnaeus established two phyla to encompass all of the known invertebrates. To one he assigned the insects and to the other the rest of the invertebrates. Linnaeus called this latter taxon Vermes (Greek, "worms"). By the thir-

Figure 10.1 Representative flatworms. (A–K) Free living flatworms. (A) *Catenula lemnae*, a catenulid. (B) *Macrostomum* sp. (a macrostomid). (C) The terrestrial triclad *Bipalium kewense*. (D) A colorful flatworm (*Bipalium* sp.) on a decayed leaf. Sarawak, Borneo, Malaysia. (E) SEM of *Cheliplana*, an interstitial rhabdocoel. (F) *Pseudoceros bajae*, an intertidal polyclad flatworm from the Sea of Cortez, Mexico (also see chapter opener photo, *Pseudobiceros bedfordi*). (G) The strikingly colored polyclad *Pseudoceros ferrugineus*. (H) The familiar freshwater triclad *Dugesia tigrina*. (I) The polyclad flatworm *Thysanozoon*, a predator on small invertebrates, including barnacles. (J) The marine polyclad, *Eurylepta californica*. (K) *Alloioplana californica*, a common polyclad on the Pacific Coast of North America. (L) *Acanthomacrostomum* sp. A meiofaunal flatworm that has a layer of calcareous spicules just below the epidermis. This skeletal framework may provide protection and support in aiding in locomotion. (M) The liver fluke *Fasciola hepatica* (Trematoda: Digenea). (N) Anterior end of the tapeworm *Taenia* (Cestoda: Cyclophyllidea).

teenth edition of *Systema Naturae* (1788), the various groups of flatworms were placed together in the order Intestina. During the early 1800s, several biologists, including Lamarck and Cuvier, questioned and rejected the concept of the phylum Vermes, although the taxon continued to surface from time to time and actually persisted into the twentieth century as a dumping ground for almost any creatures with wormlike bodies (and many that were not so wormlike).

During the nineteenth century, the flatworms were eventually separated from most other groups of worms and wormlike creatures. In 1851, C. Vogt isolated the flatworms and the nemerteans as a single taxon, which he called the Platyelmia, a name changed to Platyelminthes by Karl Gegenbaur in 1859. (Unfortunately, Gegenbaur also resurrected the phylum Vermes.) Gegenbaur's Platyelminthes (now Platyhelminthes) was eventually raised to the rank of phylum, comprising four classes:

Turbellaria, Nemertea, Trematoda, and Cestoda. In 1876 Charles Minot dropped the nemerteans from this assemblage, although many workers did not accept this change for several decades. Libbie Hyman (1951) asserted the monophyly of Platyhelminthes, a view shared by Tor Karling (1974), Peter Ax (1985) and Ulrich Ehlers (1985) who recognized three clades (Acoelomorpha, Catenulida, and Rhabditophora) that have since been supported by molecular phylogenetic studies. Later analyses of morphology and the advent of molecular gene sequence analyses have supported the monophyly of Catenulida and Rhabditophora (although these two major flatworm clades still lack unambiguous morphological synapomorphies), but suggested acoelomorphs were basal bilaterians rather than flatworms (see Chapter 9). With the removal of the Acoelomorpha, Platyhelminthes is now viewed as a monophyletic phylum.

The internal classification of flatworms has been subjected to frequent revisions. However, two recent studies by independent groups of researchers targeted platyhelminth phylogeny by analyzing different sets of thousands of genes (Egger et al. 2015; Laumer et al. 2015). Remarkably, these genomic studies, published at nearly the same time, resulted in nearly the same phylogeny. Our summary tree (Figure 10.34) and classification are based primarily on this recent work. However, students can expect continued reorganization of the flatworms in the near future. There are about 6,500 species of free-living flatworms, 12,000 species of flukes, and 8,000 species of tapeworms.

The free living flatworms (formerly classified as "turbellarians," a category now known to be a paraphyletic group, although the name is still sometimes loosely used for the non-neodermatan platyhelminths) were previously grouped into two taxa on the basis of whether yolk is deposited within the cytoplasm of the ova (endolecithal ova) or separately, in special cells outside the ova (ectolecithal ova). Those with endolecithal ova were placed in the Archoophora and those with ectolecithal ova in the Neoophora. These names have been abandoned as formal taxa because they are now known to be nonmonophyletic. However, the names are still descriptive because the placement of yolk, as well as the uterine structures that mediate this process, provide additional characters for describing the various flatworm orders. The patterns also have important implications in the early development of these animals.

BOX 10A Characteristics of the Phylum Platyhelminthes

1. Parasitic or free-living, unsegmented worms (the Cestoda are strobilated)
2. Triploblastic, acoelomate, bilaterally symmetrical; dorsoventrally flattened
3. Spiral cleavage (in non-parasitic species) and 4d mesoderm
4. Complex, though incomplete, gut usually present; gut absent in some parasitic forms (Cestoda)
5. Cephalized, with a central nervous system comprising an anterior cerebral ganglion and (usually) longitudinal nerve cords connected by transverse commissures (ladderlike nervous system)
6. With protonephridia as excretory/osmoregulatory structures
7. Hermaphroditic, with complex reproductive system

PHYLUM PLATYHELMINTHES

SUBPHYLUM CATENULIDEA Catenulids (Figure 10.1A). Simple anterior pharynx and saclike gut; mesenchyme sometimes reduced to a fluid matrix (making them effectively blastocoelomate); sometimes with statocyst bearing 1 to 3 statoliths; brain lies at base or middle of preoral lobe; with a ciliated ventro-atera groove between base of preoral lobe and the rest of the body; tubules of excretory system median dorsal; with a single bflagellate protonephridium; male genital opening dorsal and anterior; female ducts and accessory organs are lacking; with endolecithal ova and spiral cleavage. Catenulids are elongate freshwater and marine forms. A single order, Catenulida. (e.g., *Catenula*, *Paracatenula*, *Stenostomum*)

SUBPHYLUM RHABDITOPHORA With cellated rhabdites, a duo-gland adhesive system and multiflagellate terminal cell in the protonephridia; most taxa with bflagellate sperm.

INFRAPHYLUM MACROSTOMORPHA Rhabditophora with duo-gland adhesive organ consisting of viscid gland and releasing gland necks emerging in a common collar of anchor cell microvilli; with a postoral neural commissure, and a protrusible pharynx simplex; with aflagellate sperm, endolecithal ova, and spiral cleavage.

ORDER HAPLOPHARYNGIDA Minute worms (to 6 mm long) with a simple proboscis and pharynx; proboscis separate from pharynx and beneath the anterior tip of the body (reminiscent of nemerteans); anal pore weakly developed, but permanent; brain encapsulated by a unique membrane; oviduct posterior to male genital apparatus; male copulatory organ consists of a posterior prostatic vesicle and an anterior stylet apparatus. One genus (*Haplopharynx*) and at least three species

ORDER MACROSTOMIDA Macrostomids (Figure 10.1B). Simple pharynx; simple, saclike gut; with endolecithal ova and a common oviduct anterior to the male genital apparatus; small and predominately interstitial forms; marine and freshwater. (e.g., *Acanthomacrostomum*, *Macrostomum*, *Microstomum*)

INFRAPHYLUM TREPAXONEMATA Rhabditophorans with biflagellate sperm bearing a 9 × 2 + "1" pattern of microtubules.

SUPERCLASS AMPLIMATRICATA With a tendency to express an ample extracellular matr x; with spiral c eavage.

ORDER POLYCLADIDA Polyclads (Figure 10.1F,G,J K). A diverse group of re ative y arge free-living flatworms w th endo ec tha ova; nearly all are mar ne; common in littora zones throughout the wor d, espec ally n the trop cs; predom - nately benth c and free-l ving. Some are so large and colorfu as to be eas y m staken for sea s ugs; some cases of mimicry are known. Many sw m by graceful undulations of the body margins. A few are pe agic or symbiotic. (e g., *Eurylepta*, *Hoploplana*, *Leptoplana*, *Notoplana*, *Planocera*, *Prostheceraeus*, *Pseudobiceros*, *Pseudoceros*, *Stylochus*, *Thysanozoon*)

ORDER PRORHYNCHIDA Freshwater and ter restrial flatworms, of:en bearing prominent ante- r or auricles and an anter or y s tuated, complex pharynx; ovaries lecithoepitheliate, consist- ing of two kinds of cells, vitellocytes embracing the grow ng ovocytes, both types of cel s produced by a common proximal germ nal tissue. (e.g., *Geocentrophora*, *Prorhynchus*). Some classification schemes place the freshwater Prorhynchida and the marine Gnosonesimida with n the Lecthoepithe ata, a taxon compr sed of about 30 species united on the bass of an intermed ate condit on between endo ec tha and ectolec thal ova, but recent research cons ders Lec thoepithel ata to be nonmonophy et c.

SUPERCLASS GNOSONESIMORA Marine forms with apparent lec thoep thelia deve opment of ova but c oser structura and mo ecular aff nities to Euneoophora; w th ecto ecitha ova (c eavage not yet descr bed).

ORDER GNOSONESIMIDA A s ng e marine genus is known (*Gnosonesima*), bearing a coniform bul- bous pharynx.

SUPERCLASS EUNEOOPHORA Rhabditophorans whose ovary is d v ded into germ na and v telline cell produc ng parts; w th ectolec thal ova.

CLASS RHABDOCOELA Rhabdocoels. Bulbous or sometimes p cate pharynx; simp e sac ke gut without d verticula; ectolecithal ova produced by ovar es that are usually fully separate from the yo k glands; spiral c eavage.

ORDER DALYTYPHLOPLANIDA A d verse group of free-l ving or ecto- or endosymb onts of marine and freshwater invertebrates. Molecu ar data suggests three ma n groups: neoda yelids, w th an anter or mouth (e.g., *Anoplodium*, *Graffilla*, *Pterastericola*); thalassotyphloplanids, mostly marine spec es with the mouth not anterior (e g., *Kytorhynchus*, *Mesostoma*, *Typhlorhynchus*); and limnotyph oplanids, mostly freshwater spe- c es (e.g., *Castrella*, *Dalyellia*, *Microdalyelliathis*). Limnotyphloplanids are small symbionts on freshwater decapod crustaceans, although a few live on other invertebrates or on turt es. (i.e., *Temnocephala*)

ORDER KALYPTORHYNCHIA Kalyptorhynchs (Figures 10.1E and 10.11F). Mouth not term na; w th a comp ex eversible proboscis at anterior end that is separate from the mouth and pharynx; free l v ng marine and freshwater species. (e.g., *Cheliplana*, *Cystiplex*, *Gnathorhynchus*, *Gyratrix*)

CLASS PROSERIATA Freshwater and marine free- living flatworms lacking lamel ate rhabdites· bearing a cyl ndrical p icate pharynx; simp e gut; sp ral cleavage.

ORDER UNGUIPHORA Proseriates with pigment n the mantle cells of rhabdomer c receptors, and usually without a stat•cyst; mo ecu ar stud es sug- gest that th s order is n need of revision, and also that the enigmat c genus *Ciliopharyngiella* may be ong here. (e.g., *Nema-toplana*, *Polystyliphora*)

ORDER LITHOPHORA Proseriates without p gment in the mantle cells and usual y w th a statocyst; recent mo ecu ar stud es ind cate that this order is monophyletic and suggests that families Coelogynopor dae and Ca vir idae as well as Otoplanidae, Archimonocel d dae and Monocelididae may belong in th s group. (e g., *CaMiria*, *Coelogynopora*, *Otoplana*, *Otoplanella*, *Archimonocelis*, *Monocelis*)

CLASS ACENTROSOMATA Rhabditophorans lack ng genes controlling format on of centrosomes, leading to loss of high y regu ated spiral cleavage (and, in some lin- eages, blastomere anarchy) dur ng early deve opment.

SUBCLASS ADIAPHANIDA Although there are no c ear synapomorph es for th s clade, t s strongly supported by molecu ar analyses; the name s from the anc ent Greek word for "opaque' referring to the fact that most species have opaque bodies.

ORDER TRICLADIDA Tr clads. (F gure 10.1C,H) Freshwater marine, terrestria and parasit c forms; cy indrical p icate pharynx; gut three-branched w th numerous diverticu a; two germinaria located at anter or end of germov telloducts. Most are free-l ving, inc uding the famil ar p anarians. (e.g., *Bdelloura*, *Bipalium*, *Crenobia*, *Dugesia* [formerly *Planaria*], *Geoplana*, *Polycelis*, *Procotyla*)

ORDER PROLECITHOPHORA Prolecithopho rans. Pharynx plicate or bulbous; gut s mple; sperm aflagellate, w th extensive membranous folds. Reduction of duo-gland adhes ve system comp ete; genita ia var ab e but male aperture often opens forward, fema e reproductive system often opens to a common pore; smal , free-l ving, mar ne and fresh water. (e.g., *Plagiostomum*, *Urastoma*)

ORDER FECAMPIIDA Fecampiids. Endopara- s tes of various marine invertebrates and ver- tebrates; lacking a pharynx and intestine; w th a c liated epidermis but with vertica ciliary

rootlets reduced. (e.g., *Fecampia*, *Glandulioderma*, *Kronborgia*, *Piscinquilinus*)

SUBCLASS BOTHRIONEODERMATA

INFRACLASS BOTHRIOPLANATA Freshwater flatworms bearing a three branched, diverticulated gut, and medial posteriorly directed pocket pharynx; multiple follicular vitellaria.

ORDER BOTHRIOPLANIDA Monospecific, *Bothrioplana semperi* a freshwater scavenger and predator on small invertebrates.

INFRACLASS NEODERMATA Ciliated larval epidermis shed and replaced by a syncytial neodermis with subepithelial nuclei (the tegument); locomotory epidermal cilia bearing a single rootlet; epithelial sensory receptors with collars.

COHORT TREMATODA Digenean and aspidogastrean flukes (Figures 10.1I and 10.3A,B,E,F). With one or more suckers; lacking prohaptor and opisthaptor; male copulatory organ is a cirrus; 1 to 3 hosts during the life cycle, often including a mollusc; most are endoparasitic.

SUPERORDER ASPIDOGASTREA Aspidogastrean flukes.

ORDER ASPIDOGASTRIDA With a complex ventral sucker formed by lateral growth and subdivision of posterior part of sucker. Most with a single host (a mollusc) in life cycle; second host, when present, a turtle or a teleost fish; oral sucker absent (e.g., *Aspidogaster Cotylaspis*)

ORDER STICHOCOTYLIDA With complex ventral sucker formed by linear growth and subdivision of anterior part of sucker Most with single host (a lobster) in life cycle; second host, when present, is a chondrichthyan fish. (e.g., *Stichocotyle*, *Rugogaster*)

SUPERORDER DIGENEA Digenean flukes.

ORDER DIPLOSTOMIDA Endoparasites of tetrapods; adult genital pore posterior to the ventral sucker; some with blood-dwelling adult stages. Usually with 3-host life cycles but occasionally with 2; first intermediate host is a mollusc. (e.g., *Schistosoma*, *Sanguinicola*)

ORDER PLAGIORCHIIDA An extraordinarily diverse order of vertebrate endoparasites with a wide range of life cycle characteristics and hosts. Usually with at least a 2 host life cycle; first intermediate host is a mollusc. (e.g., *Microphallus*, *Opisthorchis* [= *Clonorchis*], *Fasciola*, *Echinostoma*)

COHORT MONOGENEA Monogenean flukes (Figure 10.3C). Oral sucker (prohaptor) reduced or absent; posterior hook-bearing sucker (opisthaptor) present; ventral sucker (acetabulum) absent; gut bifurcate; 3 rows of cilia on oncomiracidium larva; life cycle involves only one host. Most are ectoparasitic, usually on fishes (some occur on turtles, frogs, hippos, copepods, or squids); a few are endoparasitic in ectothermic vertebrates. Although previously classified according to the relative complexity of the opisthaptor (Figure 10.8; simple, Monopisthocotylea; complex, Polyopisthocotylea), the evolutionary relationships within and among these taxa remain unclear Nine orders are now recognized.

ORDER CAPSALIDEA Capsalids. Gill and skin ectoparasites of elasmobranch and teleost fishes; flattened, leaflike bodies with a simple aseptate or septate opisthaptor; with 3 pairs of median sclerites and 14 small hooklets at the periphery of the opisthaptor. (e.g., *Capsala*, *Benedeniella*, *Trochopus*)

ORDER CHIMAERICOLIDEA Gill parasites of holocephalan fishes. (e.g., *Chimaericola*)

ORDER DICLYBOTHRIIDEA Gill parasites of acipenseriform fishes. Oral sucker absent; mouth ventral; lateral sclerites on opisthaptor absent. (e.g., *Diclybothrium*, *Paradiclybothrium*)

ORDER DACTLOGYRIDEA Gill parasites of freshwater teleost fish; body with opisthaptor bearing 2-4 anchors with 14-16 marginal hooks, and 4 eyespots. (e.g., *Dactylogyrus*, *Ancyrocephalus*)

ORDER GYRODACTYLIDEA Skin and gill parasites of freshwater fish; body fusiform with terminal cephalic lobes; opisthaptor forms a half oval and is armed with 16 marginal hooks and a pair of medial anchors (hamuli) stabilized with median bars. (e.g., *Gyrodactylus*, *Paragyrodactyloides*, *Acanthoplacatus*)

ORDER MAZOCRAEIDEA Gill parasites of clupeid and scombrid fishes; oncomiracidium with one pair of fused eyes; opisthaptor with two pairs of lateral sclerites. (e.g., *Clupeocotyle*, *Mazocraes*, *Gnuboa*)

ORDER MONOCOTYLIDEA Gill and ectodermal tissue parasites of mostly tropical elasmobranchs; opisthaptor with a single central and multiple peripheral suckers (oculi), often armed with hamuli and marginal hooks. (e.g., *Monocotyle*, *Potamotrygonocotyle*)

ORDER MONTCHADSKYELLIDEA Gill parasites of tropical reef fishes. (e.g., *Montchadskyella*)

ORDER POLYSTOMATIDEA Skin, gill, and urogenital parasites of aquatic and semiaquatic tetrapods; opisthaptor well developed with 3 pairs of suckers or one sucker pair (e.g., *Polystoma*, *Oculotrema*, *Metapolystoma*)

COHORT CESTODA Tapeworms and their relatives (Figures 10.1M and 10.4). Exclusively endoparasitic; in most, the body consists of an anterior scolex, followed by a short neck, and then a strobila composed of a series of "segments" or proglottids, although basal taxa are monozoic (not strobilated); digestive tract absent. Previous classifications recognized

several subclasses; unt l taxonomic uncerta nty is reso ved, we recegn ze 16 orders.

ORDER AMPHILINIDEA Endoparasites in the guts or coe omic cav t es of cartl ag nous and c e r tain prim tive bony fishes, less common y in tur-tles; eaf ke bodies, lack ng sco ex and monozoic (not strobi ated); 10 m nute hooks may be present at poster or of body f reta ned from decacanth larvae that may deve op in crustaceans. (e.g., *Amphilina*; *Austramphilina, Gyrometra*)

ORDER BOTHRIOCEPHALIDEA Gut parasites of teleost fishes and occasionally n ac penseriforms and amph b ans; body strobilated w th proglot-tids wider than long; scolex with a par of bothr a; occasionally w th hooks; life cyc e w th 2 3 hosts, usua ly a crustacean first host and a te eost s ec ond host. (e.g., *Bothriocephalus*, *Triaenophorus*, *Polyonchobothrium*)

ORDER CARYOPHYLLIDEA Intestina parasites of cypr niform and siluriform fishes; body mono-zoic (not strob lated); sco ex often s mple; with 2 host life cyc es; o igochaetes as intermed ate hosts (e.g., *Archigetes*, *Paraglaridacris*)

ORDER CYCLOPHYLLIDEA Intest nal paras tes of b rds and mammals; body variab e in size, sco ex with 4 suckers, roste lum is present may be armed or not; most species are hermaphrod tes although the fami y Dioecocest dae is gonochoristic); highly diverse and possibly the most der ved order of cestodes; life cyc es w th 2–3 hosts w th diverse invertebrate and vertebrate species as inter mediate and paraten c hosts. (e.g., *Dipylidium*, *Hymenolepis*, *Moniezia*, *Taenia*)

ORDER DIPHYLLIDEA Intestina paras tes of elas mobranch fishes; body strobi ated w th midventra genita pores; scolex w th 2 bothr a and a cepha c pedunc e; l fe cycles are poor y known but larva stages occur in marine crustaceans and mol-luscs. (e g., *Echinobothrium*, *Ditrachybothridium*)

ORDER DIPHYLLOBOTHRIIDEA Intest na para sites of piscivorous vertebrates, usual y mam-mals; body strob ated but w th variab e externa differentiation; scolex always unarmed, usually with pa red attachment grooves (bothria); w th 2–3 host l fe cyc es; copepod crustaceans as first intermed ate hosts, second intermed ate hosts within vertebrates. (e.g., *Diphyllobothrium*, *Ligula*, *Spirometra*)

ORDER GYROCOTYLIDEA Intestinal paras tes of ho ocephalan f shes a though a so repo ted in sharks; body stout, monozo c with a muscu ar anterior at achment organ; poster or body termi-nates in a rosette- ke adhesive organ; latera ma r gins of en ruffled; l fe cyc es are unknown. (e.g., *Gyrocotyle*, *Gyrocotyloides*)

ORDER LECANICEPHALIDEA Smal intestinal paras tes of rays and occas ona y sharks; although probably paraphyletic, spec es are character zed by a scolex w th 4 suckers or bothria and an ap-ca structure that may have tentac es, cones, or add t ona suckers; l fe cyc es are poor y known by may nclude mol uscs, crustaceans and tele-osts as intermediate hosts (e g., *Polypocephalus*, *Quadcuspibothrium*, *Corrugatocephalum*)

ORDER LITOBOTHRIDEA Intestinal parasites of amn form sharks; sco ex with ap cal sucker and severa muscular, cruc form pseudosegments; l fe cycles are unknown. (e.g., *Lithobothrium*)

ORDER ONCHOPROTEOCEPHALIDEA Small to med um sized intestinal paras tes of e asmo-branchs, as wel as of freshwater fish, amph b-ans, rept es, and occas onally mammas; strob la po yzoic, with prog ott ds, or w th few anapo y tic (non detaching) proglottids; w th latera , irregu-a ly alternating gen ta pores; sco ex often with 4 muscular bothr d a, unarmed or with one par of hooks; occas onally with a rostellumlike ap ca structure; life cyc es nclude 1 or 2 ntermed ate hosts (crustaceans or fish); th s order has sub-sumed the former order Proteocepha dea and part of the Tetraphyllidea. (e.g., *Proteocephalus*, *Chambriella*, *Brachyplatysoma*, *Acanthobothrium*, *Platybothrium*)

ORDER PHYLLOBOTHRIIDEA Smal to medium s zed ntest nal paras tes of sharks, batoids and ratf sh; strobili polyzoic and with proglottids, scolex often with 4 muscu ar bothr dia. (e.g., *Calyptrobothrium*, *Chimaerocestos*, *Marsupio-bothrium*)

ORDER RHINEBOTHRIIDEA ntestinal paras tes of freshwater st ngrays; scolex of en with both-r d al stalks. (e.g., *Spongiobothrium*)

ORDER SPATHEBOTHRIIDEA ntest nal paras tes of Chondr chthyes and teleost fishes; body stro-bi ated without extema d f erentiation of proglot-t ds; ma e and fema e genital pores c ose together and a ternating dorsally and ventra y the ength of the body; with 2 host life cyc es; crustaceans as intermed ate hosts; progenes s (ear y maturation) of larvae is widespread. (e g., *Spathobothrium*, *Bothrimonus*)

ORDER TETRABOTHRIIDEA Intestinal para-s tes of marine homeotherms inhabit ng pe agic ecosystems; body with wel defined strobi ation; sco ex w th 4 muscu ar bothr d a of variab e form; rostellum lacking; eggs w th 3 membranes; life cycles are unknown but are like y to involve crus-taceans, cepha opods and teleosts as ntermedi-ate hosts. (e g., *Priapocephalus Tetrabothrius*, *Trigonocotyle*)

ORDER TETRAPHYLLIDEA Intestinal paras tes of e asmobranch fishes, rare y in holocepha an fishes; body strobilated w th var able apolys s of proglott ds; scolex often with 4 muscu ar bothridia that vary w de y in form, often e ongate, stalked and with hooks; l fe cyc es are poor y known; but 3–5 hosts are like y and include mol uscs,

crustaceans, teleosts and marine mammals; a recent molecular analysis has shown this order to be nonmonophyletic, and genera are being redistributed to other orders (Onchoproteocephalidea, Phyllobothriidea). (e.g., *Rhoptrobothrium*, *Dinobothrium*)

ORDER TRYPANORHYCHA Intestinal and stomach parasites of elasmobranch fishes; body strobilated with lateral genital pores; scolex with 4 eversible tentacles each bearing a complex array of hooks; 2–3 host life cycles with crustaceans and teleosts and intermediate hosts. (e.g., *Dasyrhynchus*, *Halsiorhynchus*, *Otobothrium*)

The Platyhelminth Body Plan

Compared with phyla discussed in preceding chapters, flatworms display some of the most important advances found in the animal kingdom. In many ways, they are the prototypical acoelomate bilateria and, according to some hypotheses, they represent the basic body plan from which the protostomes were ultimately derived.

The evolution of the triploblastic condition and bilateral symmetry almost certainly occurred in concert with the evolution of sophisticated internal "plumbing" (organs and organ systems) and the tendency to centralize and cephalize the nervous system and to develop specialized units within the nervous system for sensory, integrative, and motor activities. It is likely that this first step toward bilaterality took place with the Xenacoelomorpha (Chapter 9), and progressed with the Platyhelminthes. With these features came unidirectional movement and a more active lifestyle than that of radially symmetrical animals. The primary evolutionary advantages of these coinciding changes derived chiefly from the ability of these "new" creatures to move around more or less freely and thus exploit previously unavailable survival strategies.

These strategies can be appreciated by examining the rather complex structural features displayed by the free-living flatworms (Figure 10.2). The presence of mesoderm allows the formation of a fibrous and muscular mesenchyme that provides structural support and allows patterns of locomotion not possible in diploblastic radiates. Elaborate reproductive systems evolved in the platyhelminths, providing for internal fertilization and enhancing the production of yolky and encapsulated eggs. Most flatworms have abandoned free-swimming larval stages for mixed and direct life histories. Osmoregulatory structures in the form of protonephridia were most likely instrumental in the invasion of fresh water.

This body plan is not without constraints, however. Higher energy demands accompany an active lifestyle. A major limiting factor for flatworms, functionally, is the absence of an efficient circulatory mechanism to move materials throughout the body. This problem is

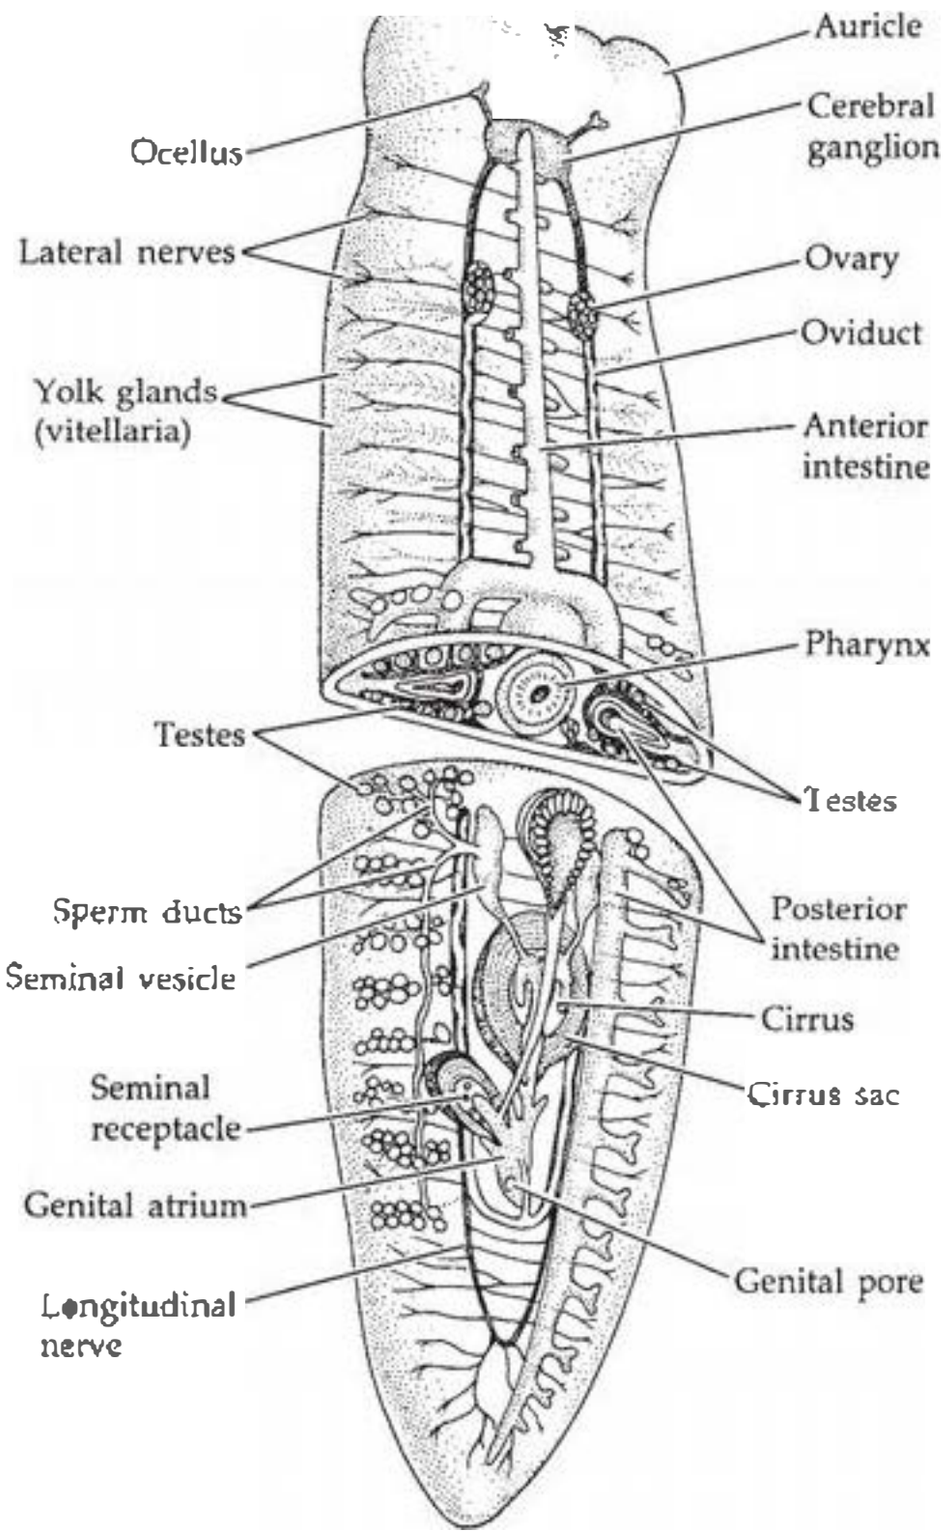

Figure 10.2 A generalized freshwater flatworm (order Tricladida).

compounded by the lack of any special structures for gas exchange. These problems relate, of course, to the surface-to volume dilemma discussed in Chapter 4. In the absence of circulatory and gas exchange structures, flatworms (particularly free-living ones) are constrained in terms of size and shape. They have remained relatively small and flat, with shapes that maintain short diffusion distances. The largest free living flatworms have highly branched guts that assume much of the responsibility of internal transport.

Having a high surface-to-volume ratio and using the entire body surface for gas exchange create potential problems of ionic balance and osmoregulation in freshwater and terrestrial species, and of desiccation in intertidal and terrestrial habitats. The permeable body surface must be kept moist; thus, flatworms have invaded land rarely and mostly in very damp areas, although a few rhabdocoels, prorhynchids, and several parasitic species have developed desiccation resistant life stages. Flatworms have, however, exploited a variety of marine and freshwater habitats, and are particularly successful as parasites and commensals, enjoying the benefits of living on or in their hosts.

Figure 10.3 Representative flukes. (A,B) *Opisthorchis* (= *Clonorchis*) *sinensis*, a plagiorchiid trematode that inhabits human livers. (C,D) *Gyrodactylus* (Monogenea), an ectoparasite on fishes. (E) *Cotylaspis* (an aspidogastrid trematode). (F) The human blood fluke, *Schistosoma mansoni* (a copulating male and female), a diplostomid fluke and one of the few gonochoristic flatworms.

The ancestral flatworm is thought to have been a free-living form, from which the present-day catenulids and rhabditophorans evolved and diversified. The flukes and tapeworms evolved from within the rhabditophoran assemblage (discussed in more detail later in this chapter). Thus, in each of the following sections we first examine the basic features of the free-living flatworms and set the stage for understanding not only the diversity within that class but the derivation of the specialized parasitic taxa as well.

The anatomy of free-living flatworms, flukes, and tapeworms is shown in Figures 10.2 through 10.6. Free-living flatworm species vary in shape from broadly oval to ribbon-like, and are typically flattened dorsoventrally, although very small ones may be nearly cylindrical. The head is usually ill defined, except for the presence of sense organs. The mouth is often located ventrally, either near the middle of the body or more anteriorly, though again, there are exceptions (e.g., prorhynchids whose raptorial mouth is fully anterior; cestodes who have no mouth at all). Most flukes (Figure 10.3) are oval or leaf shaped and bear external attachment organs such as hooks and suckers. As their common name

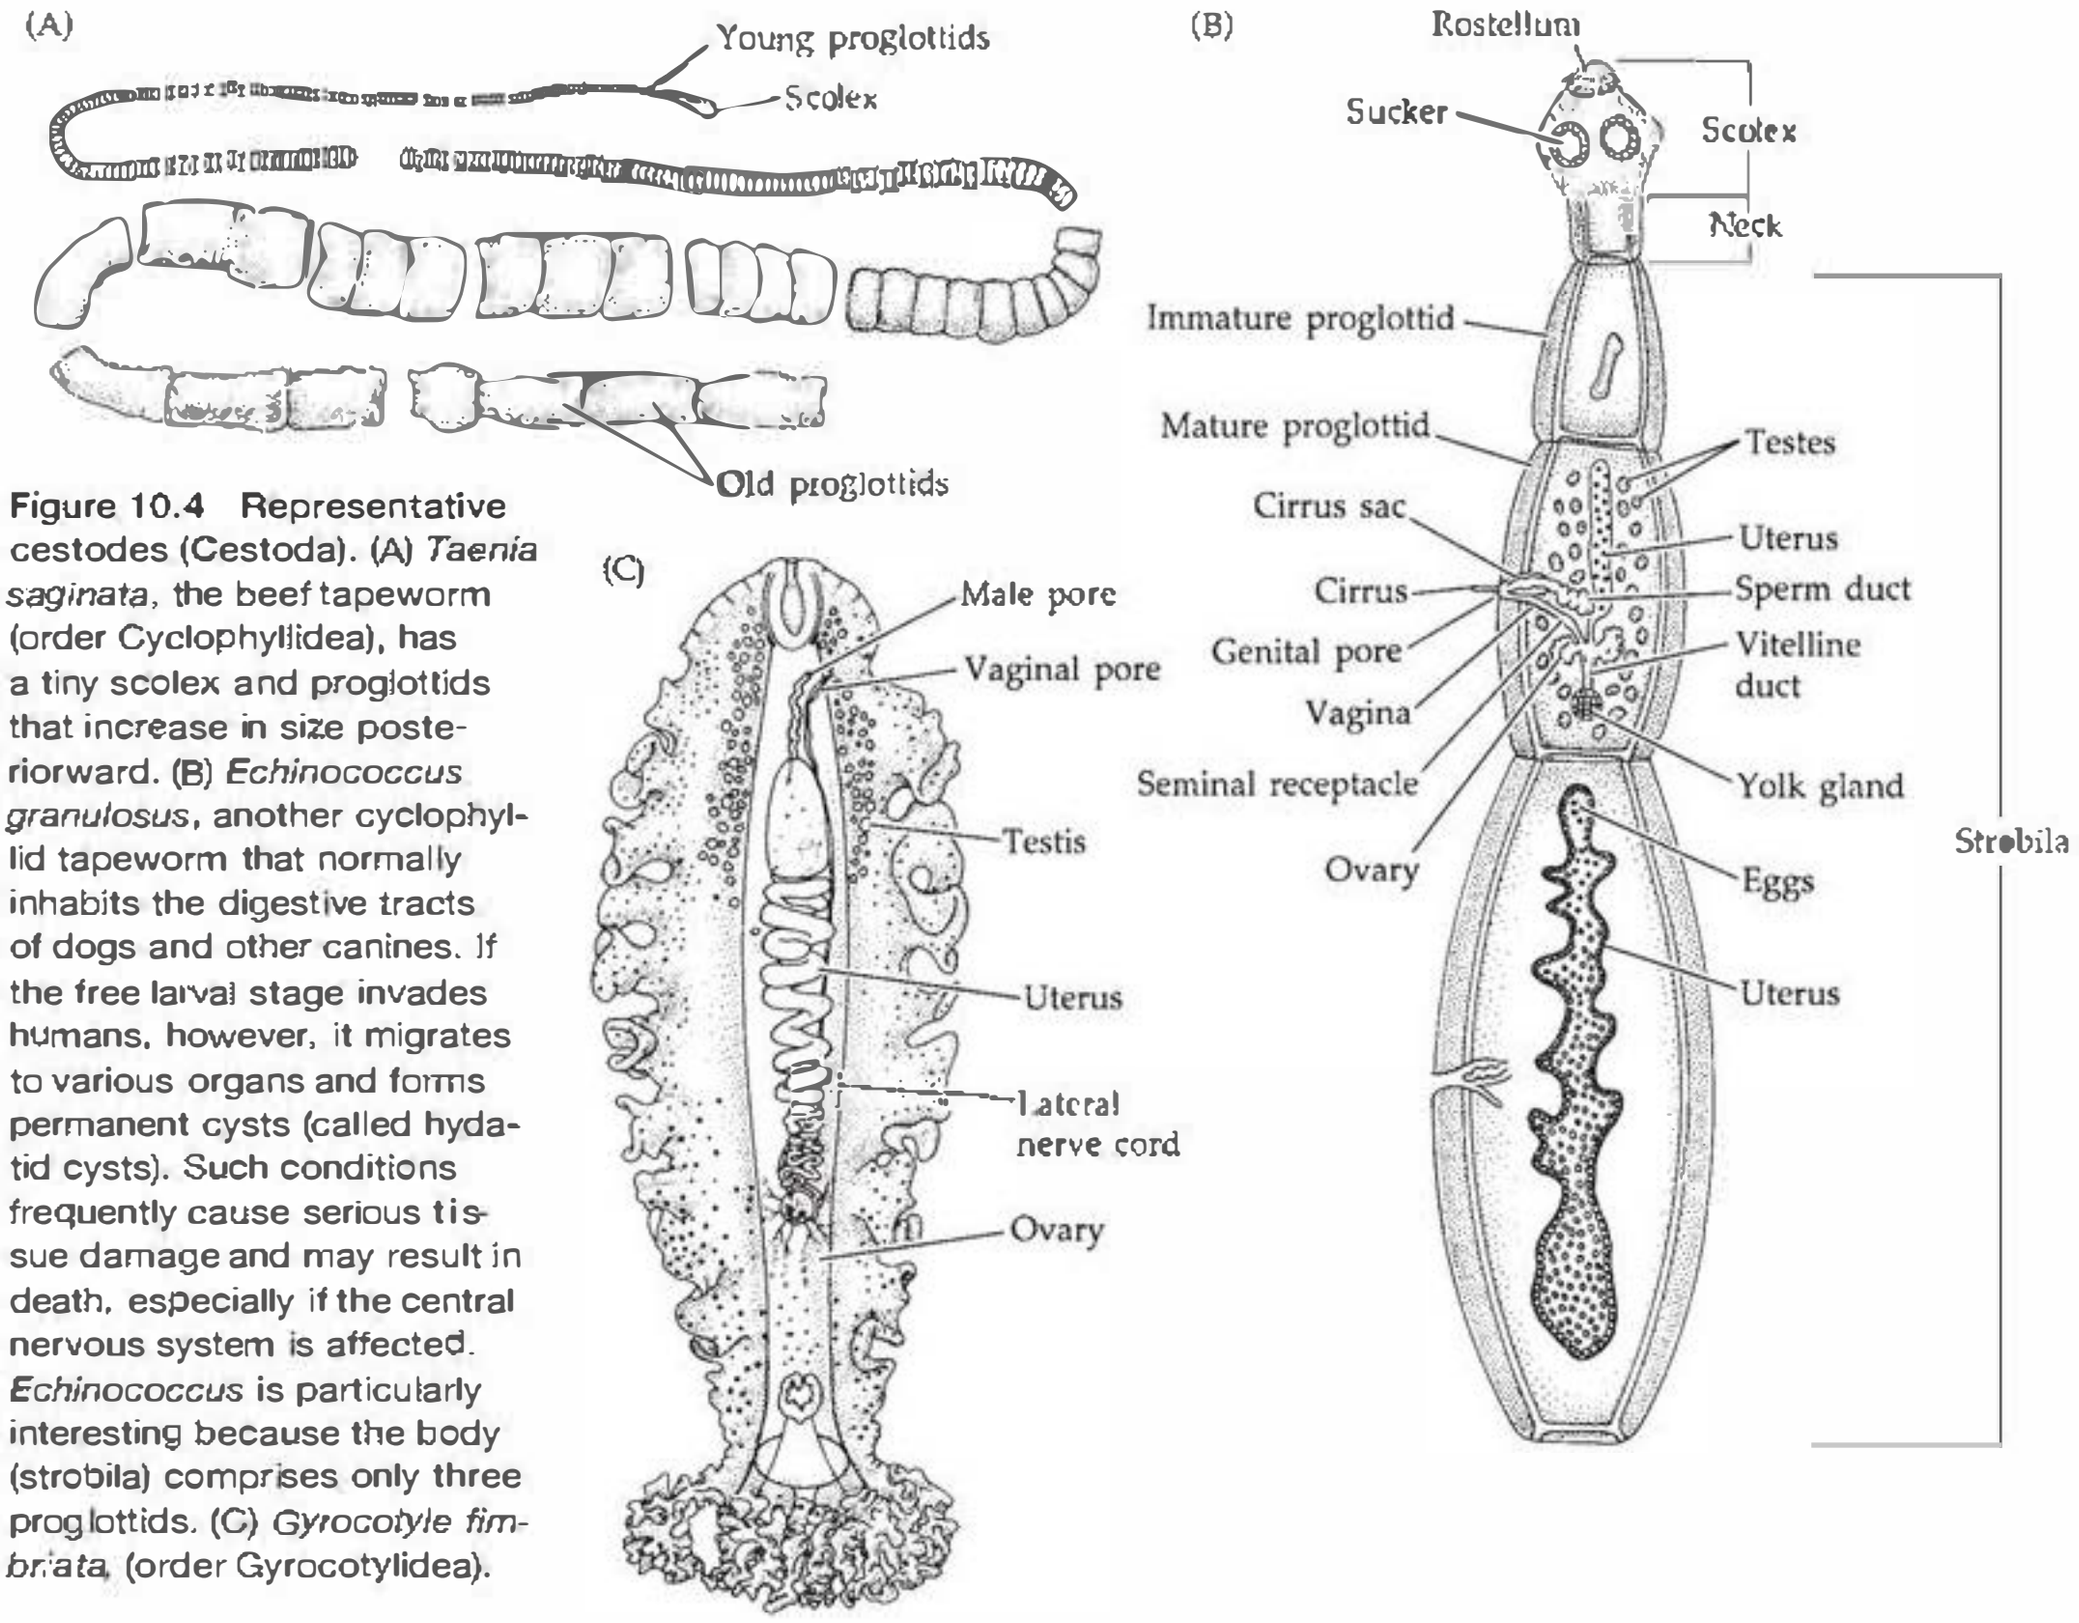

Figure 10.4 Representative cestodes (Cestoda). (A) *Taenia saginata*, the beef tapeworm (order Cyclophyllidea), has a tiny scolex and proglottids that increase in size posteriorward. (B) *Echinococcus granulosus*, another cyclophyllid tapeworm that normally inhabits the digestive tracts of dogs and other canines. If the free larval stage invades humans, however, it migrates to various organs and forms permanent cysts (called hydatid cysts). Such conditions frequently cause serious tissue damage and may result in death, especially if the central nervous system is affected. *Echinococcus* is particularly interesting because the body (strobila) comprises only three proglottids. (C) *Gyrocotyle fimbriata* (order Gyrocotylidea).

suggests, the tapeworms are typically elongate and ribbon-like (Figure 10.4). Their anterior end forms a tiny **scolex**, modified for attachment within the host; the rest of the body is essentially a reproductive machine.

Tapeworms live in the guts of vertebrates. Most species belong to the Cestoda and possess three distinguishable regions of the body. The scolex serves for attachment and is usually armed with hooks and suckers. Immediately behind the scolex is a short region called the **neck**, followed by an elongated, segmented trunk, or **strobila**, consisting of individual **proglottids**. The proglottids bud (strobilate) from a germinal zone in the neck (or at the base of the scolex when a neck is absent). As new proglottids arise, older ones move posteriorly and mature, become inseminated, and fill with embryos. Strobilation in tapeworms is thus not by way of teloblastic growth (discussed in Chapters 14 and 20), and it is clearly not homologous to the true segmentation seen in annelids and arthropods.

Tapeworms in the orders Amphilinidea and Gyrocotylidea are somewhat flukelike in appearance. They lack a scolex, and the body is not divided into proglottids. They are placed within the Cestoda because of the absence of a digestive tract and because of certain features of the life cycle. They may represent the primitive, prestrobilation body plan of the Cestoda.

Body Wall

Free-living flatworms The body wall of these species is multilayered and complex (Figure 10.5). The epidermis is composed of a wholly or partially ciliated, syncytial or cellular epithelium, with gland cells and sensory nerve endings distributed in various patterns. Beneath the epidermis is a basement membrane, which is often thick enough to lend some structural support to the body. In Catenulida and Macrostomida, the basement membrane is apparently absent, but this condition is viewed as secondarily derived. Internal to the basement membrane are smooth muscle cells, frequently arranged in rather loosely organized outer circular, middle diagonal, and inner longitudinal layers. The area between the body wall and the internal organs is usually filled with a mesenchyme (often called a parenchyme) that includes a variety of loose and fixed cells, muscle fibers, and connective tissue. Many macrostomorphans appear to lack a cellular mesenchyme.

The gland cells of the body wall are generally derived from ectoderm. When mature, many of these

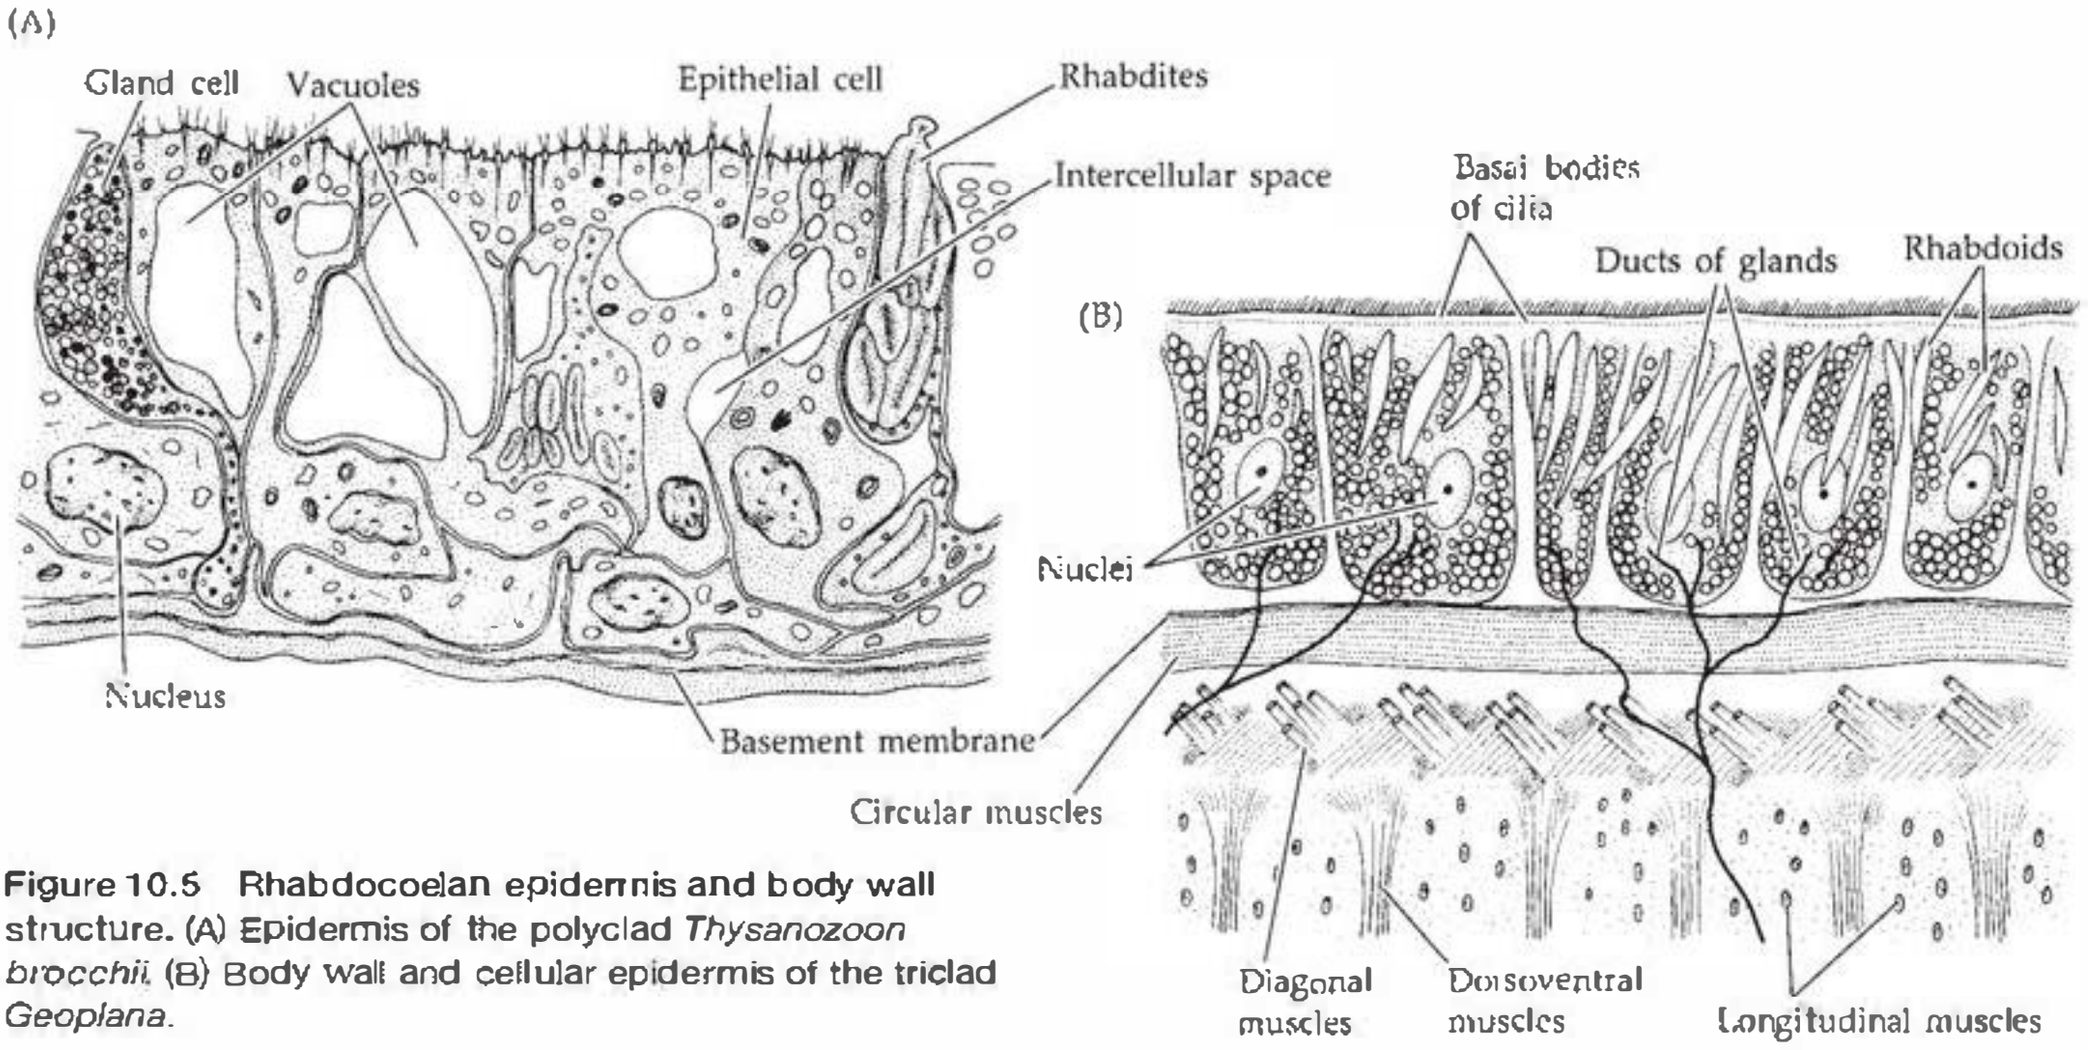

Figure 10.5 Rhabdocoelan epidermis and body wall structure. (A) Epidermis of the polyclad *Thysanozoon brocchii*. (B) Body wall and cellular epidermis of the triclad *Geoplana*.

cells lie in the mesenchyme with a "neck" extending between epidermal cells to the body surface. These cells produce mucous secretions that serve a number of functions. In semiterrestrial and intertidal flatworms, the mucus forms a moist covering that provides protection from desiccation and aids in gas exchange. Most benthic flatworms possess a ventral concentration of mucous gland cells that secrete a slime that aids in locomotion. Mucous secretion around the mouth aids in prey capture and swallowing. Other gland cells or complexes of cells provide granules containing adhesives for temporary attachment, as well as granules that break the attachment, occurring several times per second. Such duo-gland adhesion systems (often involving a third cell type that provides structural support) are widespread in free-living flatworms and other phyla with similar lifestyles. In some ectocommensal forms (e.g., *Bdelloura* triclads and various temnocephalid dalytyphloplanids; Figure 10.6) these adhesive glands are associated with special plates or suckers for attachment to the host.

In most freeliving flatworms epidermal and subepidermal cells produce structures called **rhabdoids**

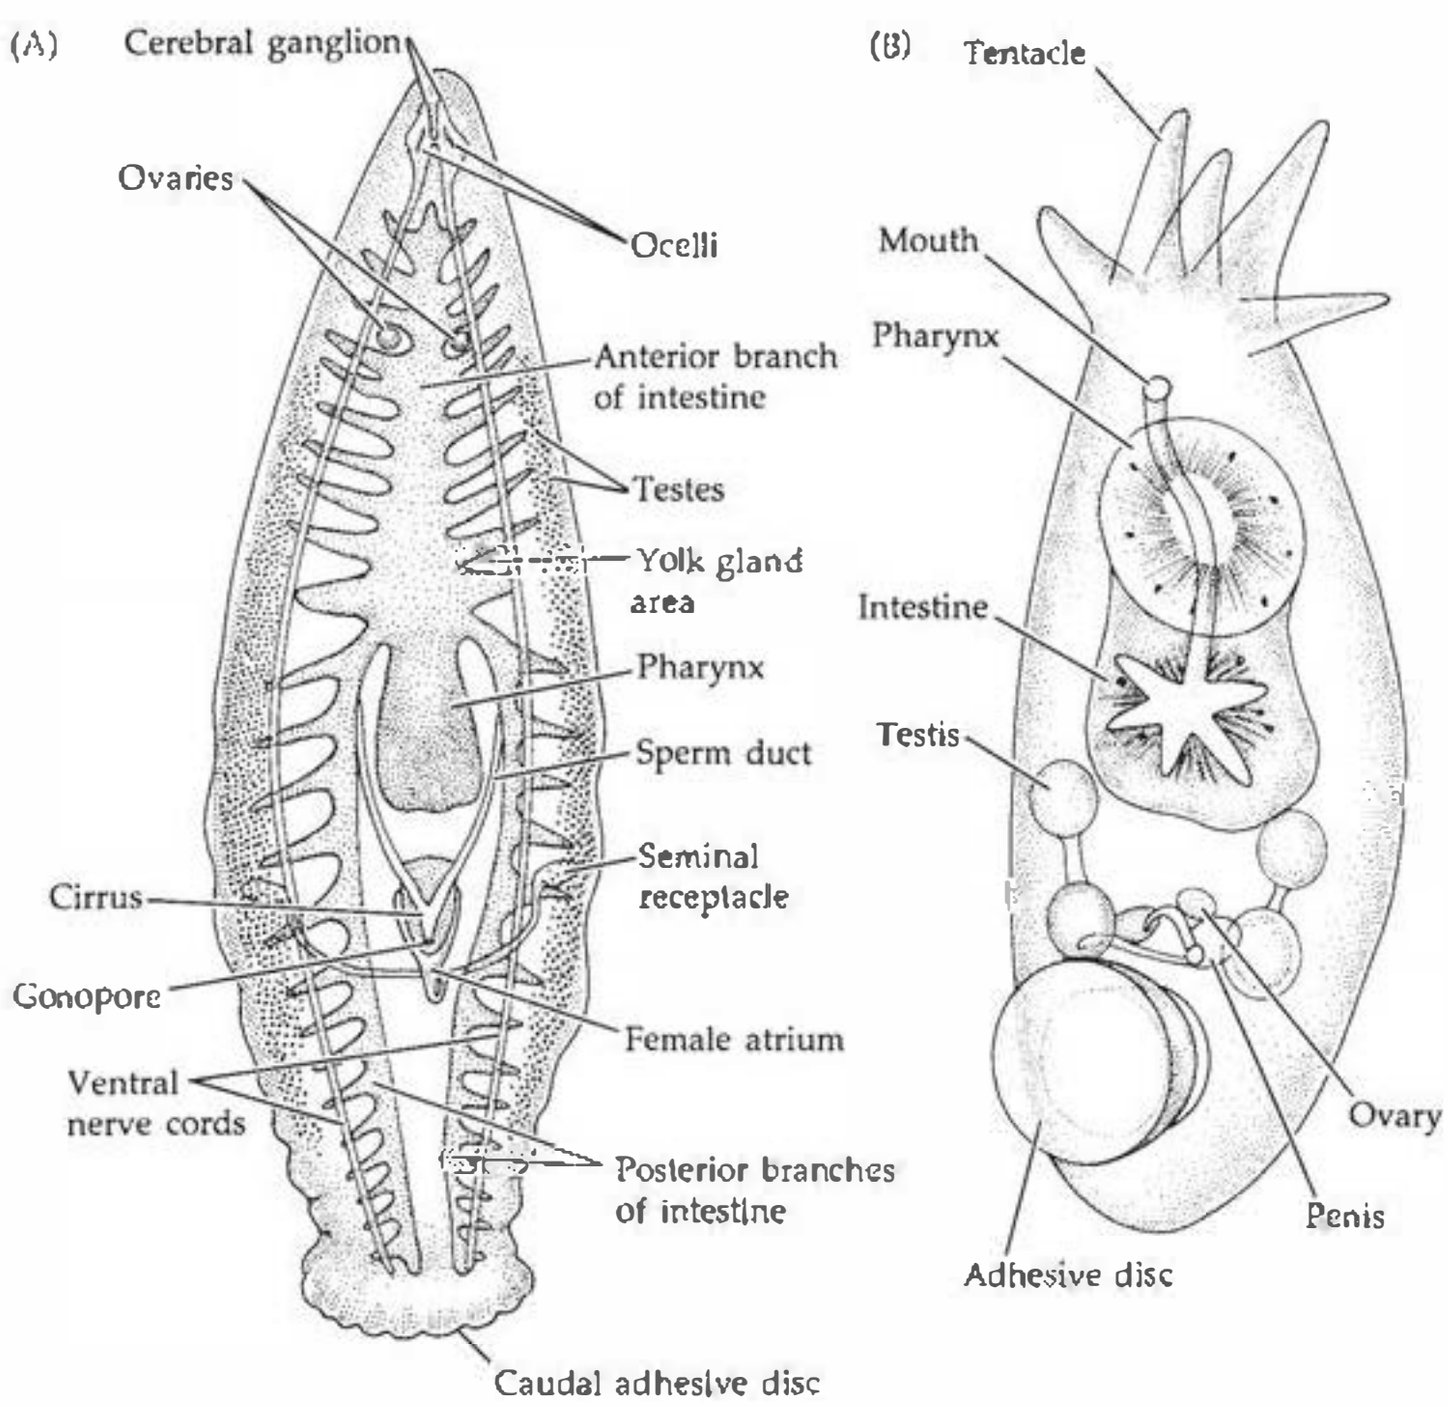

Figure 10.6 Two symbiotic euneoophoran flatworms with adhesive attachment organs. (A) *Bdelloura candida*, a triclad ectocommensal on horseshoe crabs (*Limulus*). (B) *Temnocephala caeca*, a rhabdocoel ectocommensal on *Phreatoicopis terricola* (a freshwater isopod).

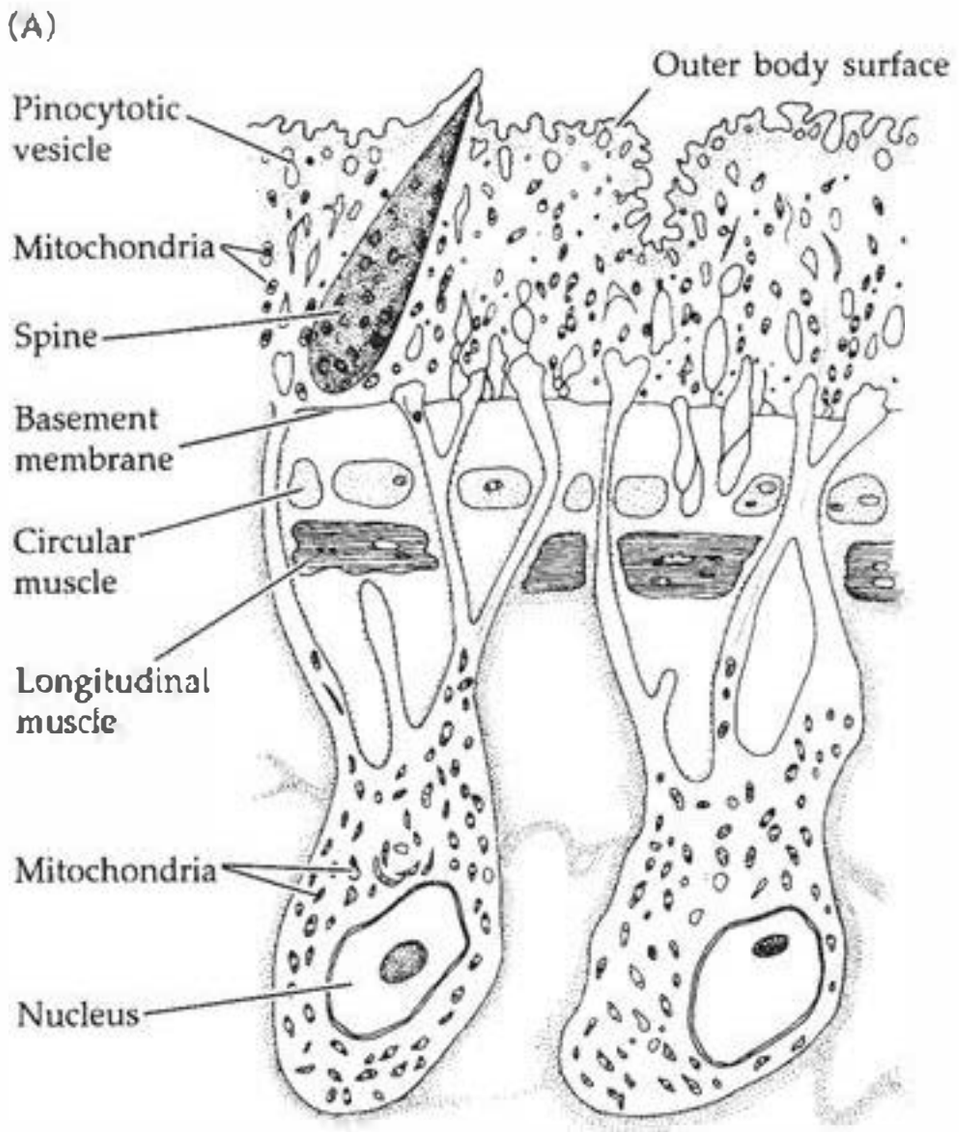

Figure 10.7 (A) The tegument and underlying body wall of a plagiorchiid fluke (*Fasciola hepatica*; longitudinal section). (B) The tegument and body wall of a cestode (cross section).

(Figure 10.5B). These rod-shaped cellular inclusions produce mucus when moved to the surface of the epithelium. Some other phyla (e.g., Xenacoelomorpha, Gastrotricha, Nemertea, Annelida) have similar, but probably convergently-evolved secretory cellular bodies. The mucus aids in ciliary gliding and also may help protect animals from desiccation and from predators. Rhabdoids that are produced by gland cells in the epidermis or mesenchyme are called **rhabdites**. These structures can reach the body surface through intercellular spaces in the epidermis (Figure 10.5A). They also contribute to mucus production and, in some species, release noxious chemicals for defense. Rhabdites are diagnostic of the huge flatworm clade (subphylum) Rhabditophora. Somewhat similar structures, called "false rhabdites," have been described from the other main flatworm clade (subphylum) Catenulidea, but they may not be homologous to those of Rhabditophora.

Some species of freeliving flatworms (e.g., macrostomids, proseriates, polyclads) have prominent tubercles covering the dorsal surface and these probably also have a defensive role. In some species, unfired nematocysts from hydroid prey are transported to the tubercles. In others, such as species of *Thysanozoon*, the tubercles appear to release a powerful acid that may deter would-be predators.

Flukes and tapeworms Modifications of the outer body covering are common among parasites, and platyhelminths are no exception. Unlike the free-living flatworms, flukes and tapeworms possess an external covering called a **tegument**, formed of nonciliated cytoplasmic extensions of large cells whose cell bodies actually lie in the mesenchyme (Figure 10.7). The extensions fuse their margins such that the outer surface of the worm forms a functional syncytium. The tegument not only provides some protection but also is an important site of exchange between the body and the environment. Gases and nitrogenous wastes move across this surface by diffusion, and some nutrients, especially amino acids, are taken in by pinocytosis. In tapeworms, the uptake of nutrients occurs solely across the body wall, and the surface area of the tegument is greatly increased by many tiny folds called microtriches (Figure 10.7B). As one of nature's more remarkable adaptations, these folds may interdigitate with the intestinal microvilli of the host organism and aid in the absorption of nutrients.

The nature of the tegument in flukes and tapeworms is viewed by some zoologists as unique and of major phylogenetic importance. The larvae of these parasitic worms have a "normal" ciliated epidermis over at least part of their bodies. However, this epidermis is shed, and postlarval stages develop a new, syncytial body covering—the **neodermis**. This phenomenon appears to be a unique synapomorphy uniting the Monogenea, Trematoda, and Cestoda as a monophyletic taxon that Ehlers named Neodermata (in reference to the "new skin" of these animals), an hypothesis that is now substantiated by several molecular phylogenetic analyses.

The tegument/neodermis is underlain by a basement membrane, beneath which is the mesenchyme. Most flukes and tapeworms have circular and longitudinal muscles within the mesenchyme, and sometimes diagonal, transverse, and dorsoventral muscles as well. The mesenchyme varies from masses of densely packed cells to syncytial and fibrous networks with fluid-filled spaces. In some digenean flukes (Trematoda: orders Diplostomida and Plagiorchiida), spaces form vessels through the mesenchyme called lymphatic channels, which contain free cells that have been likened to lymphocytes. The mesenchyme also contains gland cells with connections to the surface of the body through the tegument. These gland cells are few in number compared with those of free-living flatworms, and they are primarily adhesive in nature and associated with certain organs of attachment.

One of the least explored yet most interesting attributes of tapeworms, and indeed of all intestinal parasites, is their ability to thrive in an environment of hydrolytic enzymes without being digested. In addition to constant replacement of the outer tegument by underlying cells, one popular hypothesis is that gut parasites produce enzyme inhibitors (sometimes called "antienzymes"). One study showed that *Hymenolepis diminuta* (a common tapeworm in rats and mice) releases proteins that appear to inhibit trypsin activity. This tapeworm can also regulate the pH of its immediate environment to about 5.0 by excreting organic acids; this acidic output may also inhibit the activity of trypsin.

Support, Locomotion, and Attachment

Only a very few flatworms possess any sort of special skeletal elements. In a few free-living species, tiny calcareous plates or spicules are embedded in the body wall (Figure 10.1L). Body support in all other flatworms is provided by the hydrostatic qualities of the mesenchyme, the elasticity of the body wall, and the general body musculature.

Most free-living, benthic species move on their ventral surface by cilia-powered gliding. Mucus provides lubrication as the animal moves and serves as a viscous medium against which the cilia act. Some of the larger or more elongate forms also use muscular contractions. The ventral surface of the body is thrown into a series of alternating transverse furrows and ridges that move as waves along the animal, propelling it forward. Muscular undulations of the lateral body margins allow some large polyclads to swim for brief periods of time. Muscular action allows the body to twist and turn, providing steerage. Some interstitial forms are highly elongate and use the body wall muscles to slither between sand grains. Many of these types of flatworms possess adhesive glands, the secretions of which provide temporary stickiness and enable the animals to gain purchase and leverage as they move.

Adult flukes lack external cilia, and their movement depends on their body wall muscles or on the body fluids of their host. Some move about slowly on or within their host by muscle action, and a few (e.g., blood flukes) are carried in the host's circulatory system. However, certain larval stages are highly motile and do swim using ciliary action. Once established within or on a host, it is usually advantageous for a fluke to stay more or less in one place. In that regard, nearly all of them are equipped with external organs for temporary or permanent attachment (Figures 10.3C and 10.8). Monogenean flukes typically have an anterior and a posterior adhesive organ called the prohaptor and the opisthaptor, respectively. The prohaptor consists of a pair of adhesive structures, one on each side of the mouth, bearing suckers or simple adhesive pads. The opisthaptor is usually the major organ of attachment, and includes one or more well developed suckers with hooks or claws.

The digenean flukes possess two hookless suckers. One, the oral sucker, surroumds the mouth, and the

other, the **acetabulum**, is located elsewhere on the ventral surface (Figure 10.3B). These suckers are usually supplied with adhesive gland cells, although the well-developed ones operate mainly on suction produced by muscle action. The aspidogastrean flukes lack an oral sucker but have a large, subdivided ventral sucker (Figure 10.3E).

Adult tapeworms (Cestoda) do not move around much, but they are capable of muscular undulations of the body. They remain fixed to the host's intestinal wall by the **scolex** (or, in the case of members of the cestode order Amphilinidea, by an anterior adhesive organ) and by the microtriches. The details of scolex anatomy (Figure 10.9) are extremely variable and have great importance in the taxonomy of tapeworms. The tip of the scolex in many cestodes (e.g., *Taenia*) is equipped with a movable hook-bearing **rostellum**, which is sometimes retractable into the scolex. In others (e.g., *Cephalobothrium*) the anterior end bears a protrusible sucker, or adhesive pad, called a **myzorhynchus**. The rest of the scolex bears various suckers or sucker-like structures and sometimes hooks or spines. There are three categories of adhesive suckers upon which ordinal and subordinal classification of cestodes is partially based. **Bothria** are elongate, longitudinal grooves on the scolex. They possess weak muscles but are capable of some sucking action. Bothria occur as a single pair and are typical of the orders Diphyllobothriidea (e.g., *Diphyllobothrium*) and Bothriocephalidea. Members of the nonmonophyletic order Tetraphyllidea (e.g., *Acanthobothrium, Phyllobothrium*) bear four symmetrically placed bothridia around the scolex. These foliose structures are often equipped with suckers at their anterior ends. The third and most familiar type of attachment structures on the scolex are true suckers, or acetabula. They are identical in structure and are probably homologous to the acetabula of digenean trematodes. There are usually four acetabula, placed symmetrically around the circumference of the scolex. They are characteristic of many members of the order Cyclophyllidea (e.g., *Dipylidium, Taenia*).

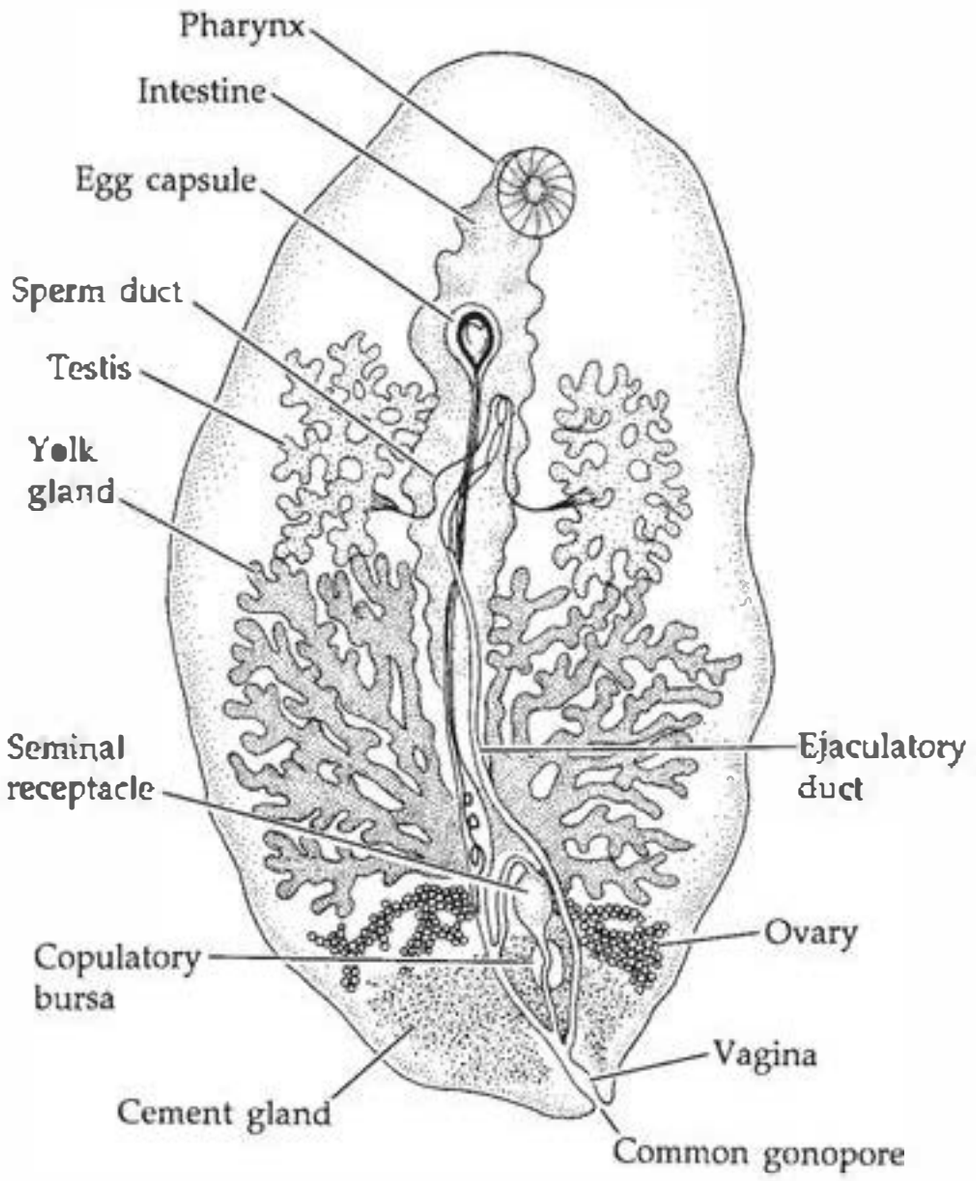
Feeding and Digestion

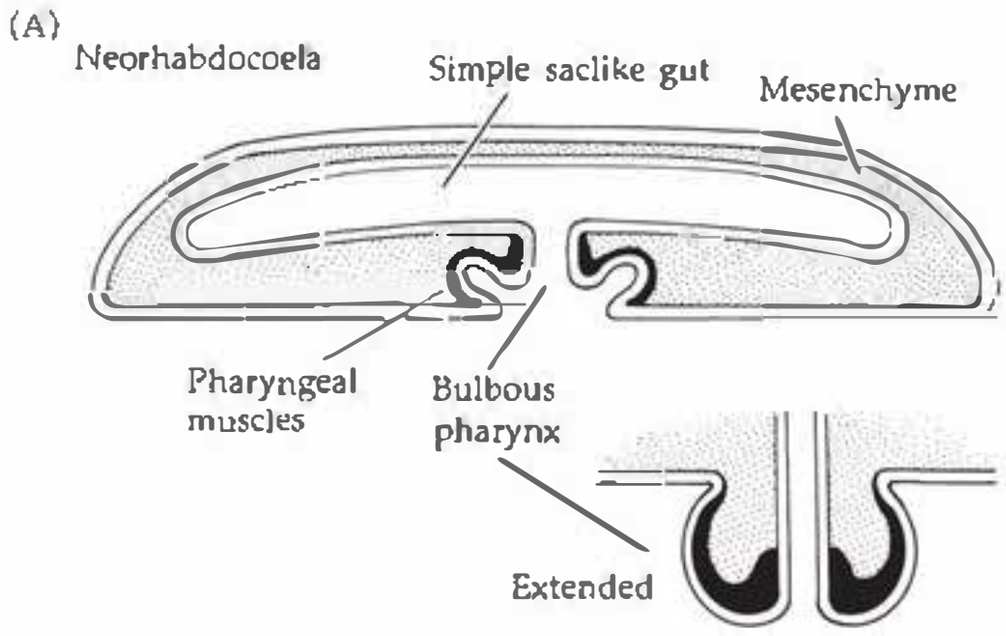
Free-living flatworms Most species are carnivorous predators or scavengers, feeding on nearly any available animal matter, or in the case of very small species, on bacteria or fungi in biofilms. A few are herbivorous

on microalgae, and some species switch from herbivory to carnivory as they mature. Their prey includes almost any invertebrate small enough to be captured and ingested (e.g., protists, small crustaceans, worms, tiny gastropods). Some species graze on sponges, ectoprocts, and tunicates, and some consume the flesh of barnacles, leaving behind the empty shell. Most free-living flatworms locate food by chemoreception. Land planarians capture and consume earthworms (e.g., *Bipalium*), land snails (e.g., *Platydesmus, Endeavouria*), and insects (e.g., *Rhynchodemus, Microplana*). *Platydesmus maniokwari*, the 6.5 cm long "New Guinea flatworm," is a highly invasive species that is a threat for endemic terrestrial molluscs; it has invaded throughout the Pacific, as well as in Europe, the Caribbean, and most recently Florida (USA).

More than 100 species of free-living flatworms are known to be symbiotic with other invertebrates. Some of these are simply commensals that derive some protection from their associations, showing only physical modifications for temporary attachment. Others, however, feed upon their hosts, causing various degrees of damage and displaying true physiological dependency in the relationship. While we can devote space to mentioning only a few examples of symbiotic free-living flatworms, recognition of these situations is of considerable importance. First, it emphasizes the evolutionary adaptability of the flatworm body plan; and second, it provides some essential foundation for our later discussion of the origins of the flukes and tapeworms. (For an excellent survey of the symbiotic free-living flatworms, see Jennings 1980).

Most of the symbiotic free-living flatworms belong to the infraclass Rhabdocoela. Species in the family Temnocephalidae (Figure 10.6B) are ectocommensals within the branchial chambers of freshwater decapod crustaceans, where they feed on microorganisms in the host's gas exchange currents. Temnocephalids also occur on aquatic insects, molluscs, turtles, and a few other kinds of hosts. Several families of Dalytyphloplanida include symbiotic members. For example, *Syndesmis* live within the gut and coelomic fluid of echinoids, where they feed on protists and bacteria, and some may devour cells of their hosts (Figure 10.10). The genera *Graffilla* and *Paravortex* include several species of parasites in the digestive tracts of gastropod and bivalve molluscs, where they derive nutrients from the host tissues. Members of the family Fecampiidae (*Fecampia, Kronborgia, Glanduloderma*) are parasites in marine crustaceans and certain polychaete worms, where they reside in the host's body fluids and absorb soluble organic nutrients. Non-rhabdocoelan symbiotic species include the triclad *Bdelloura* (Figure 10.6A), an ectocommensal on the gills of *Limulus*, the horseshoe crab. At least two polyclads live and feed on coral (*Prosthiostomum* on Hawaiian *Montipora; Amakusaplana acroporae* on Australian *Acropora*).





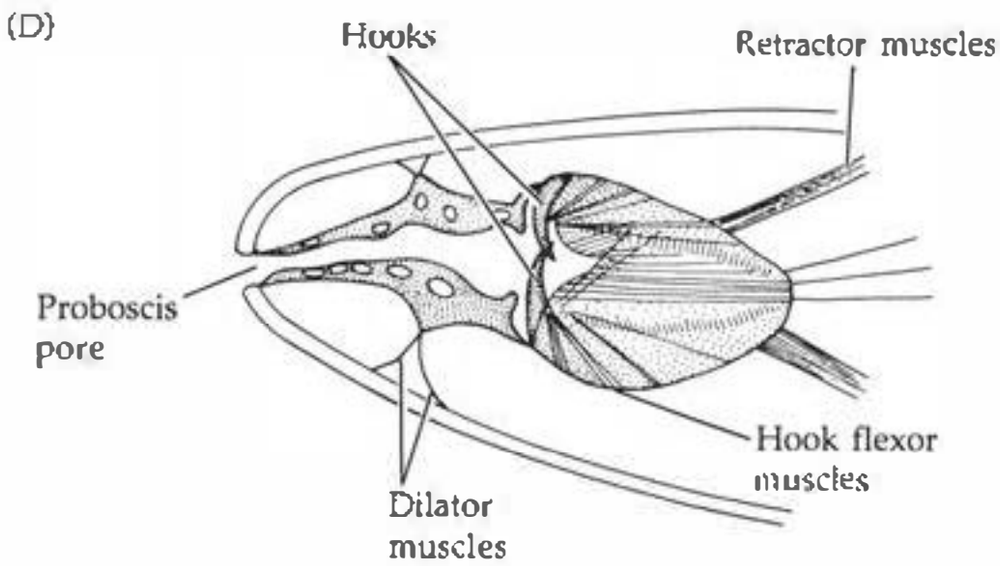


Figure 10.10 *Syndesmis*, a rhabdocoel from the gut of a sea urchin.

The digestive system of the free-living flatworms includes a mouth and a pharynx, which lead to an intestine, or enteron. Like that of cnidarians and Xenacoelomorpha, the free-living flatworm gut is incomplete, bearing a single opening, and thus may be called a gastrovascular cavity. The mouth varies in position from midventral to anterior. The pharynx is derived from embryonic ectoderm (i.e., it is stomodeal) and lined with epidermis. Epithelial pharyngeal glands are associated with the lumen of the pharynx; they produce mucus that aids in feeding and swallowing, and (in some species) proteolytic enzymes that initiate digestion outside the body.

The feeding methods of free-living flatworms vary with the size of the animal and the complexity of their food-getting apparatus, especially the pharynx. As noted in the classification scheme, the nature of the pharynx varies greatly among taxa. There are three basic pharynx types among the free-living flatworms: simple, bulbous, and plicate (Figures 10.11 and 10.12).

A simple pharynx (or pharynx simplex) is a short, ciliated tube connecting the mouth and intestine (Figure 10.12). This type of pharynx has been considered plesiomorphic within the phylum Platyhelminthes and is found in the orders Macrostomida and Catenulida. In all members of these orders, the pharynx leads to a simple saclike or elongate intestine generally lacking extensive diverticula. Free-living flatworms with a simple tubular pharynx are generally quite small, with the mouth located more or less midventrally. They usually

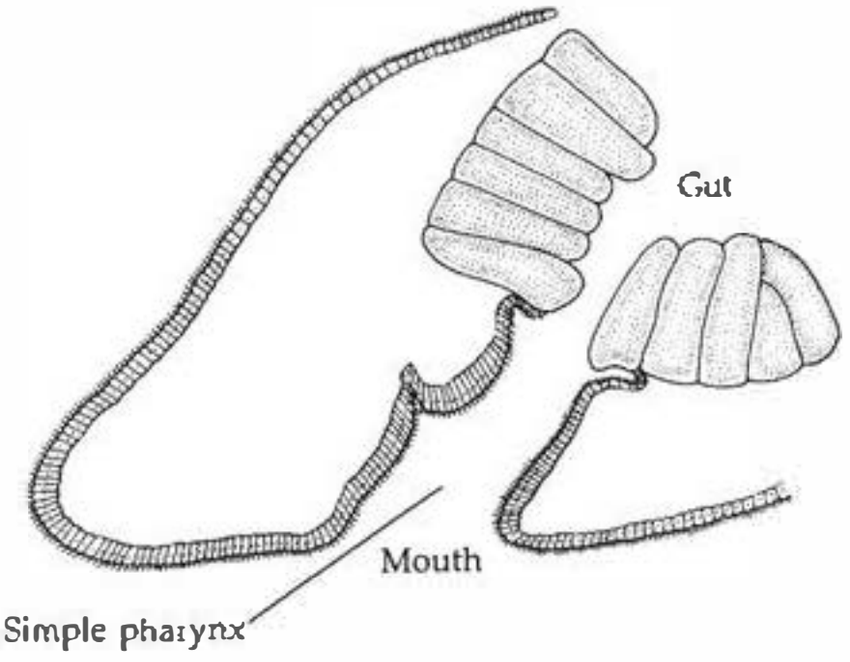

Figure 10.12 Sagittal section through anterior end of *Macrostomum* (Macrostomorpha), which has a simple tubular pharynx.

feed by sweeping small organic particles and tiny prey into the pharynx by ciliary action. Those with an eversible pharynx usually fold their body around the prey or other food source and cover it with mucus from the epidermal glands. Then the pharynx is everted over or into the food item.

Some freeliving flatworms, especially triclads, secrete digestive enzymes externally via special glands that empty through the pharyngeal lumen or from the tip of the pharynx. The food is partially digested and reduced to a soupy consistency prior to swallowing. Many other species swallow their food whole by the action of powerful pharyngeal muscles.

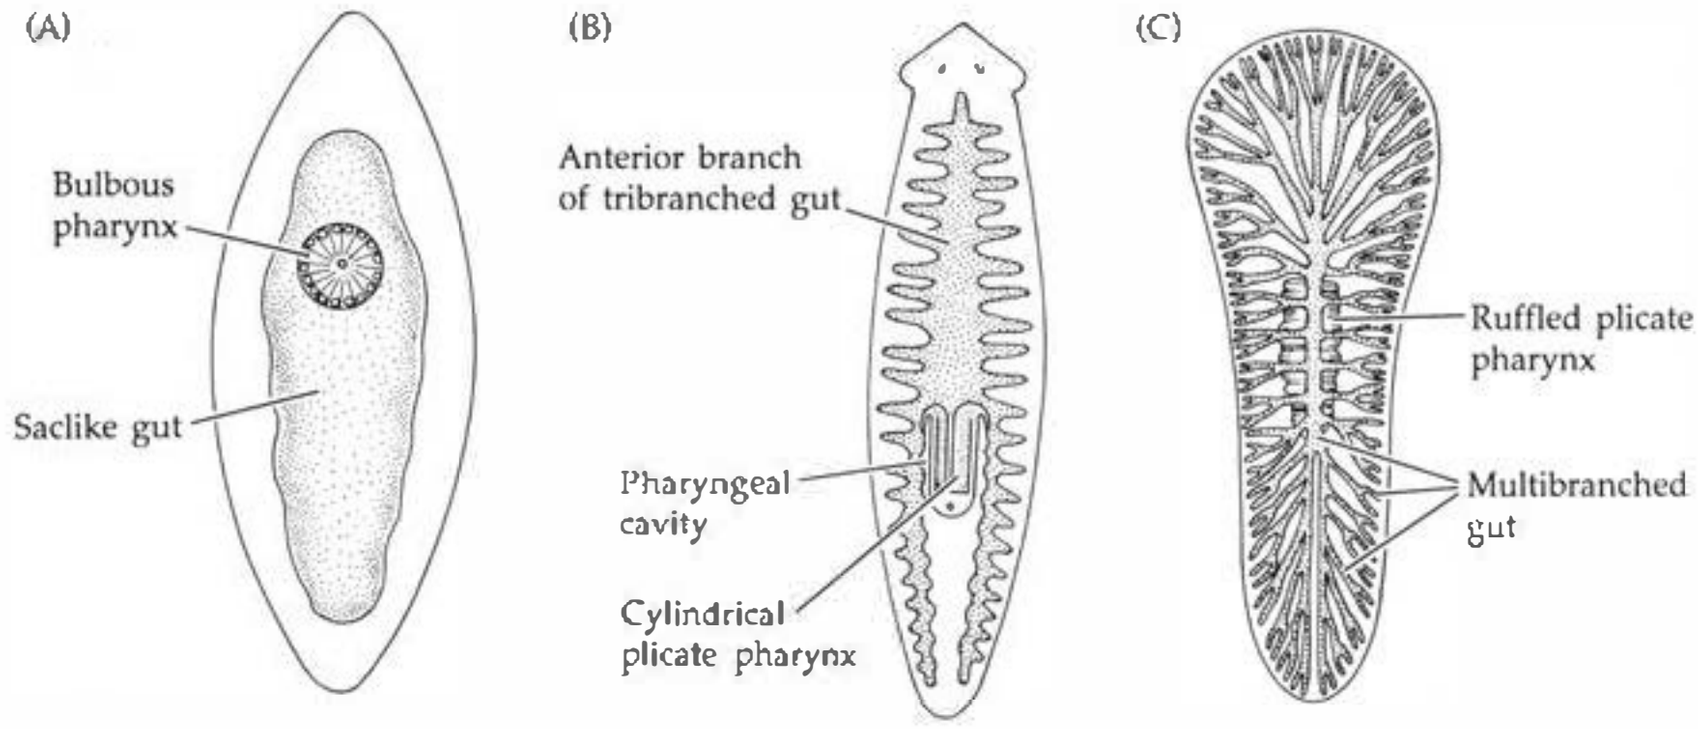

Figure 10.13 Pharynx type and gut shape combinations among free-living flatworms. (A) Rhabdocoela. (B) Tricladida. (C) Polycladida.

Rhabdocoels typically possess a slightly protractile, muscular, bulbous pharynx and a simple saclike gut (Figure 10.13A). Members of the Proseriata, Tricladida, and Polycladida have eversible plicate pharynges. The eversible portion of a plicate pharynx lies within a space called the pharyngeal cavity, which is produced by a muscular fold of the body wall (Figures 10.11 and 10.13).

Proseriates and triclads possess cylindrical plicate pharynges oriented along the body axis. Most polyclads have a ruffled, skirtlike plicate pharynx attached dorsally within the pharyngeal cavity. During feeding, a plicate pharynx is protruded by a squeezing action of extrinsic pharyngeal muscles. Once extended, the pharynx can be moved about by intrinsic muscles of its wall. Retractor muscles pull the pharynx back inside the cavity.

Active prey can be subdued in several ways. Some free-living flatworms produce mucus, which, in addition to entangling the prey, may contain narcotic or poisonous chemicals such as tetrodotoxin. A few flatworms use the sharp stylet of the copulatory organ to stab prey and even to introduce venom; one cannot help but concede the remarkable adaptive capacity of the flatworms. Members of the Kalyptorhynchia (Rhabdocoela) are unique among free-living flatworms in their possession of a muscular proboscis that is situated at the anterior end of the body and is separate from the mouth (Figure 10.11D,E); the proboscis, which in some species is armed with hooks, can be everted to grab prey.

Most of the free-living flatworms that possess a plicate pharynx are relatively large, especially the triclads and the polyclads. Associated with this large body size is an elaboration of the intestine. As the names imply, the triclad intestine comprises three main branches, one anterior and two posterior, each with numerous diverticula, whereas the intestine of polyclads is multibranched with diverticula (Figure 10.13B,C). These ramifications of the intestine provide not only an increased surface area for digestion and absorption, but also are a means of distributing the products of digestion through the relatively large body in the absence of a circulatory system. The lining of the intestine is a single cell layer of phagocytic nutritive cells and enzymatic gland cells (Figure 10.14). In some groups, the gastrodermis is ciliated.

In most free-living flatworms, initial digestion is extracellular, mediated by endopeptidases secreted from the pharyngeal glands or from enzymatic gland cells within the intestine. The partially digested material is distributed throughout the gut, then phagocytized by the intestinal cells, wherein final (intracellular) digestion occurs. There are, however, some notable exceptions to this sequence. Bowen (1980) described an interesting phagocytic process in the freshwater triclad *Polycelis tenuis*. Following the ingestion of tiny food

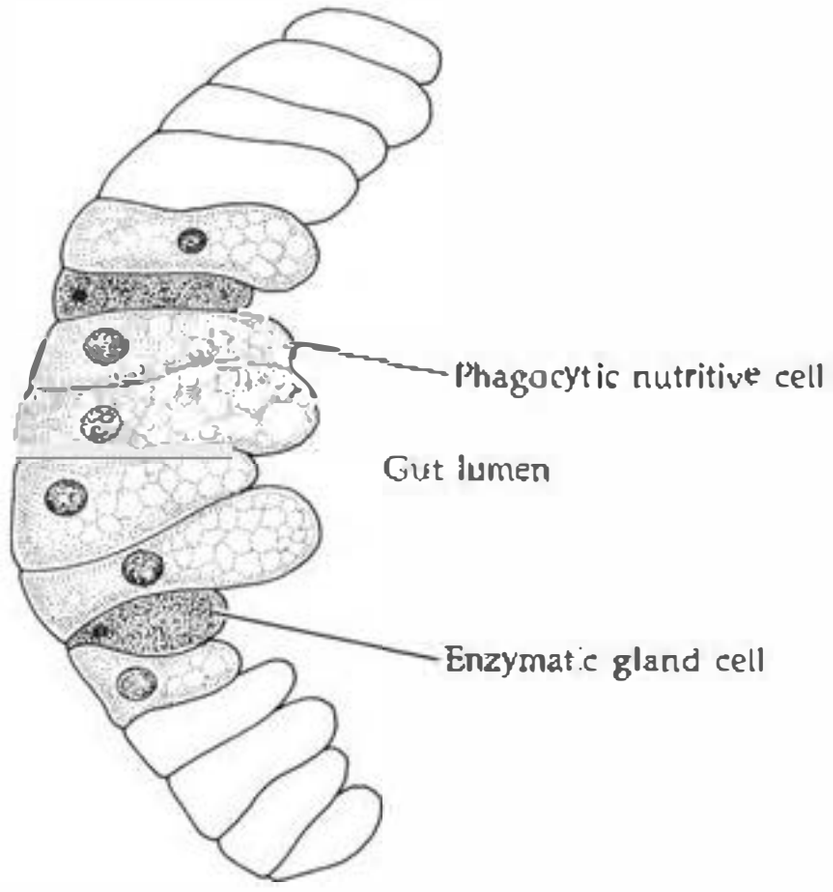

Figure 10.14 The gut lining (partial cross section) of a freshwater triclad contains enzymatic gland cells and phagocytic nutritive cells.

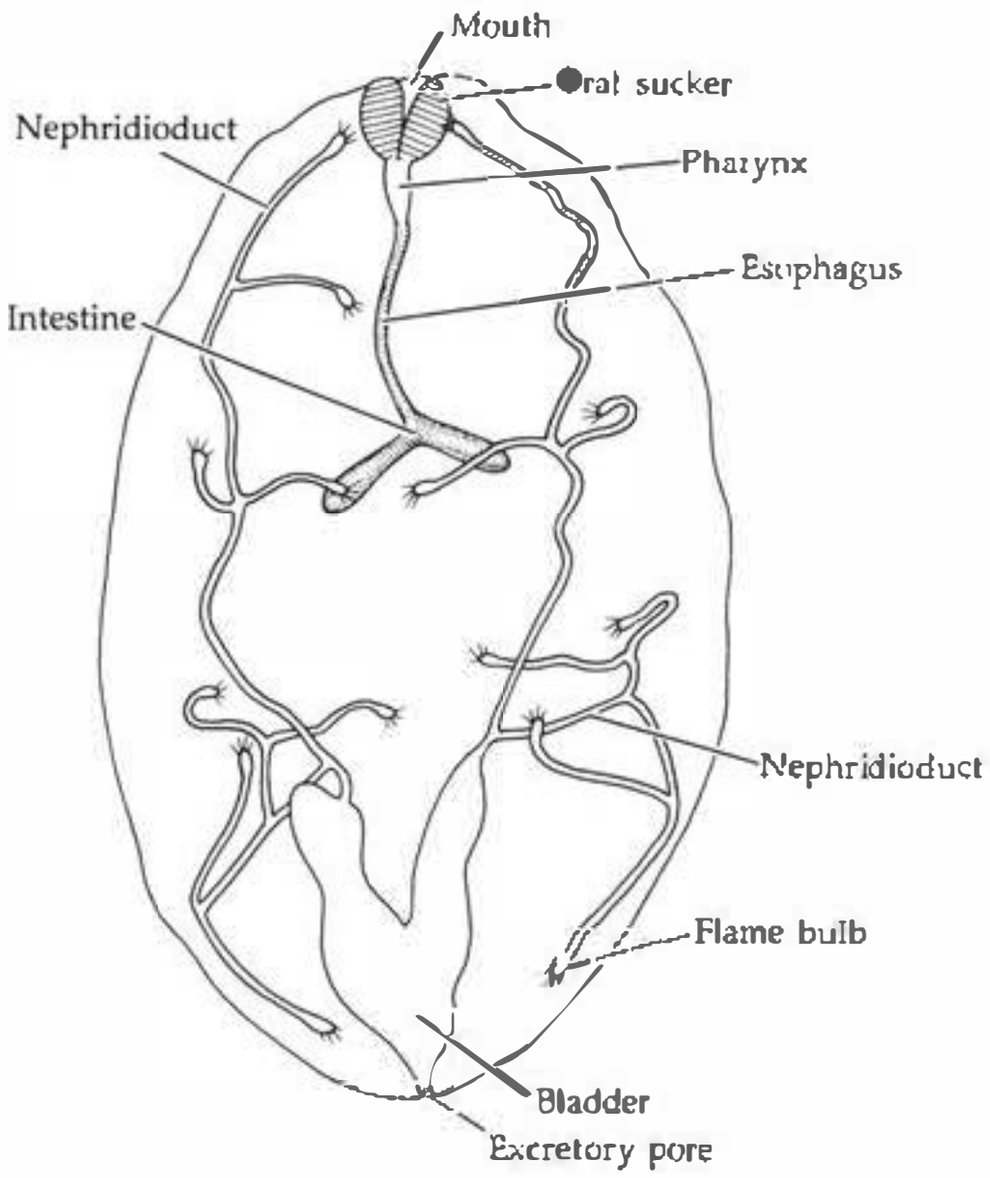

Figure 10.15 Gut and protonephridial system of *Microphallus* (order Plagiorchiida; see also Figure 10.3). In most monogenean flukes, the protonephridial ducts are separate and terminate anteriorly in separate pores.

particles or the preliminary extracellular digestion of larger food, the intestinal phagocytic cells extend processes into the gut lumen, nearly occluding the digestive cavity. These processes interdigitate to form a complex web, forcing food material into the phagocytes, where digestion is completed.

Since flatworms generally lack a through gut, any undigested material must be expelled through the mouth. As discussed in Chapter 4, the major limitation of single-opening guts is the restriction on regional specialization. However, an incipient anus occurs in several flatworms, suggesting that evolutionary "experimentation" with a complete gut began in this group. One macrostomorphan, *Haplopharynx rostratus*, possesses a minute anal pore, and some polyclads have pores at the ends of gut branches; some proseriatians (e.g., *Tabaota*) may form a temporary anus.

Flukes and flatworms Adult flukes feed on host tissues and fluids or, in some cases, material within the host's gut. Most of the food is taken in through the mouth by a pumping action of the muscular pharynx, but some organic molecules are picked up across the tegument by pinocytosis. The anterior part of the digestive system includes a mouth, a muscular pharynx, and a short esophagus. The esophagus leads to a pair of intestinal ceca (occasionally, a single cecum), which extend(s) posteriorly in the body (Figures 10.3 and 10.15). The lining of the ceca includes absorptive nutritive cells and enzymatic gland cells. Digestion is at least partly extracellular. Some flukes secrete enzymes from the gut out the mouth, or from the suckers, to partially digest host tissue prior to ingestion.

Cestodes lack any vestige of a mouth or digestive tract. All nutrients must be taken into the body across the tegument. Uptake probably occurs by pinocytosis and by diffusion across the increased surface area of the microtriches. Some work suggests that tapeworms are unable to take in large molecules and thus rely to a considerable extent on the digestive processes of their hosts and the secretion of enzymes outside their bodies to chemically reduce the size of potential nutrient material. It has also been proposed that the surface of the scolex may absorb host tissue fluids through the site of attachment to the gut wall.

Many parasites, in numerous phyla, have been shown to alter the behavior of their hosts in ways that are beneficial to themselves, usually by causing the host to position itself such that the odds of success in the next stage in the parasite's life cycle is improved. Parasitic platyhelminths are no exception. For example, larvae of the trematode, *Microphallus papillorobustus*, encyst in the nervous systems of two species of amphipods (*Gammarus* spp.). There, they induce photophilia in animals that are usually photophobic. Consequently, infected amphipods are more than twice as likely as uninfected animals to be eaten by seagulls (a potential final host). When the cestode *Eubothrium salvelini* reaches the developmental stage where it is infective to the final host (brook trout, *Salvelinus frontinalis*), its intermediate host—the copepod *Cyclops vernalis*—begins to swim more often than normal, making it more like to be eaten by the fish. The beetle, *Tribolium confusum*, is intermediate host to the tapeworm *Hymenolepis diminuta*. Evidence suggests the beetle might be more attracted to rat feces that contain the cestode's eggs than to uninfected feces. The same may be true of cockroaches (*Periplaneta americana*) confronted with the feces of rats parasitized by the acanthocephalan *Moniliformis moniliformis*.

Circulation and Gas Exchange

As mentioned earlier, except for the lymphatic channels in some flukes, flatworms lack special circulatory or gas exchange structures. This condition imposes restrictions on size and shape. The key to survival with such limitations and a generally solid mesenchyme is the maintenance of small diffusion distances. Thus, the flatness of their bodies facilitates gas exchange across the body wall, between the tissues and the environment; nutrients are distributed internally by the digestive system and by diffusion, which is aided by general body movements.

The endoparasitic flatworms are capable of surviving in areas of their host where oxygen is absent. In

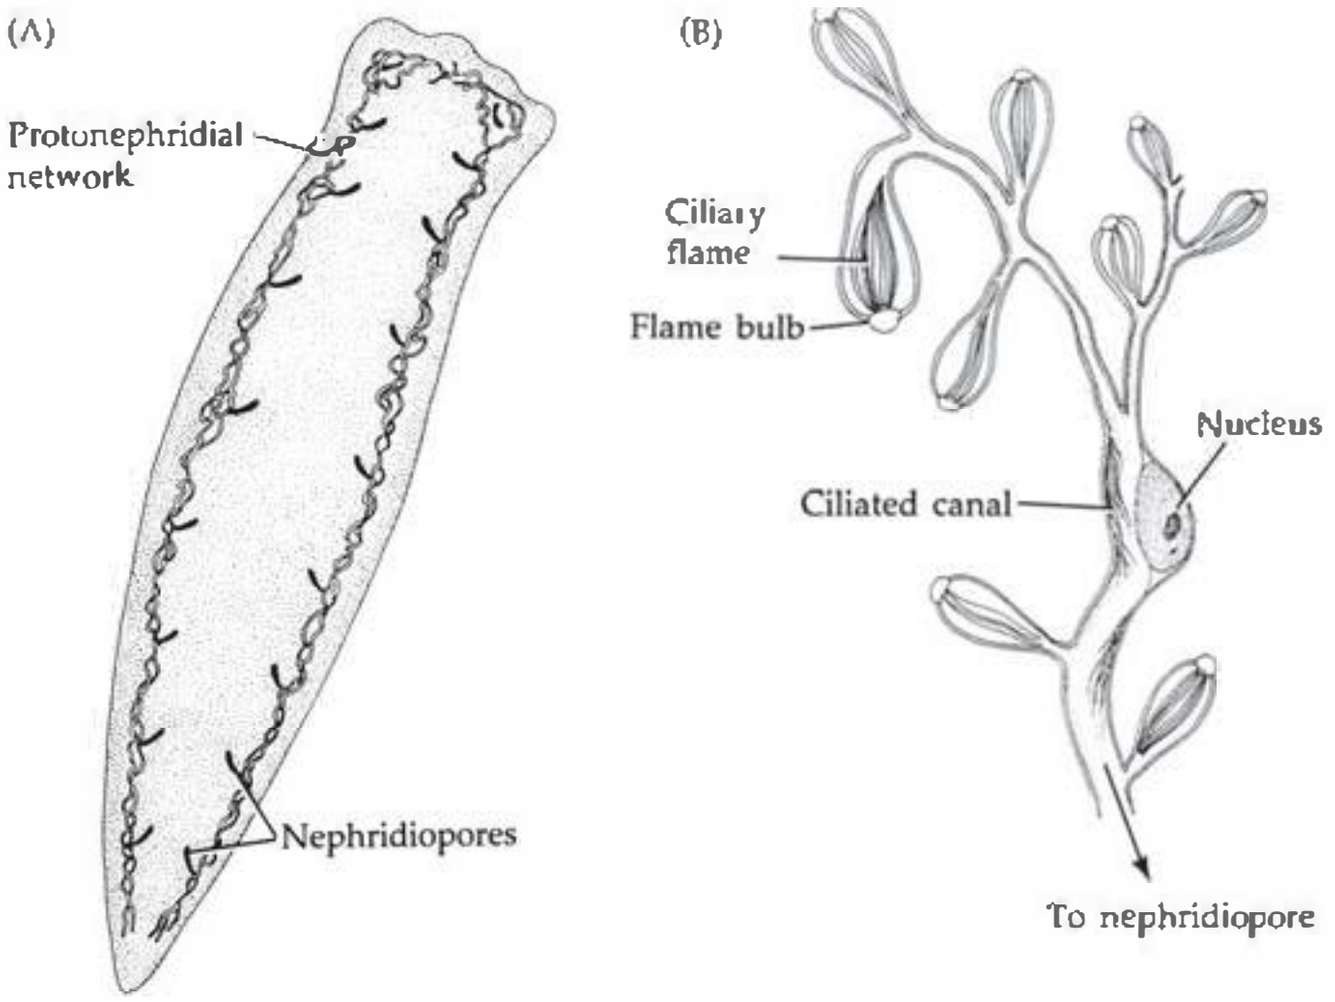

Figure 10.16 (A) The protonephridial system in a freshwater triclad. (B) The nephridial arrangement in a rhabdocoel that has anucleate flame bulbs attached to collecting tubules.

such cases, they rely on anaerobic metabolism, producing a variety of reduced end products (e.g., lactate, succinate, alanine, and long-chain fatty acids). Most of these adaptable animals also possess the appropriate enzymes for and are capable of aerobic respiration in the presence of oxygen.

Excretion and Osmoregulation

One of the major advances of flatworms over diploblastic animals is the development of protonephridia (see Chapter 4 for a review of nephridia among Metazoa). These structures occur in all free-living flatworms except some marine catenulids and consist of flame bulbs that may occur singly (as they do in some catenulids) or in pairs (from one to many pairs in different taxa). The protonephridia are connected to networks of collecting tubules that lead to one or more nephridiopores (Figure 10.16). Protonephridia in free-living flatworms function primarily as osmoregulatory structures. Freshwater species tend to have more protonephridia and more complex tubule systems than do their marine counterparts. Although a small amount of ammonia is released via the protonephridia, most metabolic wastes are lost by diffusion across the body wall.

Flukes also possess variable numbers of flame bulb protonephridia. Two nephridioducts drain the nephridia and lead to a storage area, or bladder, which in turn connects with a single posterior nephridiopore in the digenean flukes, or a pair of anterior pores in the monogenean types (Figure 10.15). Nitrogenous waste in the form of ammonia is excreted largely across the tegument. As in free-living flatworms, the protonephridia of flukes are primarily osmoregulatory.

Tapeworms possess numerous flame bulb protonephridia throughout the body. The flame bulbs drain to pairs of dorsolateral and ventrolateral nephridioducts that run the length of the body (Figures 10.15 and 10.17). Although some variation in plumbing occurs, the ventral ducts are typically connected to one another by transverse tubules near the posterior end of each proglottid. In relatively young worms that have not lost any proglottids (see the section on Reproduction and Development), the excretory ducts lead to a collecting bladder in the most posterior proglottid. Once this terminal proglottid is lost, the nephridioducts open separately to the outside on the posterior margin of the remaining hindmost proglottid.

There is still much to be learned about the protonephridia of cestodes. They probably function both in

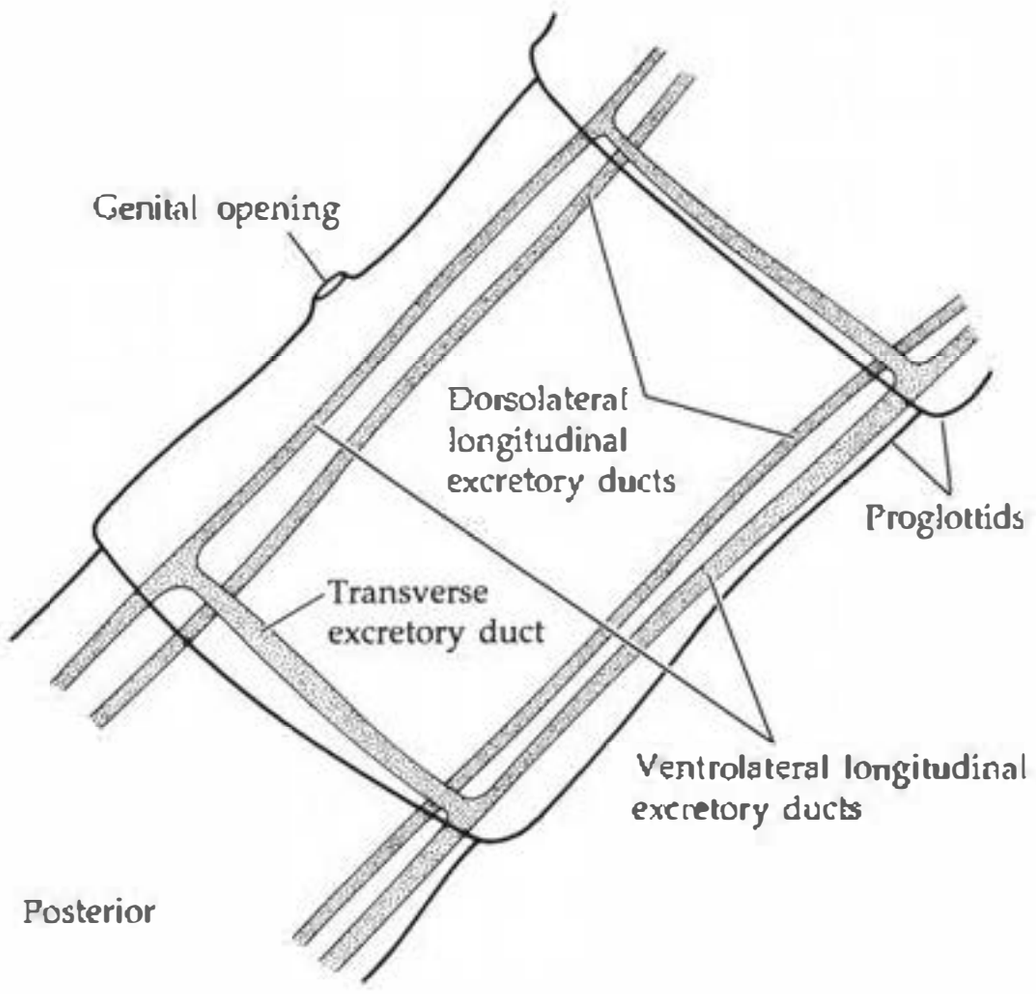

Figure 10.17 The arrangement of major protonephridial ducts in a cestode proglottid (ventral view).

excretion and osmoregulation. They may also serve to eliminate certain organic acid products of anaerobic cellular metabolism. Some experimental work indicates that tapeworms are capable of precipitating and storing some waste products within their proglottids.

Nervous System and Sense Organs

Free living flatworms The nervous system of these species varies from a simple netlike nerve plexus with only a minor concentration of neurons in the head (similar to that seen in the phylum Xenacoelomorpha), to a distinctly bilateral arrangement with a well-developed cerebral ganglion and longitudinal nerve cords connected by transverse commissures (Figure 10.18). The more advanced condition is referred to as a ladder like nervous system. Even many of those species that possess distinctly centralized nervous systems have a plexus formed by the repeated branching of nerve endings (e g , polyclads). In general, larger flatworms show an increasing concentration of the peripheral nerves into fewer and fewer longitudinal cords and an accumulation of neurons in the head as an associative center or cerebral ganglion. Furthermore, they show a tendency to separate the elements of the nervous system into distinct sensory and motor pathways and to develop a circuitry that operates primarily on unidirectional impulse transmission.

The nervous system and sense organs of free living flatworms appear to have been elaborated in association with bilateral symmetry and unidirectional movement. The result is a general concentration of sense organs at the anterior end of the body and an elaboration of those receptor types that are compatible with these animals' lifestyle. Tactile receptors are abundant over much of the body surface as sensory bristles projecting from the epidermis. These receptors tend to be concentrated at the anterior end and around the pharynx. Benthic free living flatworms orient to the substratum by touch; they are positively thigmotactic ventrally and negatively thigmotactic dorsally.

Most free-living flatworms are equipped with chemoreceptors that aid in food location. Although sensitive over most of the body, free-living flatworms have distinct concentrations of chemoreceptors anteriorly, particularly on the sides of the head. Some forms, such as the familiar freshwater planarians, and prorhynchidans have the chemoreceptors located in flaplike processes called auricles on the head (Figures 10.2 and 10.18C), whereas others have these sense organs in ciliated pits, on tentacles, or distributed over much of the anterior end of the body. The epithelium bearing the chemoreceptors is often ciliated and frequently forms depressions or grooves. The cilia are the receptor organelles, but also circulate water, thus facilitating sensory input from the environment.

The utilization of chemoreception in locating food has been demonstrated in many free-living flatworms. Some are known to home in on concentrations of dissolved chemicals associated with potential food. Others, such as *Dugesia*, hunt by waving the head back and forth as they crawl forward, exposing the auricles to any chemical stimulus in their path. When exposed to diffuse chemical attractants, some free living flatworms begin a trial-and-error behavior pattern. If unable to determine the direction of the attractant, the worm begins moving in a straight line. If the stimulus weakens, the animal makes apparently random turns until it encounters sufficient stimulus, then moves toward it. This behavior can eventually bring the animal near enough to the food source to home in on it directly. Some species orient to water movements by rheoreceptors located on the sides of the head (Figure 10.18D).

Statocysts are common in certain flatworms, notably in members of the Catenulida and Proseriata. These groups include mostly swimming and interstitial forms in which orientation to gravity cannot be accomplished by touch. When present, the statocyst is usually located on or near the cerebral ganglion Ehlers (1991) presents details on the ultrastructure of some flatworm statocysts.

Most free-living flatworms possess photoreceptors in the form of inverted pigment-cup ocelli (Figure 10.18E). A few macrostomids possess simple pigment-spot ocelli, which are presumed to be primitive within the flatworms. Many species bear a single pair of ocelli on the head; but some, such as certain polyclads and terrestrial triclads, may have many pairs of eyes. In a few terrestrial forms (e g., *Geoplana mexicana*) and many of the large tropical polyclads, numerous eyes extend along the edges of the body. Most free-living species are negatively phototactic. The dorsal placement of the eyes and the orientation of the pigment cups facilitate the detection of light direction as well as intensity.

Larvae of the polyclad flatworm *Pseudoceros cadensis* possess two dissimilar kinds of eyes. The right eye appears to be microvillar (i e., rhabdomeric), but the left one has components of both microvillar and ciliary origin (Eakin and Brandenberger 1980). The histories of these two eye types were noted in Chapter 4. The discovery of both types of eyes in a flatworm larva suggests to some researchers the possibility that this animal stands at a major point of evolutionary divergence.

Neurosecretory cells have been known in free-living flatworms for more than three decades, and work continues on exploring their functions. These special cells are generally located in the cerebral ganglion, but they also occur along major nerve cords in at least some species. Neurosecretions play important roles in regeneration, asexual reproduction, and gonad maturation in free-living species that could serve as models for understanding similar functions in parasitic species.

(C) The cerebral ganglion and associated nerves in the triclad *Crenobia*. (D) The anterior end (cross section) of the rhabdocoel *Mesostoma*, showing tactile, chemo-, and rheoreceptors. (Rheoreceptors detect water movements over the surface of the animal.) (E) A typical freeliving flatworm inverted pigment cup ocellus (section). (F) An interstitial free-living flatworm with a distinct statocyst and numerous anterior sensory bristles.

Flukes and tapeworms The nervous system of flukes is distinctly ladderlike and very similar to that in many free-living flatworms (Figure 10.19). The cerebral ganglion comprises two well-defined lobes connected by a dorsal transverse commissure. Nerves from the cerebral ganglion extend anteriorly to supply the area of the mouth, adhesive organs, and any cephalic sense organs. Extending posteriorly from the cerebral ganglion are up to three pairs of longitudinal nerve cords with transverse connectives. A pair of ventral cords is usually most well developed, and dorsal cords are present in the digenean flukes. Most flukes also have a pair of lateral nerve cords.

The suckers of flukes bear tactile receptors in the form of bristles and small spines. There is also some evidence of reduced chemoreceptors. Nearly all monogenean flukes possess a pair of rudimentary pigment-cup ocelli near the cerebral ganglion.

The cerebral ganglion of cestodes is usually a complex nerve ring located in the scolex (Figure 10.20). The ring bears ganglionic swellings and gives rise to a number of nerves. Anterior nerves, in the form of a ring or plexus, serve the rostellum (when present) and other attachment organs. Lateral cerebral ganglionic swellings give rise to a pair of major lateral longitudinal nerves, which extend the length of the animal. In each proglottid, these nerves bear additional ganglia from which transverse commissures arise and connect the two longitudinal cords. Additional longitudinal nerves are often present; the most typical pattern includes two pairs of accessory lateral cords—a pair of dorsal cords and a pair of ventral cords. As might be expected, sense organs are greatly reduced in cestodes and are limited to abundant tactile receptors in the scolex.

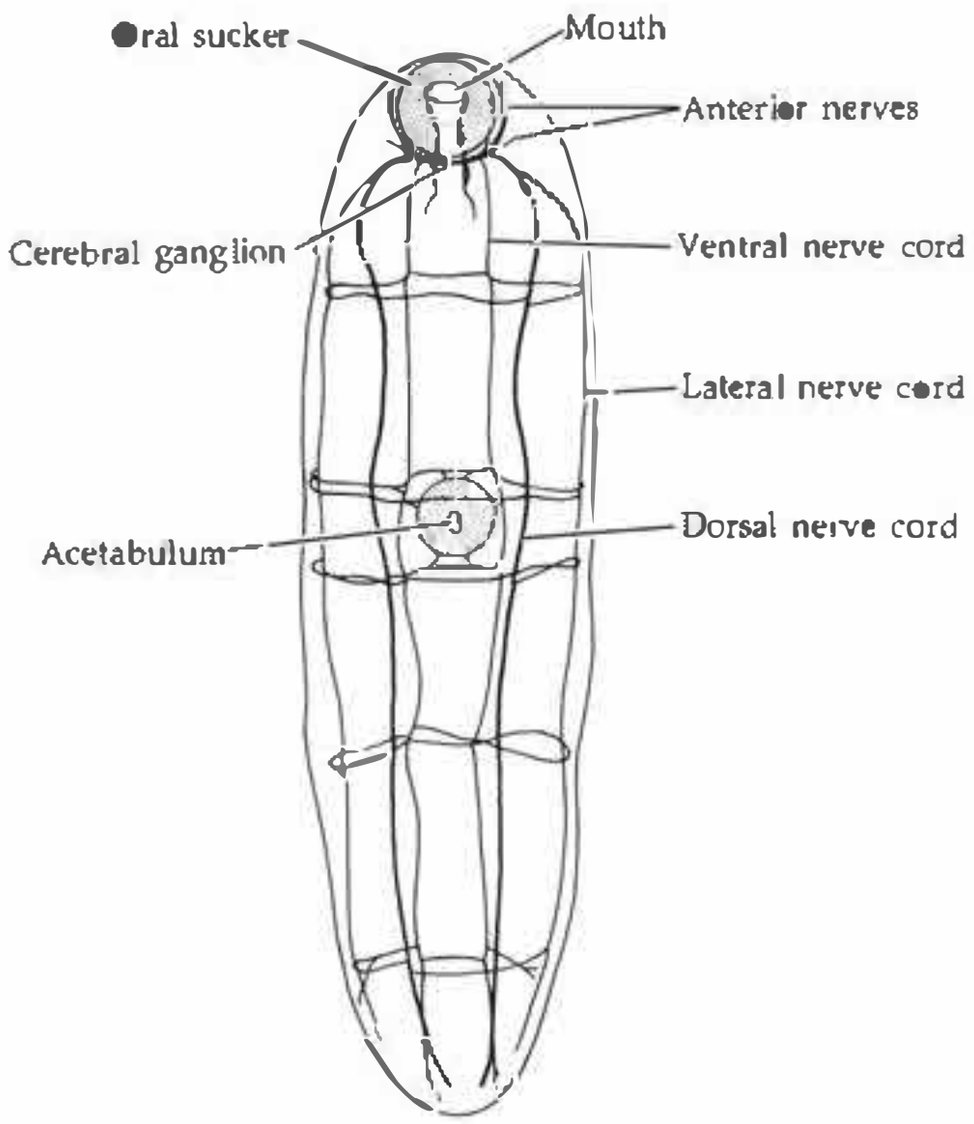

Figure 10.19 A generalized ladderlike nervous system of a trematode (ventral view).

Reproduction and Development

Asexual processes Asexual reproduction is common among freshwater and terrestrial free-living flatworms, and it generally occurs by transverse fission. Geographical variation exists in the tendency for individuals to undergo this process. In the catenulideans and macrostomorphans, an odd sort of multiple transverse fission occurs wherein the individuals thus produced remain attached to one another in a chain until they mature enough to survive alone (Figure 10.21A). Some freshwater triclads (e.g., *Dugesia*) split in half behind the pharynx, and each half goes its own way, eventually regenerating the lost parts. A few (e.g., *Phagocata*) reproduce by fragmentation, each part encysting until the new worm forms.

The remarkable regenerative abilities of free-living flatworms have been studied intensely for many years. Much of the experimental work has been conducted on the common triclad *Dugesia*, a familiar animal to beginning zoology students. Underlying all of the bizarre results of various surgeries performed on these animals (Figure 10.21B,C) is the fact that the cells of organisms like *Dugesia* are not totipotent; an anterior–posterior body polarity exists in terms of the regenerative capabilities of the cells. However, the cells in the midbody region are less fixed in their potential to produce other

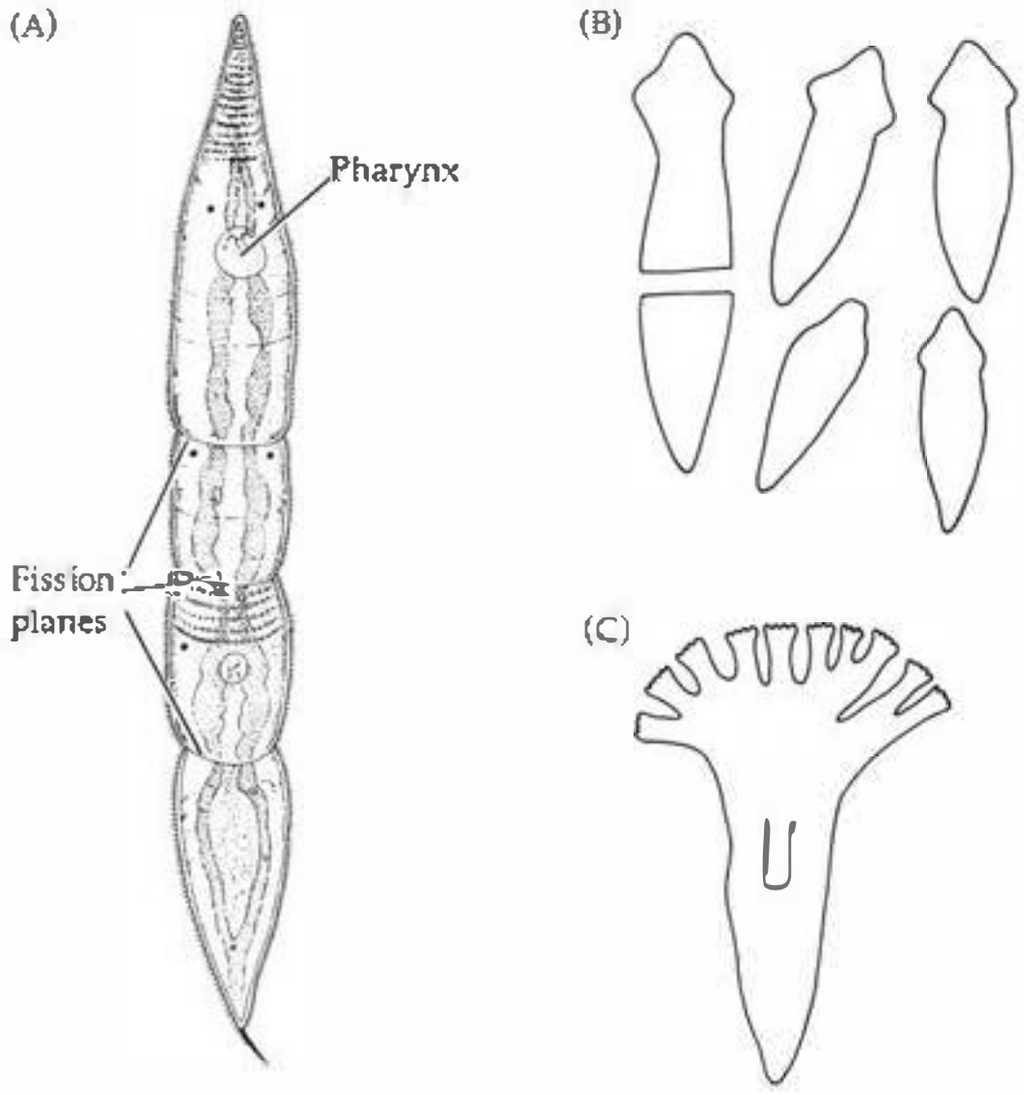

Figure 10.21 (A) Asexual reproduction by transverse fission in the catenulid flatworm, *Alaurina*. (B,C) Regeneration after experimental injuries in planarians.

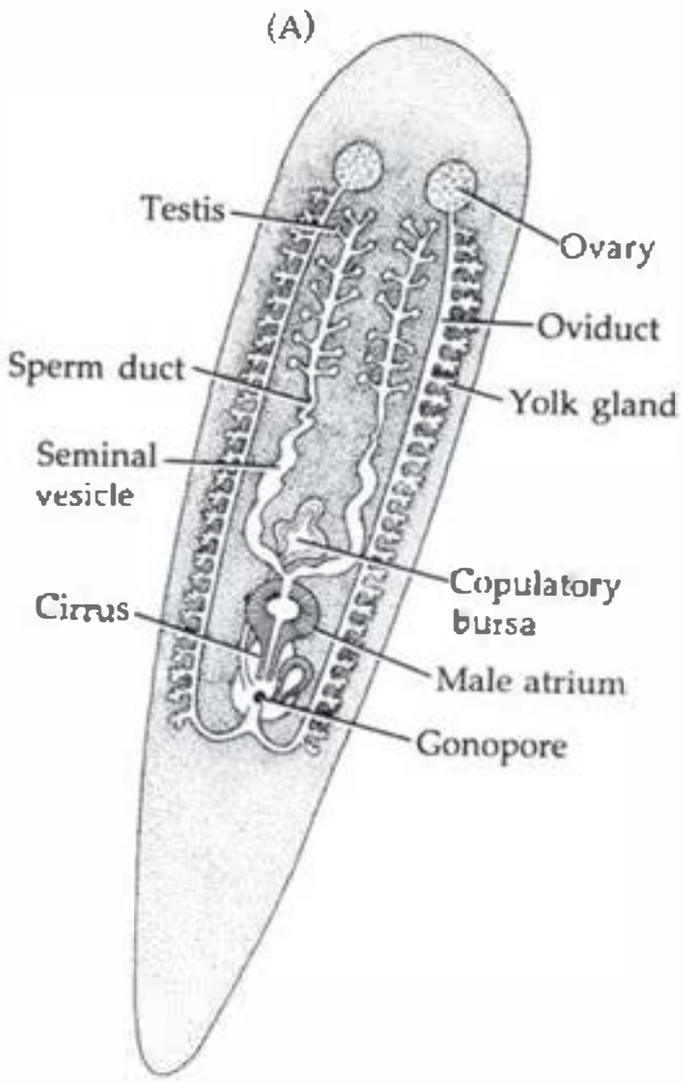
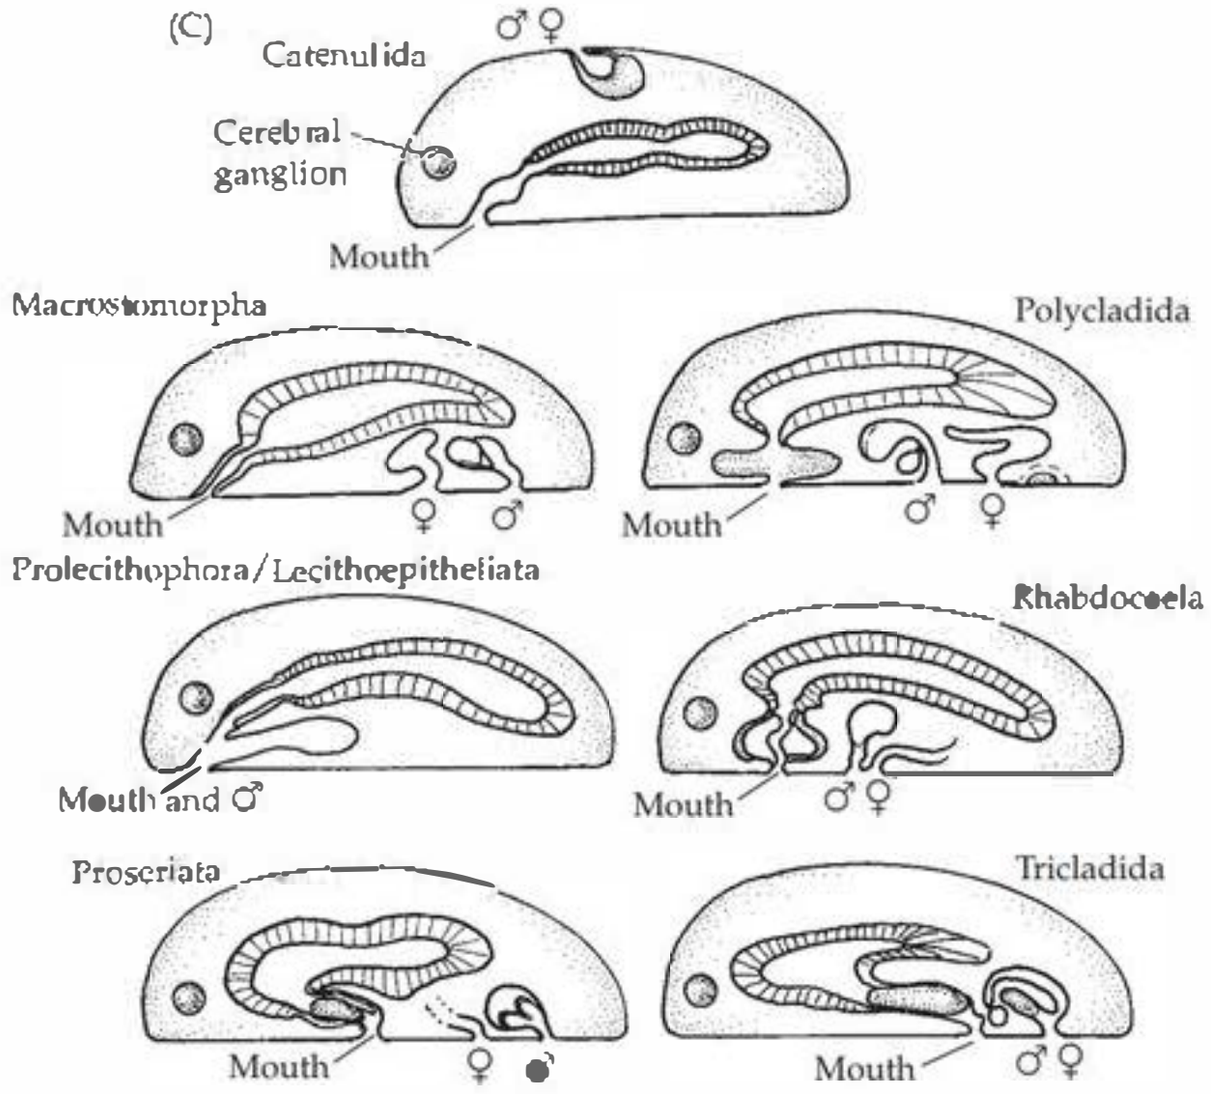
parts of the body than are those toward the anterior or posterior ends. Thus, if the flatworm is cut through the middle of the body (as occurs in natural transverse fission), each half will regenerate the corresponding lost part. However, if the animal is cut transversely near one end—say, separating a small piece of the tail from the rest of the body—the larger piece will grow a new posterior end, but the piece of tail lacks the capability to produce an entire new anterior end. This gradient of cell potency has been of particular interest to cell biologists and medical researchers because of its relevance to healing and regeneration potential in higher animals.

Asexual reproduction is an important feature of the life cycle of flukes, where the ability to reproduce asexually helps ensure survival, particularly when potential mates may not be nearby.

Sexual reproduction: Free-living flatworms Most free-living flatworms are hermaphroditic and possess complex and highly diverse reproductive systems (Figure 10.22). The male system includes single (e.g., Macrostomorpha), paired (e.g., many Rhabdocoela), or multiple (e.g., Polycladida) testes. The testes are generally drained by collecting tubules that unite to form one or two sperm ducts, which often lead to a precopulatory storage area or seminal vesicle. Prostatic glands, which supply seminal fluid to the sperm, are often associated with and empty into the seminal vesicle. The seminal vesicle is typically part of a muscular chamber called the **male atrium**, which houses the copulatory organ. The actual organ of sperm transfer may be a papillalike penis or an eversible cirrus, through which sperm are forced by muscular action of the atrium.



The female reproductive system is more variable than that of the male. Much of the variation is related to whether the flatworm in question produces **endolecithal** or **ectolecithal** ova—that is, whether the worm is described as **archoöphoran** or **neoöphoran**. The archoöphorans (e.g., Macrostomida, Polycladida) typically possess an organ that produces both eggs and yolk. The final product is endolecithal ova. Such an organ is called a **germovitellarium**, and may occur either singly or paired. In the neoöphorans (e.g., the order Prolecithophora and the entire superclass Euneoophora), the ovary (**germarium**) is separate from the yolk gland (**vitellarium**). Yolk-free eggs are produced by the ovary and then cellular yolk is transported through a vitelline duct and deposited alongside the ova inside the eggshell, a process resulting in ectolecithal ova.



In both cases, the eggs are typically moved via an oviduct toward the female atrium, which often bears special chambers for receipt and storage of sperm (i.e., copulatory bursa and seminal receptacle). Associated with this arrangement may be a variety of accessory glands, such as **cement glands**, for the production of shells and egg cases.

The male and female gonopores are often separate, the female opening usually located posterior to the male pore. In some species, however, the two systems share a common genital opening, and in a few the male atrium opens just inside the mouth. In the latter case, the mouth is referred to as an **orogenital pore**.

Mating is usually by mutual cross-fertilization. The two mates align themselves so that the male gonopore of each is pressed against the female gonopore of the mate (Figure 10.23A). The male copulatory organ, or stylet (or penis or cirrus) is everted by hydrostatic pressure caused by the muscles surrounding the atrium and is inserted into the mate's female atrium, where sperm are deposited. The mates then separate, each going its own way and carrying foreign sperm. Fertilization usually occurs as the eggs pass into the female atrium or within the oviduct itself. The zygotes are frequently stored for a period of time in special parts of the female system or in enlarged oviducts; any such storage area is called a **uterus**.

Some macrostomorph and polyclad flatworms exhibit hypodermic insemination, whereby the male stylet is thrust through the body wall of the mate and sperm are forcibly injected into the mesenchyme. In other polyclads, individuals receive spermatophores from partners on their dorsal surface. Whereas most flatworms mate in pairs, such dermal impregnation may occur in groups. By a method not yet understood,

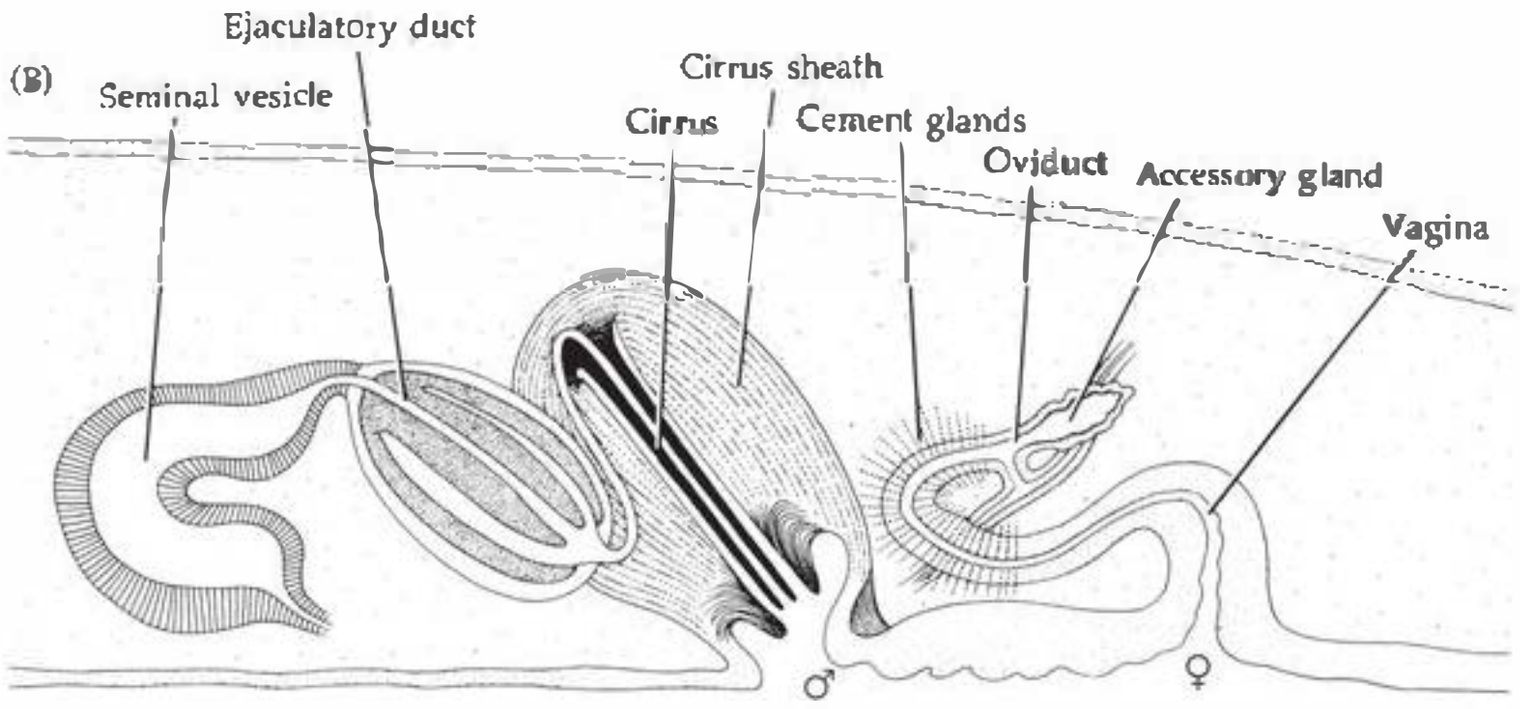


Figure 10.22 Reproductive systems of free-living flatworms. (A) Generalized triclad condition with separate ovaries and yolk glands (neoöphoran condition). (C) Generalized scheme of the relative position of male (♂) and female (♀) reproductive structures with respect to the location of the mouth in seven taxa.

after mating, the sperm find their way to the female system and fertilize the eggs.

In the genus *Macrostomum*, a close correspondence exists between the morphology of sperm, the morphology of the male stylet, and whether insemination is hypodermic or occurs by copulation (Figure 10.23C,D). Sperm in all *Macrostomum* have "feelers," anterior projections that embed themselves into the wall of the female reproductive tract in position to allow fertilization. However, depending on the species, sperm may also possess backwardly-directed bristles. Species in which the stylet is hooked engage in hypodermic insemination and sperm lack bristles. In contrast, species in which the stylet is not hooked tend to copulate, and sperm do possess bristles. Bristles appear to maintain sperm in position within the female reproductive tract after mutual insemination by mating pairs. After pairs separate, each individual applies its mouth to its own vagina and "sucks," evidently removing unattached sperm. The sperm that have imbedded their feelers into the female reproductive tract are in position for fertilization, and bristles appear to assist in this process. Unattached sperm are removed from the vagina by suction and are apparently eaten.

Ingestion of sperm from mating partners may in fact be widespread. In other free-living flatworms from several taxa, the presence of Lang's vesicle is associated with species that engage in copulation. Although this structure is thought to be a sperm storage organ its significance is still in doubt. The structure is usually

attached to the digestive system suggesting that it may be involved in sperm digestion.

Once fertilization is accomplished, the zygotes are either retained by the parent within the uteri of the female reproductive tract or laid in various sorts of gelatinous or encapsulated egg masses (Figure 10.23B). Thus, most maternal free-living flatworms are obliged to contribute substantially toward the care of their embryos; they may be described as oviparous or ovoviviparous. Some freshwater triclads produce special overwintering zygotes, which are encapsulated and retained within the female reproductive tract until spring.

The general strategy of the vast majority of free-living flatworms is to produce relatively few zygotes, which are protected by brooding or encapsulation and undergo direct development. A few polyclads produce Müller's larvae, which swim about for a few days prior to settling and metamorphosing (Figures 10.24 and 10.25). This larva is equipped with eight ventrally directed ciliated lobes, by means of which it swims. A few species of parasitic polyclads of the genus *Stylochus* produce a Götte's larva, which bears four rather than eight lobes; and members of the freshwater catenulidean genus *Rhynchoscolex* pass through a vermiform stage in their development that has been referred to as a larval form.

Early embryogeny differs greatly between the archoöphoran and neoöphoran flatworms. The endolecithal ova of the archoöphorans undergo some form of spiral cleavage (although some authors question the details of this process). The pattern and cell fates in many of these archoöphoran embryos are distinctly

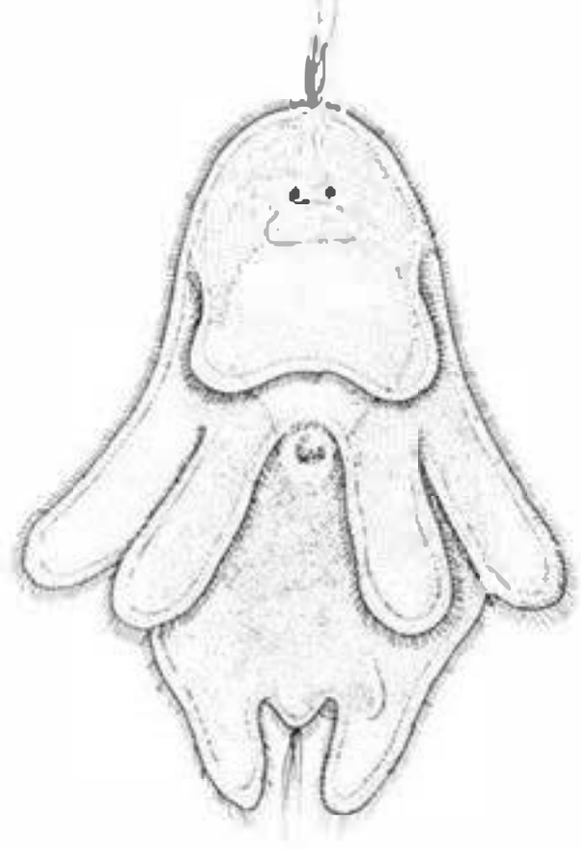

Figure 10.24 "Face-on" view of Müller's larva of a polyclad (*Planocera*).

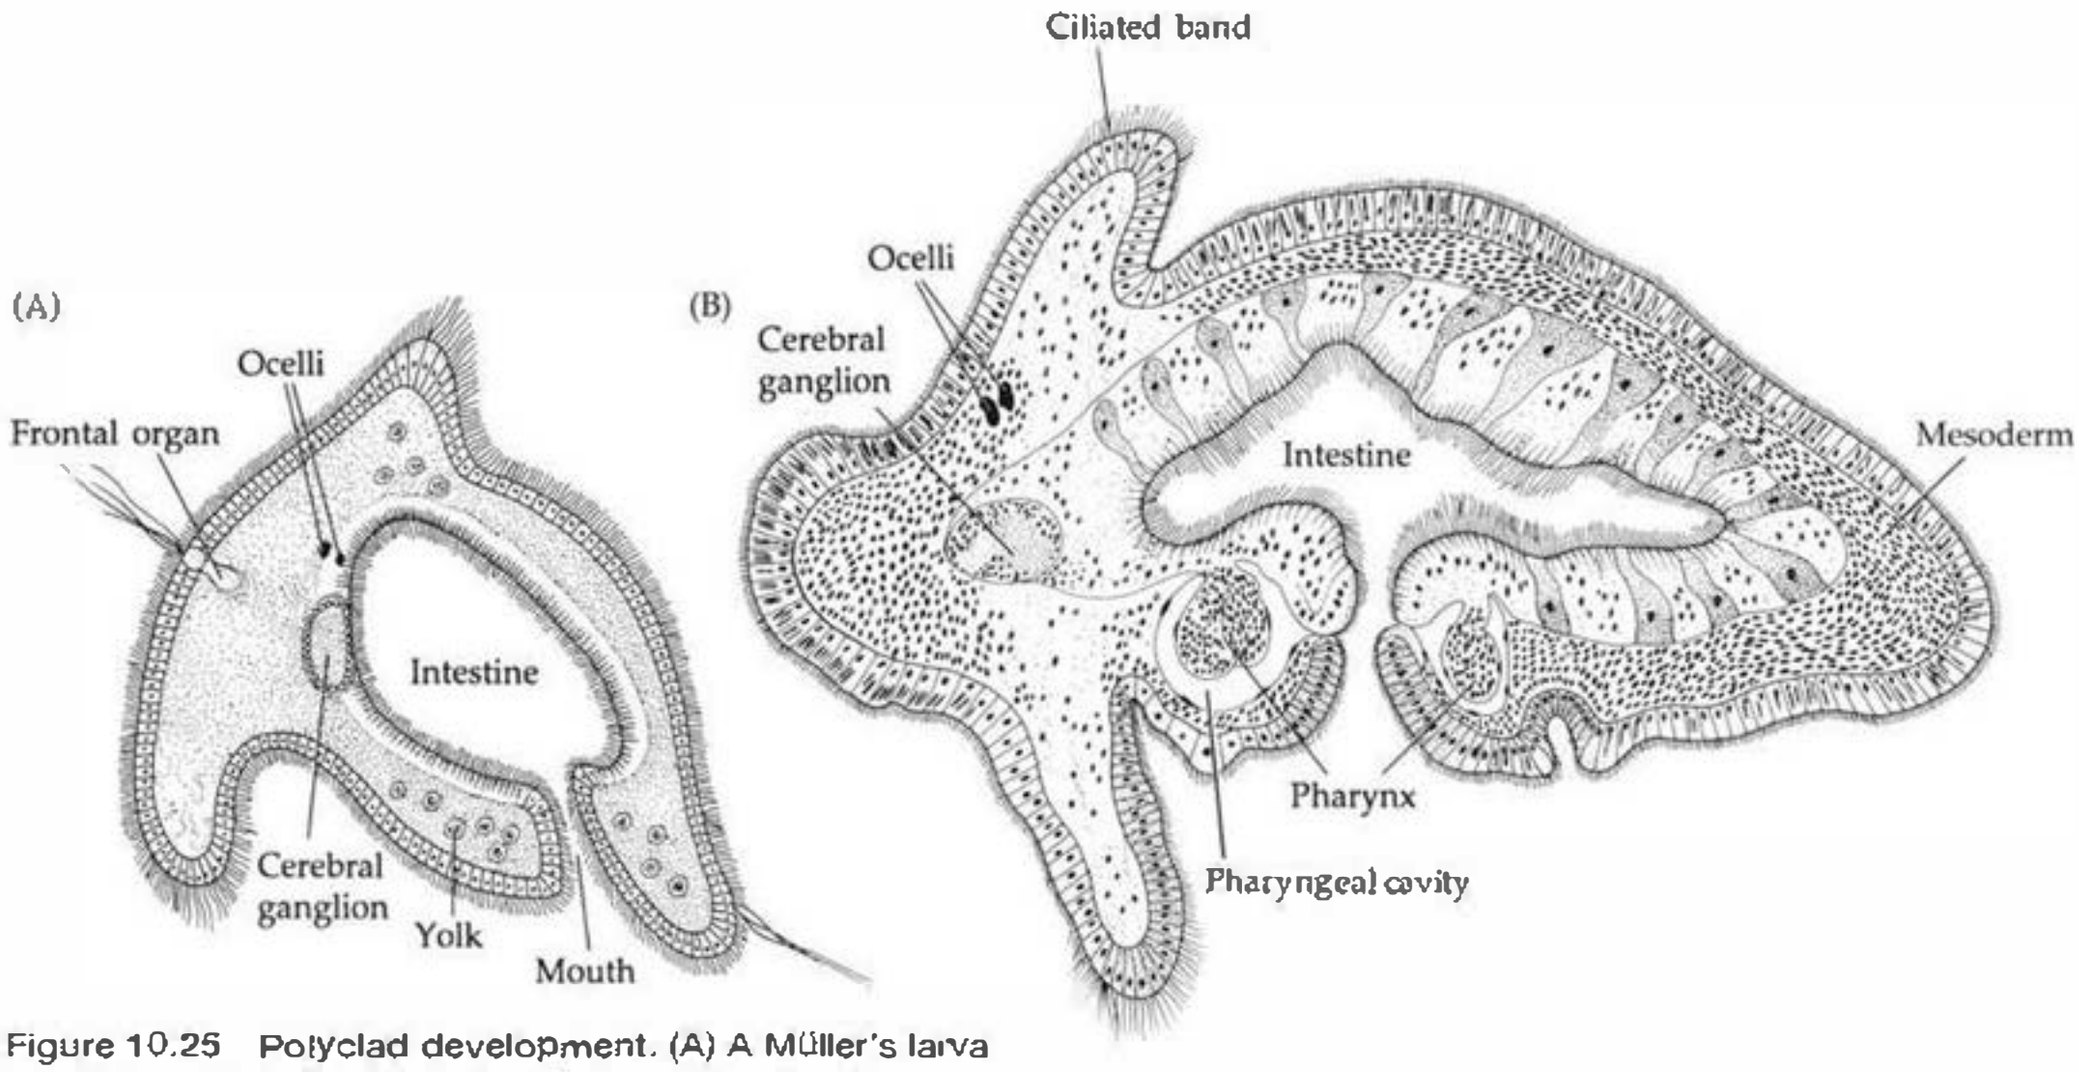

Figure 10.25 Polyclad development. (A) A Müller's larva (sagittal section). (B) A later larval stage, showing formation of the pharyngeal apparatus (sagittal section).

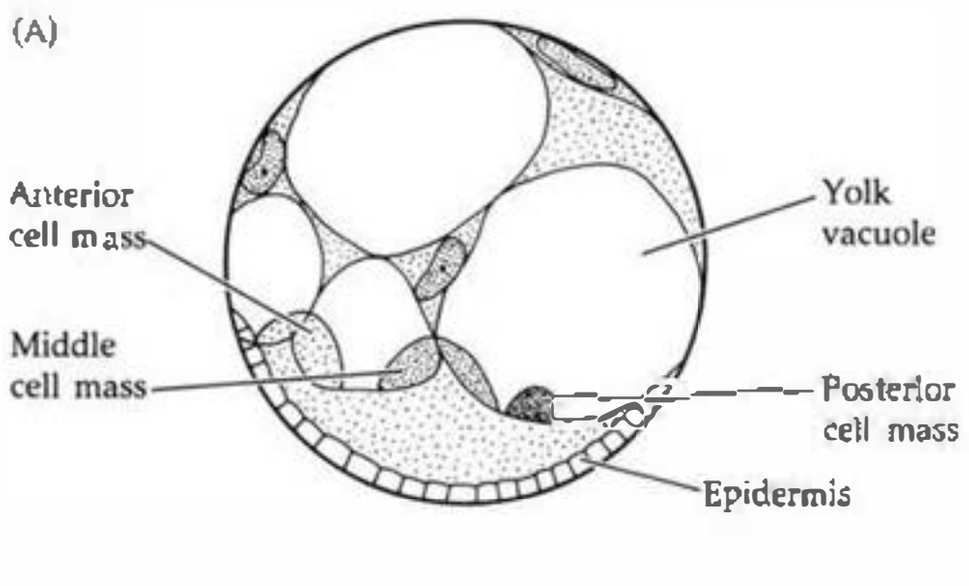
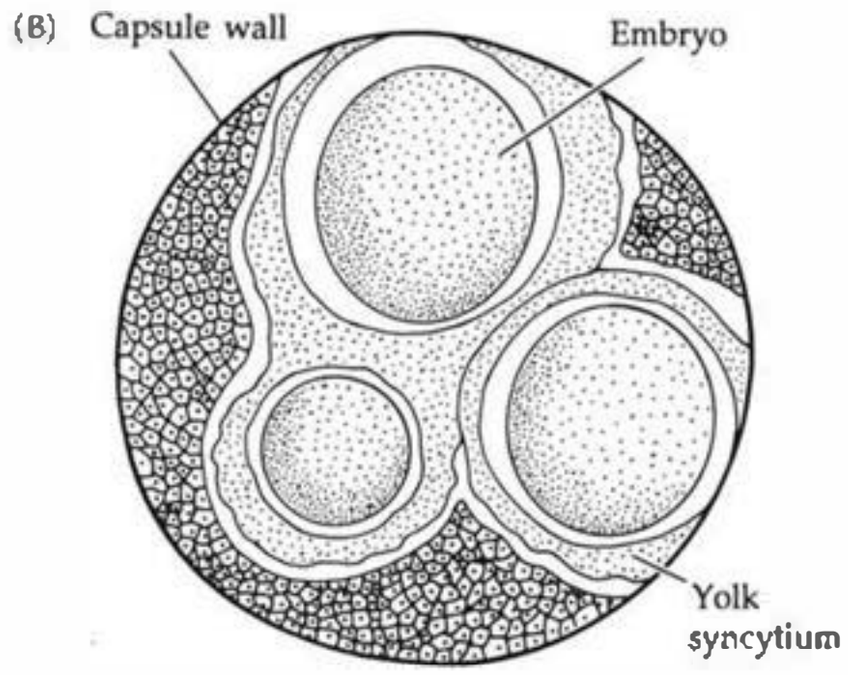
protostome-like, and this spiral cleavage has been well studied (especially in polyclads). Quartets of cells are produced, the fates of which may be described using Wilson's coding system (Chapter 5). By the end of spiral cleavage, the embryo is considered a stereoblastula, oriented with the derivatives of the first micromere quartet at the animal pole and the macromeres at the vegetal pole. The 1q cells become the anterior ectoderm, cerebral ganglion, and most of the rest of the nervous system. The 2q derivatives contribute to ectoderm and ectomesoderm, particularly that of the pharyngeal apparatus and its associated musculature. The remainder of the ectoderm and probably some ectomesoderm are formed from the derivatives of the third micromere quartet. The 4d cell, normally associated solely with endomesoderm in typical protostomes, divides to produce a $4d_1$ and $4d_2$ cell in polyclads. The $4d_1$ gives rise to endoderm and thus to the intestine; the $4d_2$ produces the endomesoderm from which the body wall and mesenchymal muscles, much of the mesenchymal mass, and most of the reproductive system are derived. The remaining cells (4a, 4b, 4c, and the 4Q) include most of the yolk and are incorporated into the developing archenteron as embryonic food.

Gastrulation is by epiboly of the presumptive ectoderm derived from some of the cells of the first three micromere quartets. The ectoderm grows from the animal pole to the vegetal pole, surrounding the 4q and 4Q cells. At the vegetal pole the ectoderm turns inward as a stomodeal invagination, which later elaborates as the pharynx and connects with the developing intestine (Figure 10.25). As development proceeds, the embryo flattens, with the mouth directed ventrally, and hatches as a tiny flatworm. If development is indirect, the larva emerges about the time the intestine is hollowing

Because of the deposition of extracellular yolk with ectolecithal ova, the development of neoöphoran species is highly modified from the plan described above. Certain species of rhabdocoels and triclads have been most extensively studied, and the two groups differ—especially in the early stages. In both cases, cleavage is so distorted that cell fates and germ layer formation cannot easily be compared with the typical spiralian pattern. In the rhabdocoels, early cleavage leads to the formation of three masses of cells positioned along the presumptive ventral surface of the embryo beneath the mass of yolk (Figure 10.26A). The cell masses then produce a layer of cells that extends around to enclose the yolk. This covering thickens to several cell layers, the innermost eventually becoming the intestinal lining (and enclosing the yolk), the outermost becoming the epidermis. The anterior cell mass produces the nervous system, the middle cell mass the pharynx and associated muscles. The posterior cell mass forms the rear portion of the worm and the reproductive system.



Early development in triclads differs from that of other neoöphorans. During early cleavage, the blastomeres are loose within a surrounding mass of fluid yolk, a condition described as "blastomere anarchy." A few of the blastomeres migrate away from the others and flatten to produce a thin membrane enclosing a packet of the yolk including the remaining blastomeres (Figure 10.26B,C). These migrating blastomeres are often called hull cells, but the yolk-enclosing hull membrane they create can be variable and may not be



homologous among flatworm taxa. Additional yolk cells are produced as a syncytial mass around a group of developing embryos and encapsulated, as many as 40 per capsule. Through migration and differentiation of various blastomeres, each embryo forms a temporary intestine, pharynx, and mouth, through which it ingests the yolky syncytium. The embryonic mouth eventually closes and the wall of the embryo thickens to form anterior, middle, and posterior cell masses, whose fates are similar to those in rhabdocoels.

Sexual reproduction: Flukes Like the free-living flatworms, flukes are hermaphroditic and typically engage in mutual cross-fertilization. Self-fertilization occurs only in rare cases. There is a great deal of variation in the details of the reproductive systems among flukes, but most are built around a common plan similar to that in certain free-living flatworms (Figure 10.27). The male system includes a variable number of testes (usually many in the monogenean flukes and two in the digenean flukes), all of which drain to a common sperm duct that leads to a copulatory apparatus, usually an eversible cirrus. The lumen of the cirrus is continuous with that of the sperm duct, and their junction is frequently enlarged as a seminal vesicle. Prostatic glands are typically present, opening into the cirrus lumen near the seminal vesicle. All of these terminal structures are housed within a muscular cirrus sac, the contraction of which causes eversion of the cirrus as an intromittent organ (Figure 10.27C). The common genital pore opens ventrally near the anterior end of the animal and leads to a shallow atrium, usually shared by both the male and female systems. Many monogenean flukes have simpler male systems than that just described, often lacking much elaboration of the terminal structures and possessing a simple penis papilla rather than an eversible cirrus.

The female reproductive system (Figure 10.27B) usually bears a single ovary connected by a short oviduct to a region known as the **ootype**. The oviduct is joined by a yolk duct (= vitelline duct) formed by the union of paired ducts, which carry yolk from the multiple laterally placed yolk glands. A seminal receptacle is usually present as a blind pouch off the oviduct. Extending anteriorly to the genital atrium is a single uterus, which is sometimes modified as a **vagina** near the female gonopore.

Sperm are produced in the testes and stored prior to copulation in the seminal vesicle (Figure 10.27C). During mating, two flukes align themselves such that the cirrus of each can be inserted into the female orifice of the other. Sperm, along with semen from the prostatic glands, are ejaculated into the female system by muscular contractions. The sperm move to, and are stored within, the seminal receptacle, and the mates separate. As eggs pass through the oviduct to the ootype, they are fertilized by sperm released from the seminal receptacle into the oviduct.

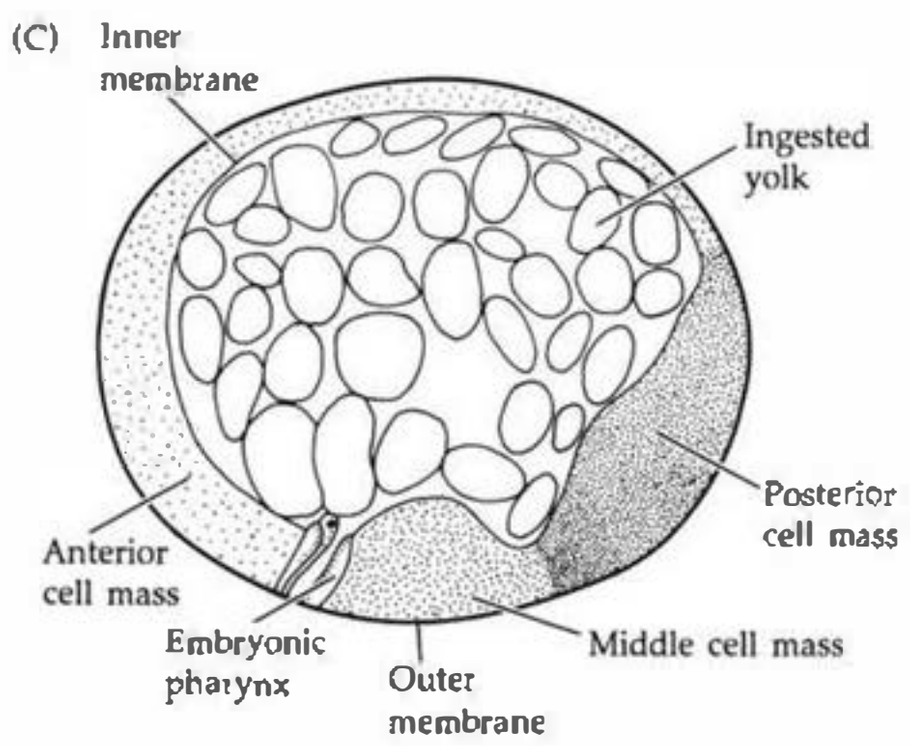


Figure 10.26 Neoöphoran development. (A) The embryo of a typical rhabdocoel has three cell masses with large, vacuolated external yolk cells. (B) A triclad egg capsule containing three embryos surrounded by yolk syncytium. (C) This single triclad embryo has ingested the yolk through the temporary embryonic pharynx, and shows the three cell masses.

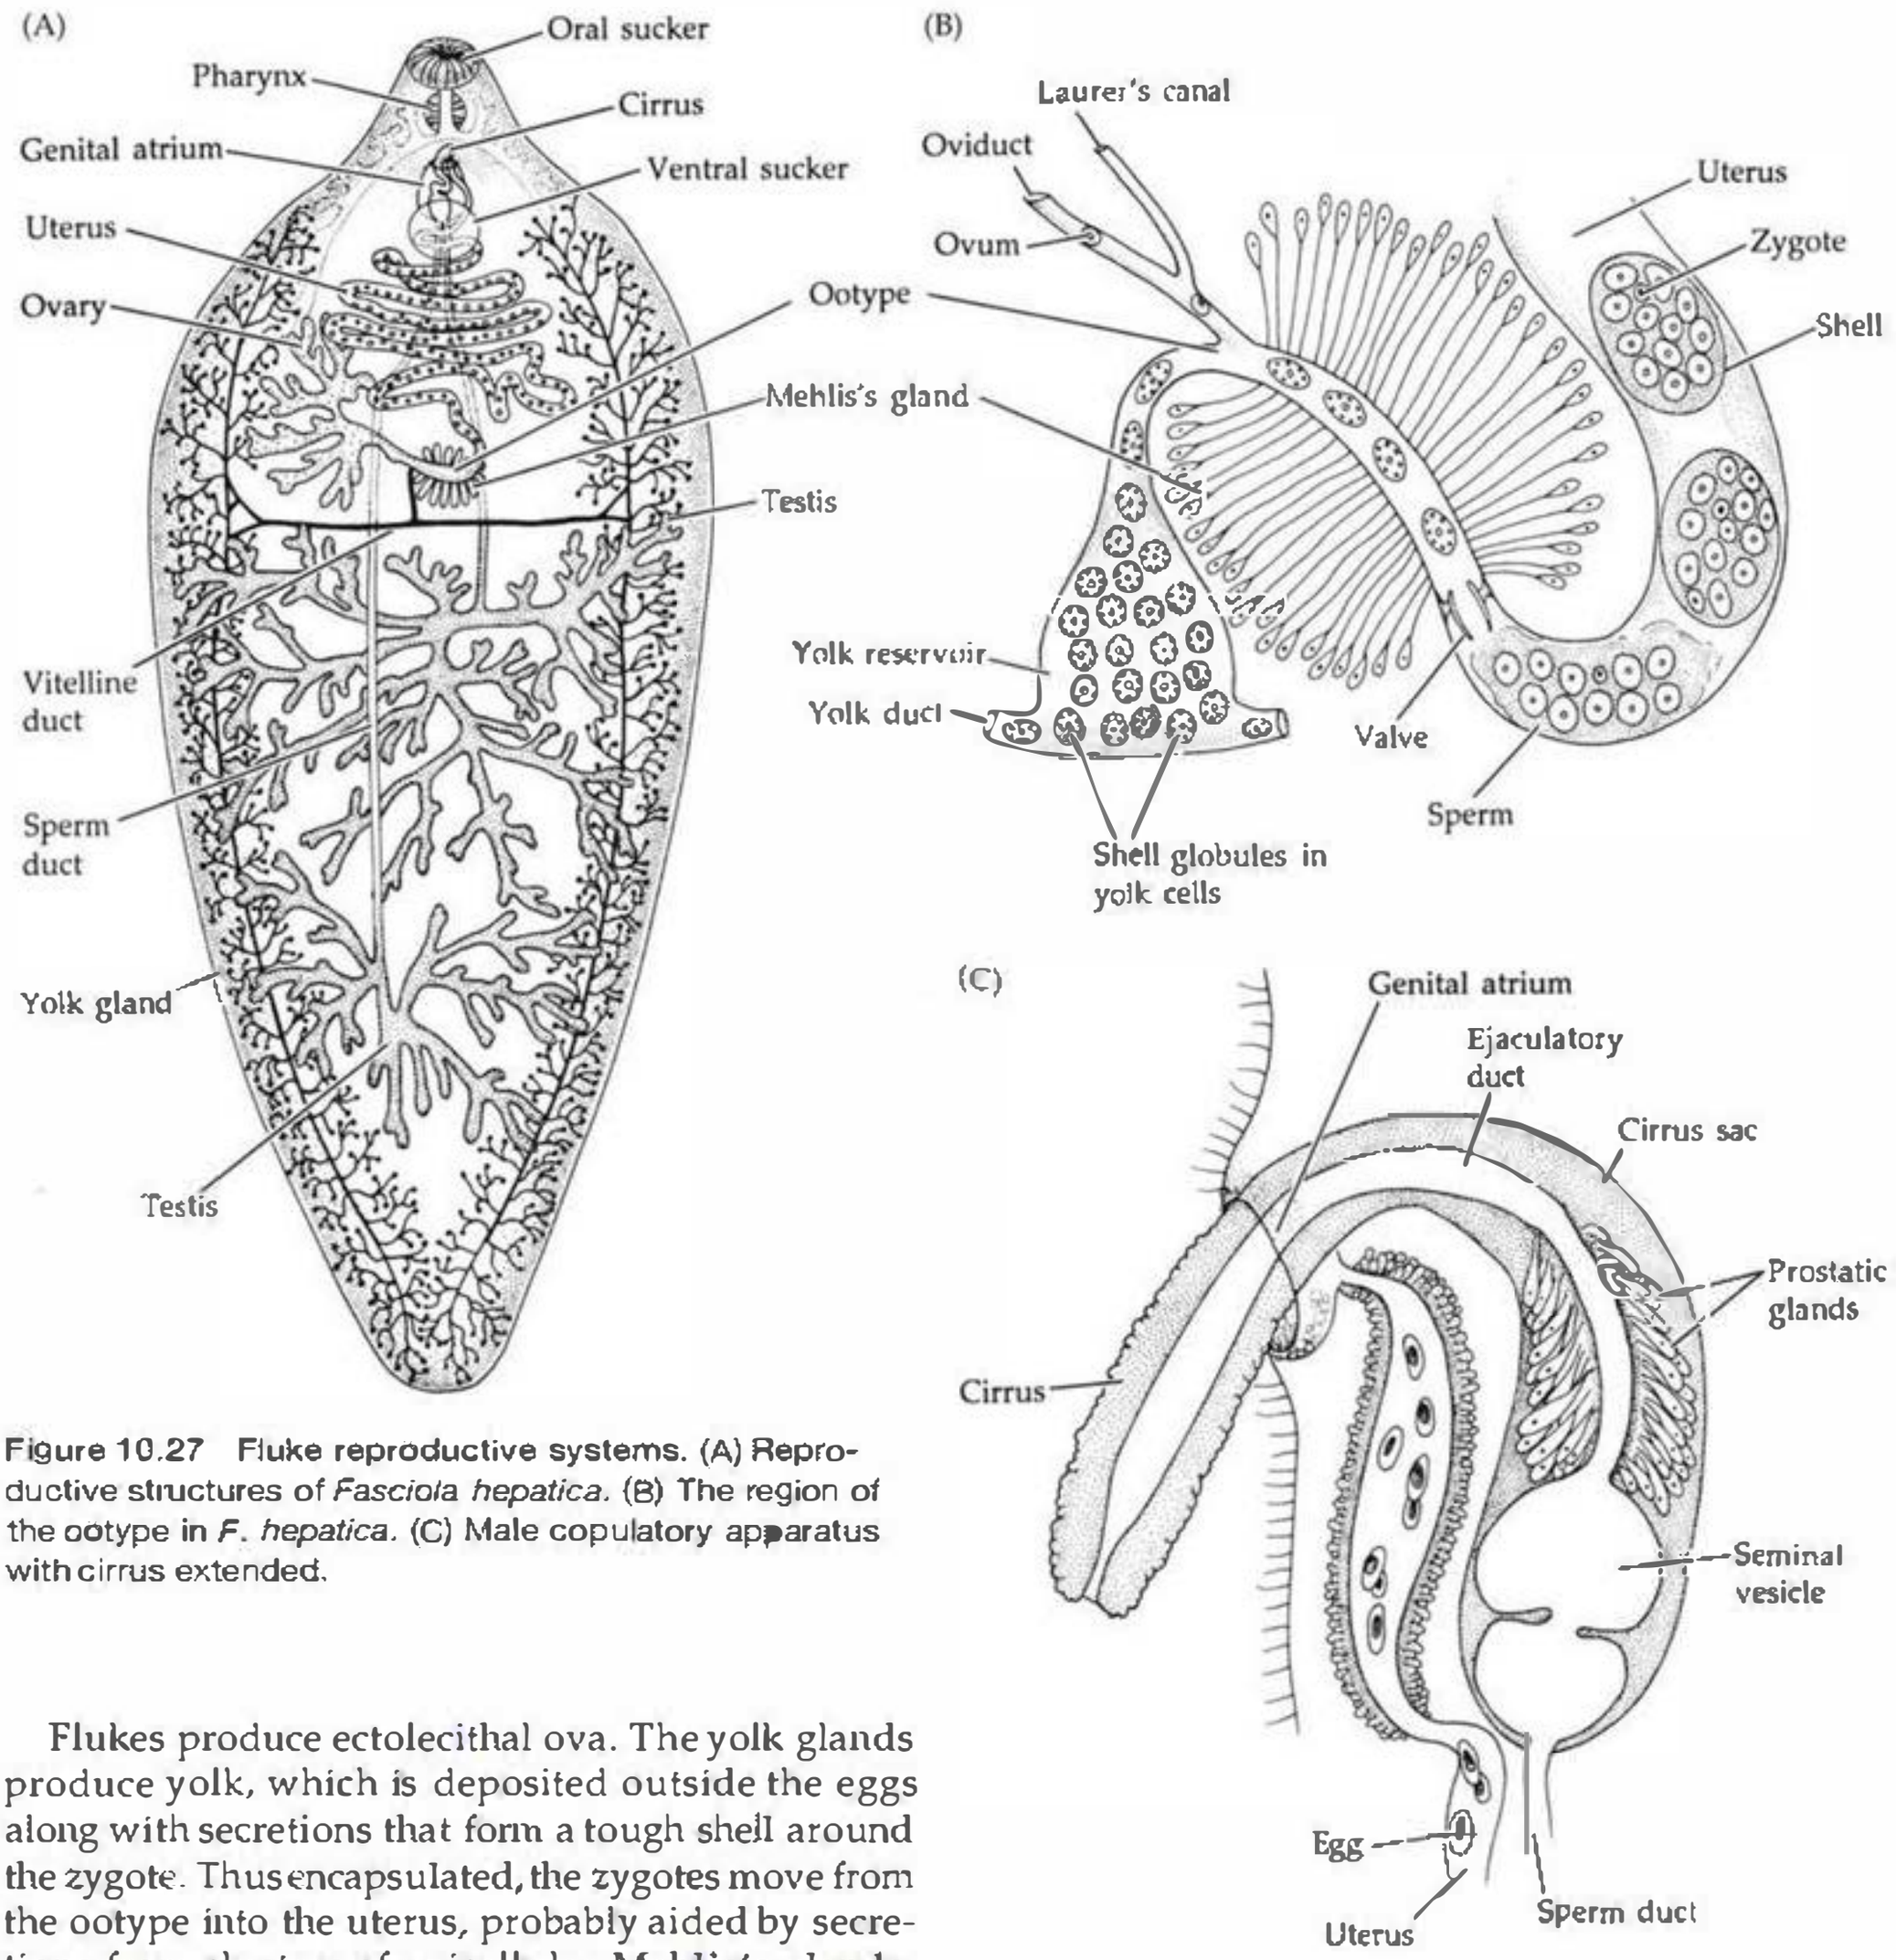

Figure 10.27 Fluke reproductive systems. (A) Reproductive structures of *Fasciola hepatica*. (B) The region of the ootype in *F. hepatica*. (C) Male copulatory apparatus with cirrus extended.

Flukes produce ectolecithal ova. The yolk glands produce yolk, which is deposited outside the eggs along with secretions that form a tough shell around the zygote. Thus encapsulated, the zygotes move from the ootype into the uterus, probably aided by secretions from clusters of unicellular Mehlis's glands. The zygotes may be stored within the uterus for various lengths of time prior to release through the female gonopore.

Some flukes possess an additional canal that arises from the oviduct and serves as a special copulatory duct. This duct, called Laurer's canal, opens on the dorsal body surface and receives the male cirrus during mating. A few polyclad and triclad free-living flatworms also possess a similar copulatory duct.

High fecundity is a general rule among parasites, and the flukes are no exception. The dangers of complex life cycles and host location result in extremely high mortality rates that must be offset by increased zygote production or asexual processes. Flukes may produce as many as 100,000 times as many eggs as free-living species.

The early stages of development in flukes are usually highly modified because of the ectolecithal nature of the ova. In species where little yolk is present, cleavage is holoblastic, and cell fates and germ layer formation have been traced accurately. Development is virtually always mixed, involving one or more independent larval stages.

The life cycles of monogenean flukes are relatively simple and involve only a single host. Most of the adults are ectoparasites on fishes, although some attach to turtles, various amphibians, and even some

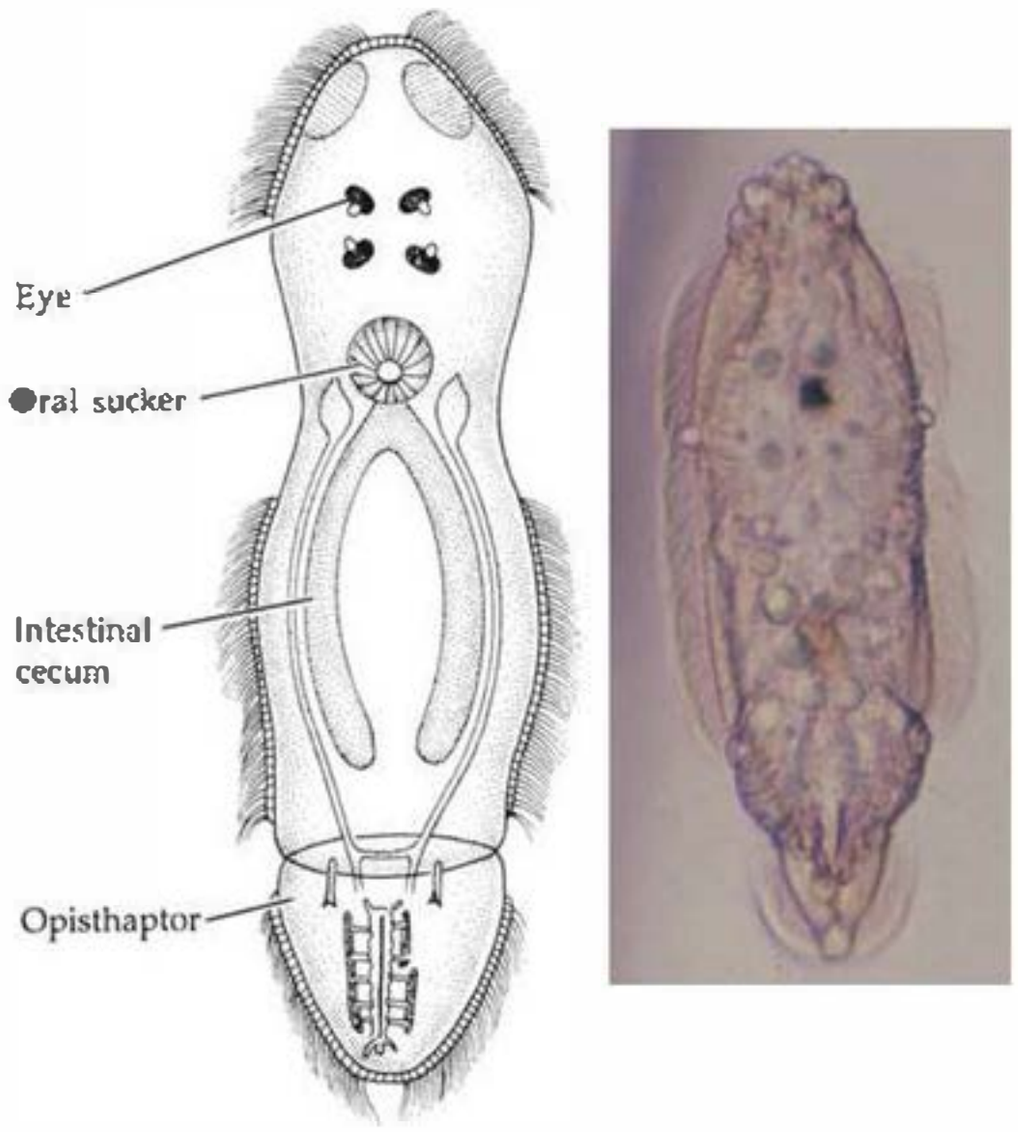

Figure 10.28 Photograph and drawing of an oncomiracidium larva of a monogenean fluke.

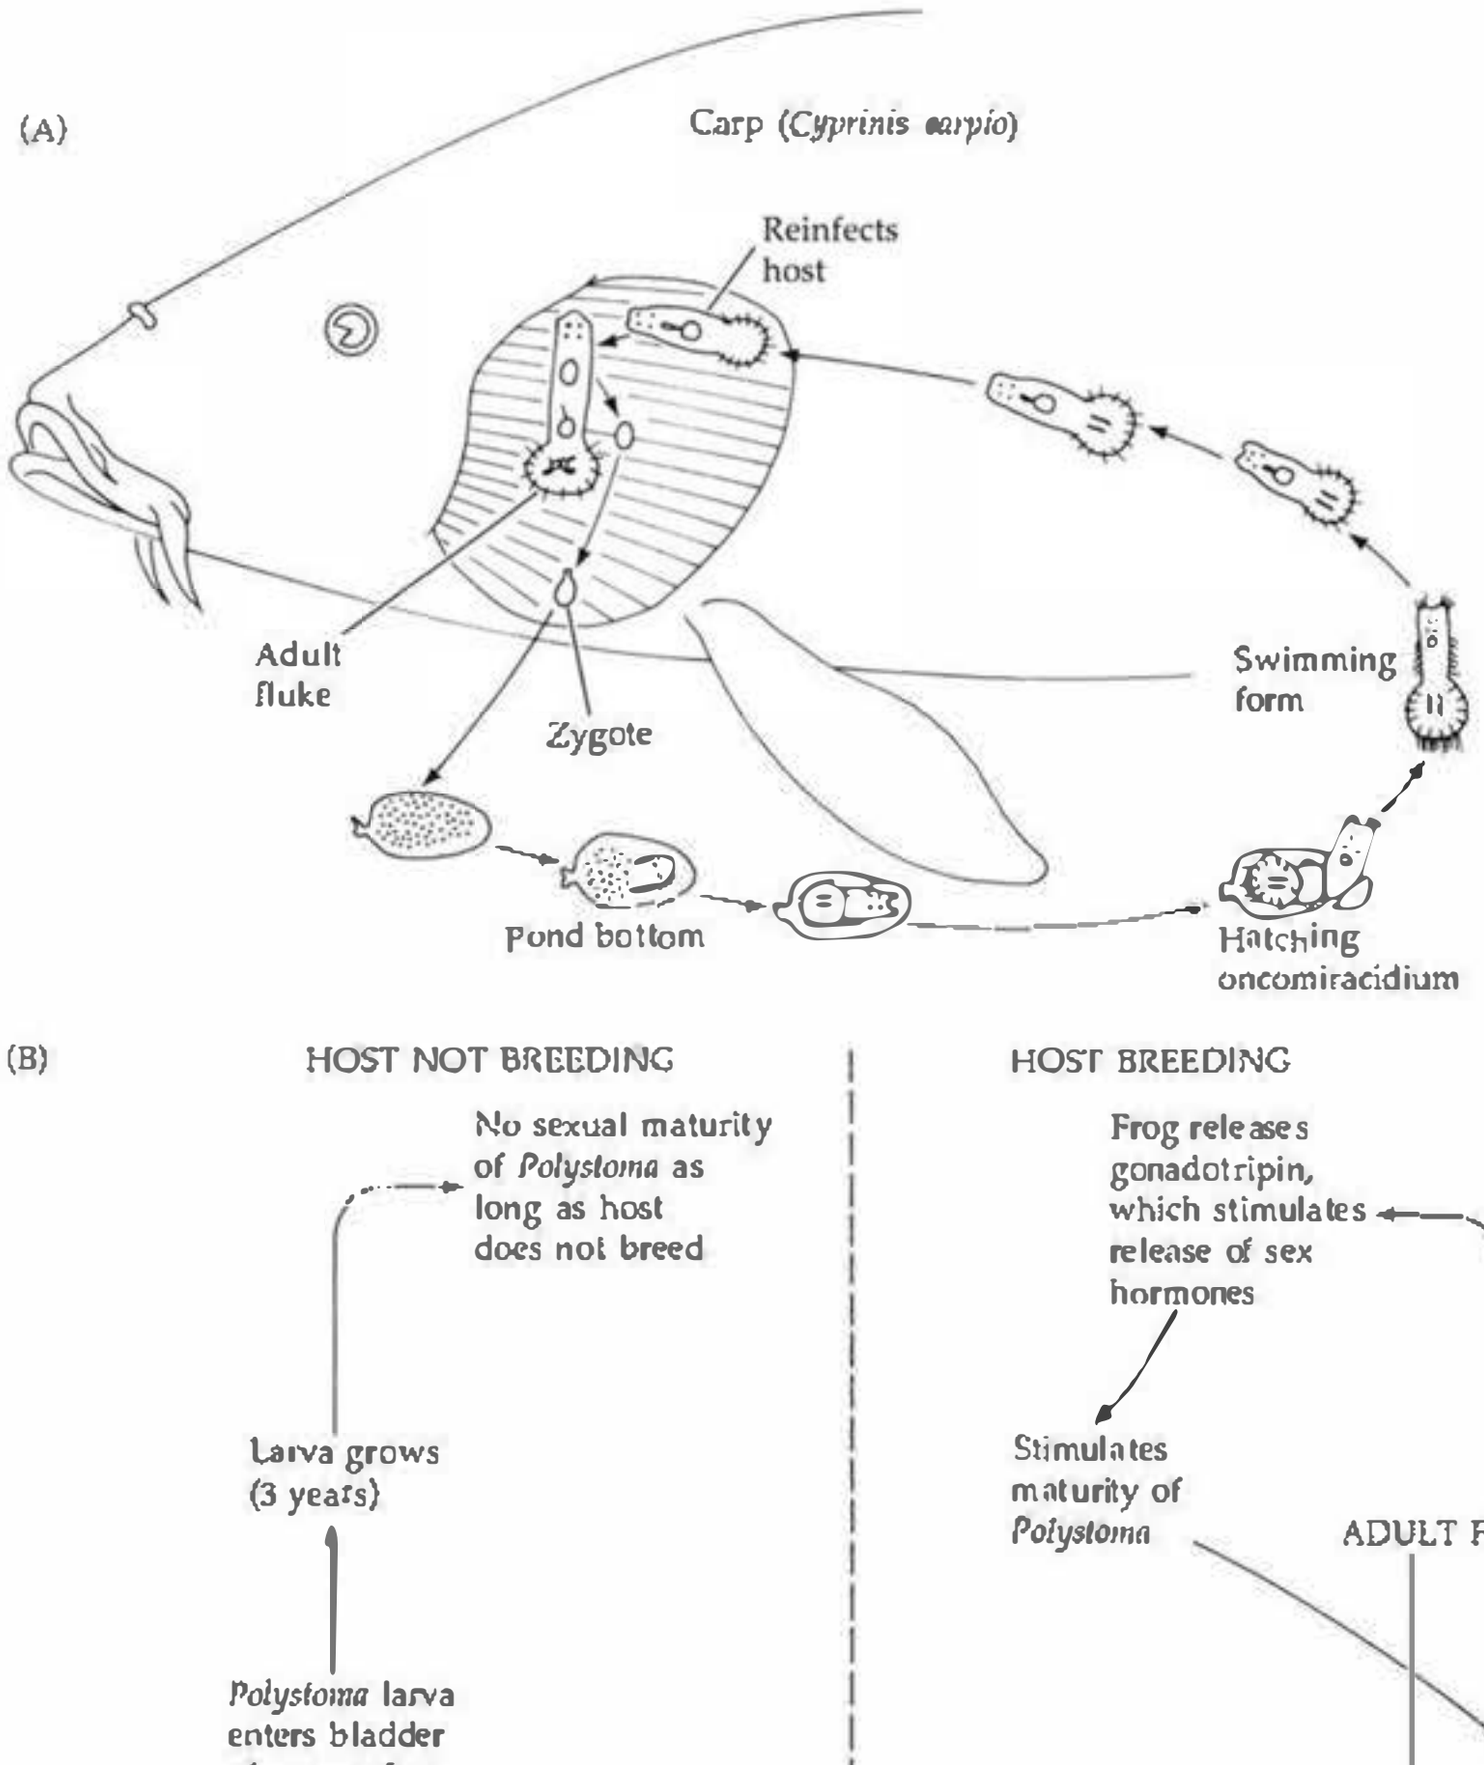

invertebrates. A few members of the Monogenea have taken up a mesoparasitic life style and reside in host body chambers that open to the environment (e.g., gill chambers, mouth, bladder, cloacal cavity). When the embryos are released from the uterus they often attach to the host tissue by means of special adhesive threads on the shell. Upon hatching, a larval stage called an **oncomiracidium** is released to the environment (Figure 10.28). The oncomiracidium is densely ciliated and swims about until it encounters another appropriate host. The cues larvae use to locate particular hosts may be tactile, chemical, or may vary depending on local densities of hosts and other larvae. The prohaptor and especially the opisthaptor develop during the larval stage and facilitate attachment to the new host, whereupon the larva metamorphoses to a juvenile fluke. It is about this time that the ciliated larval skin is shed and the tegument (= neodermis) forms. There are many variations on this basic life cycle among members of the class Monogenea; we present two in outline form in Figure 10.29.

Digenean flukes (orders Diplostomida and Plagiorchiida) include some of the most successful parasites known. A good deal of variation exists not only in adult morphology but also in life cycles (Figure 10.30). In general, eggs are produced by adult worms in their definitive host. After fertilization, the zygotes are eventually discharged via the host's feces, urine, or sputum. Upon reaching water they either are eaten by an intermediate host or hatch as free-swimming ciliated larvae called **miracidia**, which actively penetrate an intermediate host. Several asexual generations of larval forms occur in the intermediate host, eventually producing free-swimming forms called **cercaria**. The cercaria usually encyst within a second intermediate host, becoming **metacercaria**. Infection of the definitive host occurs when the metacercaria are eaten or, if there is no second intermediate host, when the cercaria penetrate directly. The larval skin is lost in the definitive host and the syncytial tegument develops.

In their adult stages, nearly all of the digenean flukes are endoparasites of vertebrates. They are known to inhabit nearly every organ of the body, and many are serious pathogens of humans and livestock. The intermediate hosts of all trematode flukes are gastropods, although some are known to use other invertebrates or even certain vertebrates. Most species of snails host one or more species of digenean flukes; the common California tidal flat gastropod *Cerithideoposis californica* serves as intermediate host to nearly two dozen species of digenean flukes, most of which ultimately infect shore birds. Almost all of the trematodes that infect *C. californica* castrate the snail, thus, theoretically, freeing up the host's energy reserves for their own purposes as they live out their life producing their own offspring. Space does not permit an account of more than a few of the life cycles of these worms. We begin below with a general case, using the Chinese liver fluke *Clonorchis sinensis* (order Plagiorchiida) as an example. This trematode is widespread in the Far East. It displays all the common stages found in the life cycles of most digenetic flukes. In northern Thailand a related fluke, *Opisthorchis viverrini*, has a similar life cycle and pathology.

The adult Chinese liver fluke usually lives within the branches of the bile duct in humans. This animal may reach several centimeters in length and in high numbers causes serious problems, including cholangiocarcinoma, a deadly cancer of the bile duct. While still in the uterus of the female reproductive tract, the zygotes develop to miracidia, each housed within its original egg case. Once released from the female system and passed out of the host with the feces, the miracidia are eaten by the first intermediate host, a snail of the genus *Parafossarulus*. The ciliated, swimming miracidium hatches from its egg case in the gut of the snail and migrates into the digestive gland. Here each miracidium becomes an asexually active form called a **sporocyst**, within which germinal cells become yet another larval form called a **redia**. Subsequently, germinal cells within the redia produce the cercaria larvae. This double sequence of rapid asexual reproduction results in perhaps 250,000 cercariae from each original miracidium!

The cercariae leave the snail, swim about, and enter the second intermediate host, the Chinese golden carp (*Macropodus opercularis*). The cercariae of *C. sinensis*

◀ **Figure 10.29** Life cycles of two monogenean trematodes. (A) The l fe cycle of *Dactylogyrus vastator*, a para- s te of freshwater cypr nodont f shes. (B) The life cycle of *Polystoma integerrimum*, a parasite in the urinary bladders of frogs. This fascinating life history demonstrates the dramat c influences exerted by the developmental stage of the host on the deve opment of the parasite. Under normal conditions, the adult f uke resides in the b ad- der of adult frogs. The fluke releases fertilized eggs into the water, where they hatch as oncomiracidia. These in turn become so-called gyrodactylid larvae, which attack the tadpole larva stages of the host. If the tadpole is very young, the fluke larvae attach to the external gills of the host and undergo precocious sexua maturat on (progenes s) to produce more zygotes; these f ukes die upon metamorphos s of the host. However, if the fluke larvae encounter more advanced tadpoles, they enter the branchial chambers and attach to the host's gills, where they res de until the host undergoes metamorphos s. At that time, the f ukes leave the branchial chamber m grate to the c oacal pore, and enter the host's bladder Here the flukes l ve and grow, but they do not become sexu- ally act ve until they are influenced by the host's sex hormones. Thus, sexual reproduction of the host and its parasites are synchronized—a pattern that guarantees avai ability of larval hosts for larval paras tes!

burrow through the skin of the fish and encyst in the muscle tissue as metacercaria. If the fish is insufficiently cooked and then eaten by a human, the metacercaria survive and are released from their cysts by the action of the host's digestive enzymes. Once freed, they migrate into the bile duct, metamorphose into juvenile worms, mature, and complete the cycle. Adult flukes can inhabit their hosts for many years, causing irritation and blockages. With this general life cycle in mind, we refer you to Figure 10.30 for a brief overview of two additional examples.

A critical point here are the strategies for survival displayed by these parasites. There is, of course, no assurance of finding the proper hosts a t the proper times, and mortalities are extremely high. The advantages of high specialization could be efficiency and reduced competition with other species once established in a proper host However, multiple infections and within-host competition can be intense, favoring a wide range of competitive adaptations among species, including in at least one trematode species (*Himasthla*), soldier and reproductive castes within molluscan hosts, similar to those observed in social insects. Such adaptations imply the existence of strong selection, acting on larval as well as adult life stages. As we have emphasized earlier, the compensation for such high mortality is high fecundity coupled with asexual reproduction—and therein lies the expense.

Sexual reproduction: Tapeworms That the "business of animals is to reproduce themselves" is a lesson the cestodes demonstrate well. Most of their time, energy, and body mass are devoted to the production of more tapeworms. Like other flatworms, cestodes are hermaphroditic and practice mutual cross-fertilization when mates are available. However, some cestodes are known to self fertilize. The orders Amphilinidea and Gyrocotylidea possess a single male and a single female reproductive system, whereas the more derived cestodes contain complete systems repeated within each proglottid. There is a good deal of variation in the details of these systems; the following is a generalized description of the male and female systems as they occur in a single proglottid of a cestode (Figure 10.31).

The testes are numerous. Some are scattered throughout the mesenchyme, but most are concentrat ed along the lateral margins. Collecting tubules lead from the testes to a single coiled sperm duct, which extends laterally (as a seminal vesicle) to a cirrus housed within a muscular cirrus sac. The male system empties into a common genital atrium.

The female system usually includes two ovaries from which an oviduct extends to an ootype surrounded by shell glands. The uterus is a branched blind sac extending from the ootype. A duct extends from the female gonopore in the genital atrium to the oviduct; its junction with the oviduct, near the tube, is swollen as a seminal receptacle The portion of the duct near the genital atrium is called the vagina. A diffuse yolk gland empties via a vitelline duct into the oviduct.

During mutual cross-fertilization the cirrus of each mate is inserted into the vagina of the other. Many tapeworms double back on themselves so that two pro glottids of the same worm crossfertilize; in some species, self-fertilization is known to occur within a single proglott d. Sperm are injected into the vaginal duct and are stored in the seminal receptacle. Eggs are fert. ized as they move through the oviduct from the ovaries to the ootype. Capsule material and yolk cells are deposit ed around each zygote, and the zygotes are moved into the uterus for temporary storage.

The reproductive systems mature and become func tional with age as they are moved more posteriorly along the body by the production of new proglottids. If mating has occurred, the proglottids toward the posterior end become filled with an expanded uterus engorged with developing embryos (Figure 10.31B). These proglottids eventually break free from the body and are lost from the host with the feces, although in some cases the proglottids release embryos inside the host and the embryos pass out with the feces. Early development of tapeworm embryos is drastically modified from the pattern seen in free-living flatworms and varies somewhat among different groups. However, like all Neodermata, after fertilization the ectolecithal ova of cestodes show no vestiges of spiral cleavage, and even germ layer for mation is often difficult or impossible to trace.

Figure 10.30 Life cycles of two digenean trematodes. (A) Life cycle of *Paragonimus westermani*, the human lung fluke (order Plagiorchiida). (B) Life cycle of the blood fluke *Schistosoma mansoni* (order Diplostomida), one of three species that causes schistosomiasis (bilharzia) in humans. Schistosomiasis is among the most widespread diseases in tropical areas of the world and is of major medical importance. Depending on the species of schistosome involved, various organs of the body are affected (e.g., blood vessels, urinary bladder, liver). In *S. mansoni*, larvae are disseminated from freshwater snails; when people come into contact with the contaminated water, the larvae attach to and penetrate the skin. The resulting disease, bilharzia or schistosomiasis, afflicts approximately 67 million people in Africa and South America. (C) Trematode redia. (D) Trematode cercariae from the California horn snail (*Cerithideoposis californica*).

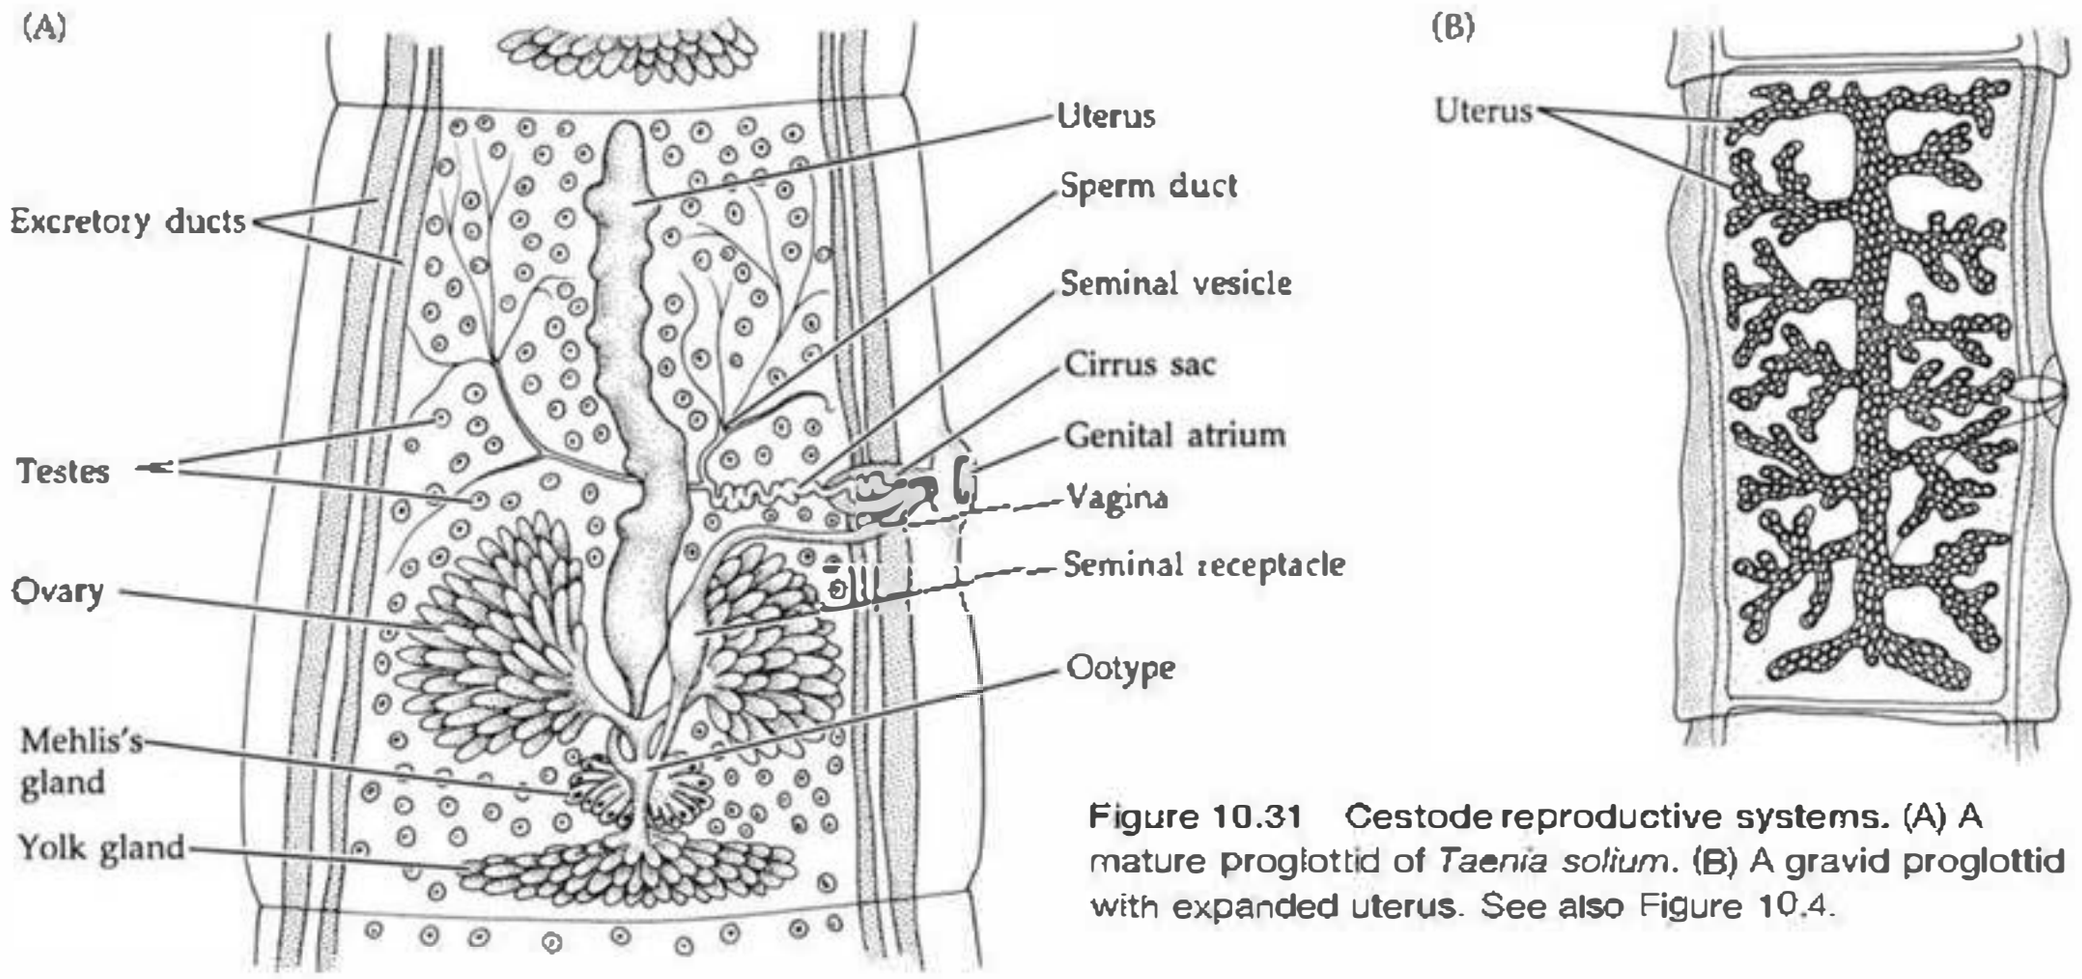

Figure 10.31 Cestode reproductive systems. (A) A mature proglottid of *Taenia solium*. (B) A gravid proglottid with expanded uterus. See also Figure 10.4.

Most adult tapeworms live in the digestive tracts of vertebrates and usually require one or more intermediate hosts to complete their life cycles. A few can complete their life cycle in a single host. Depending on the number of hosts and other factors, tapeworm life cycles are quite variable, and we describe only two examples.

Taenia saginata (order Cyclophyllidea) is known as the beef tapeworm, since cattle are the intermediate host. The adults, which may exceed 1 m in length, reside in human small intestines (Figure 10.32A). As proglottids mature, they are released in the host's feces. The fertilized eggs break free into the environment as the proglottids disintegrate. By this time each zygote has developed to a stage called an oncosphere surrounded by a resistant coat called an **embryophore**, which allows the embryo to remain in the environment for two or three months. Usually six tiny hooks are evident in the embryo; thus the oncosphere is sometimes called a **hexacanth larva**.

If grazing cattle ingest the oncosphere, it is released from its covering, the hexacanth larva penetrates the intestinal wall using its hooks, and is carried by the circulatory system to the cow's skeletal muscle. Here the hexacanth develops into a stage called the cysticercus, or bladder worm, which encysts in the connective tissue within the muscle of the intermediate host. Each cysticercus contains an invaginated developing scolex. If humans eat raw or poorly cooked infected beef, the scolex evaginates and attaches to the lining of the new host's small intestine, where the adult worm grows and matures. (Another tapeworm, *Taenia solium*, utilizes pigs as its intermediate host and follows a similar life cycle.)

The life cycles of some cestodes involve two or more hosts, such as that of *Diphyllobothrium latum*, the so-called broad fish tapeworm (order Diphyllobothriidea) (Figure 10.32B). Nearly any fish-eating mammal, including humans, can serve as the definitive host for this tapeworm. Encapsulated zygotes are released from mature proglottids and shed in the host's feces. After one or two weeks in water, the embryos develop to the oncosphere (hexacanth) stage. At this time, each oncosphere is encased in a ciliated embryophore and it hatches as a free-swimming larva called a coracidium. To successfully continue the life cycle, the coracidium must be eaten by the first intermediate host, a copepod (Crustacea). The cilia are shed and the released hexacanth larva bores through the gut wall into the host's body cavity, where it develops into a procercoid stage. Certain species of freshwater fish can serve as the second intermediate host. The fish eats the copepod, the procercoid bores through the gut and into the fish's muscle tissue, and there it grows into a segmented plerocercoid stage, complete with a tiny scolex. When a human consumes raw or undercooked infected fish, the plerocercoid attaches to the intestinal wall and matures.

Platyhelminth Phylogeny

Ideas about the origin of flatworms, their relationships to other phyla, and evolution within the group have been debated since early in the nineteenth century. The lack of a robust fossil record and their extreme anatomical simplicity have made morphology-based phylogenetic analysis difficult—there is a paucity of reliable characters that might identify and differentiate clades. In fact, unambiguous synapomorphies that define the phylum Platyhelminthes itself have yet to be identified. Platyhelminth fossils consist mainly of structures left on hosts by parasitic species, or occasional evidence

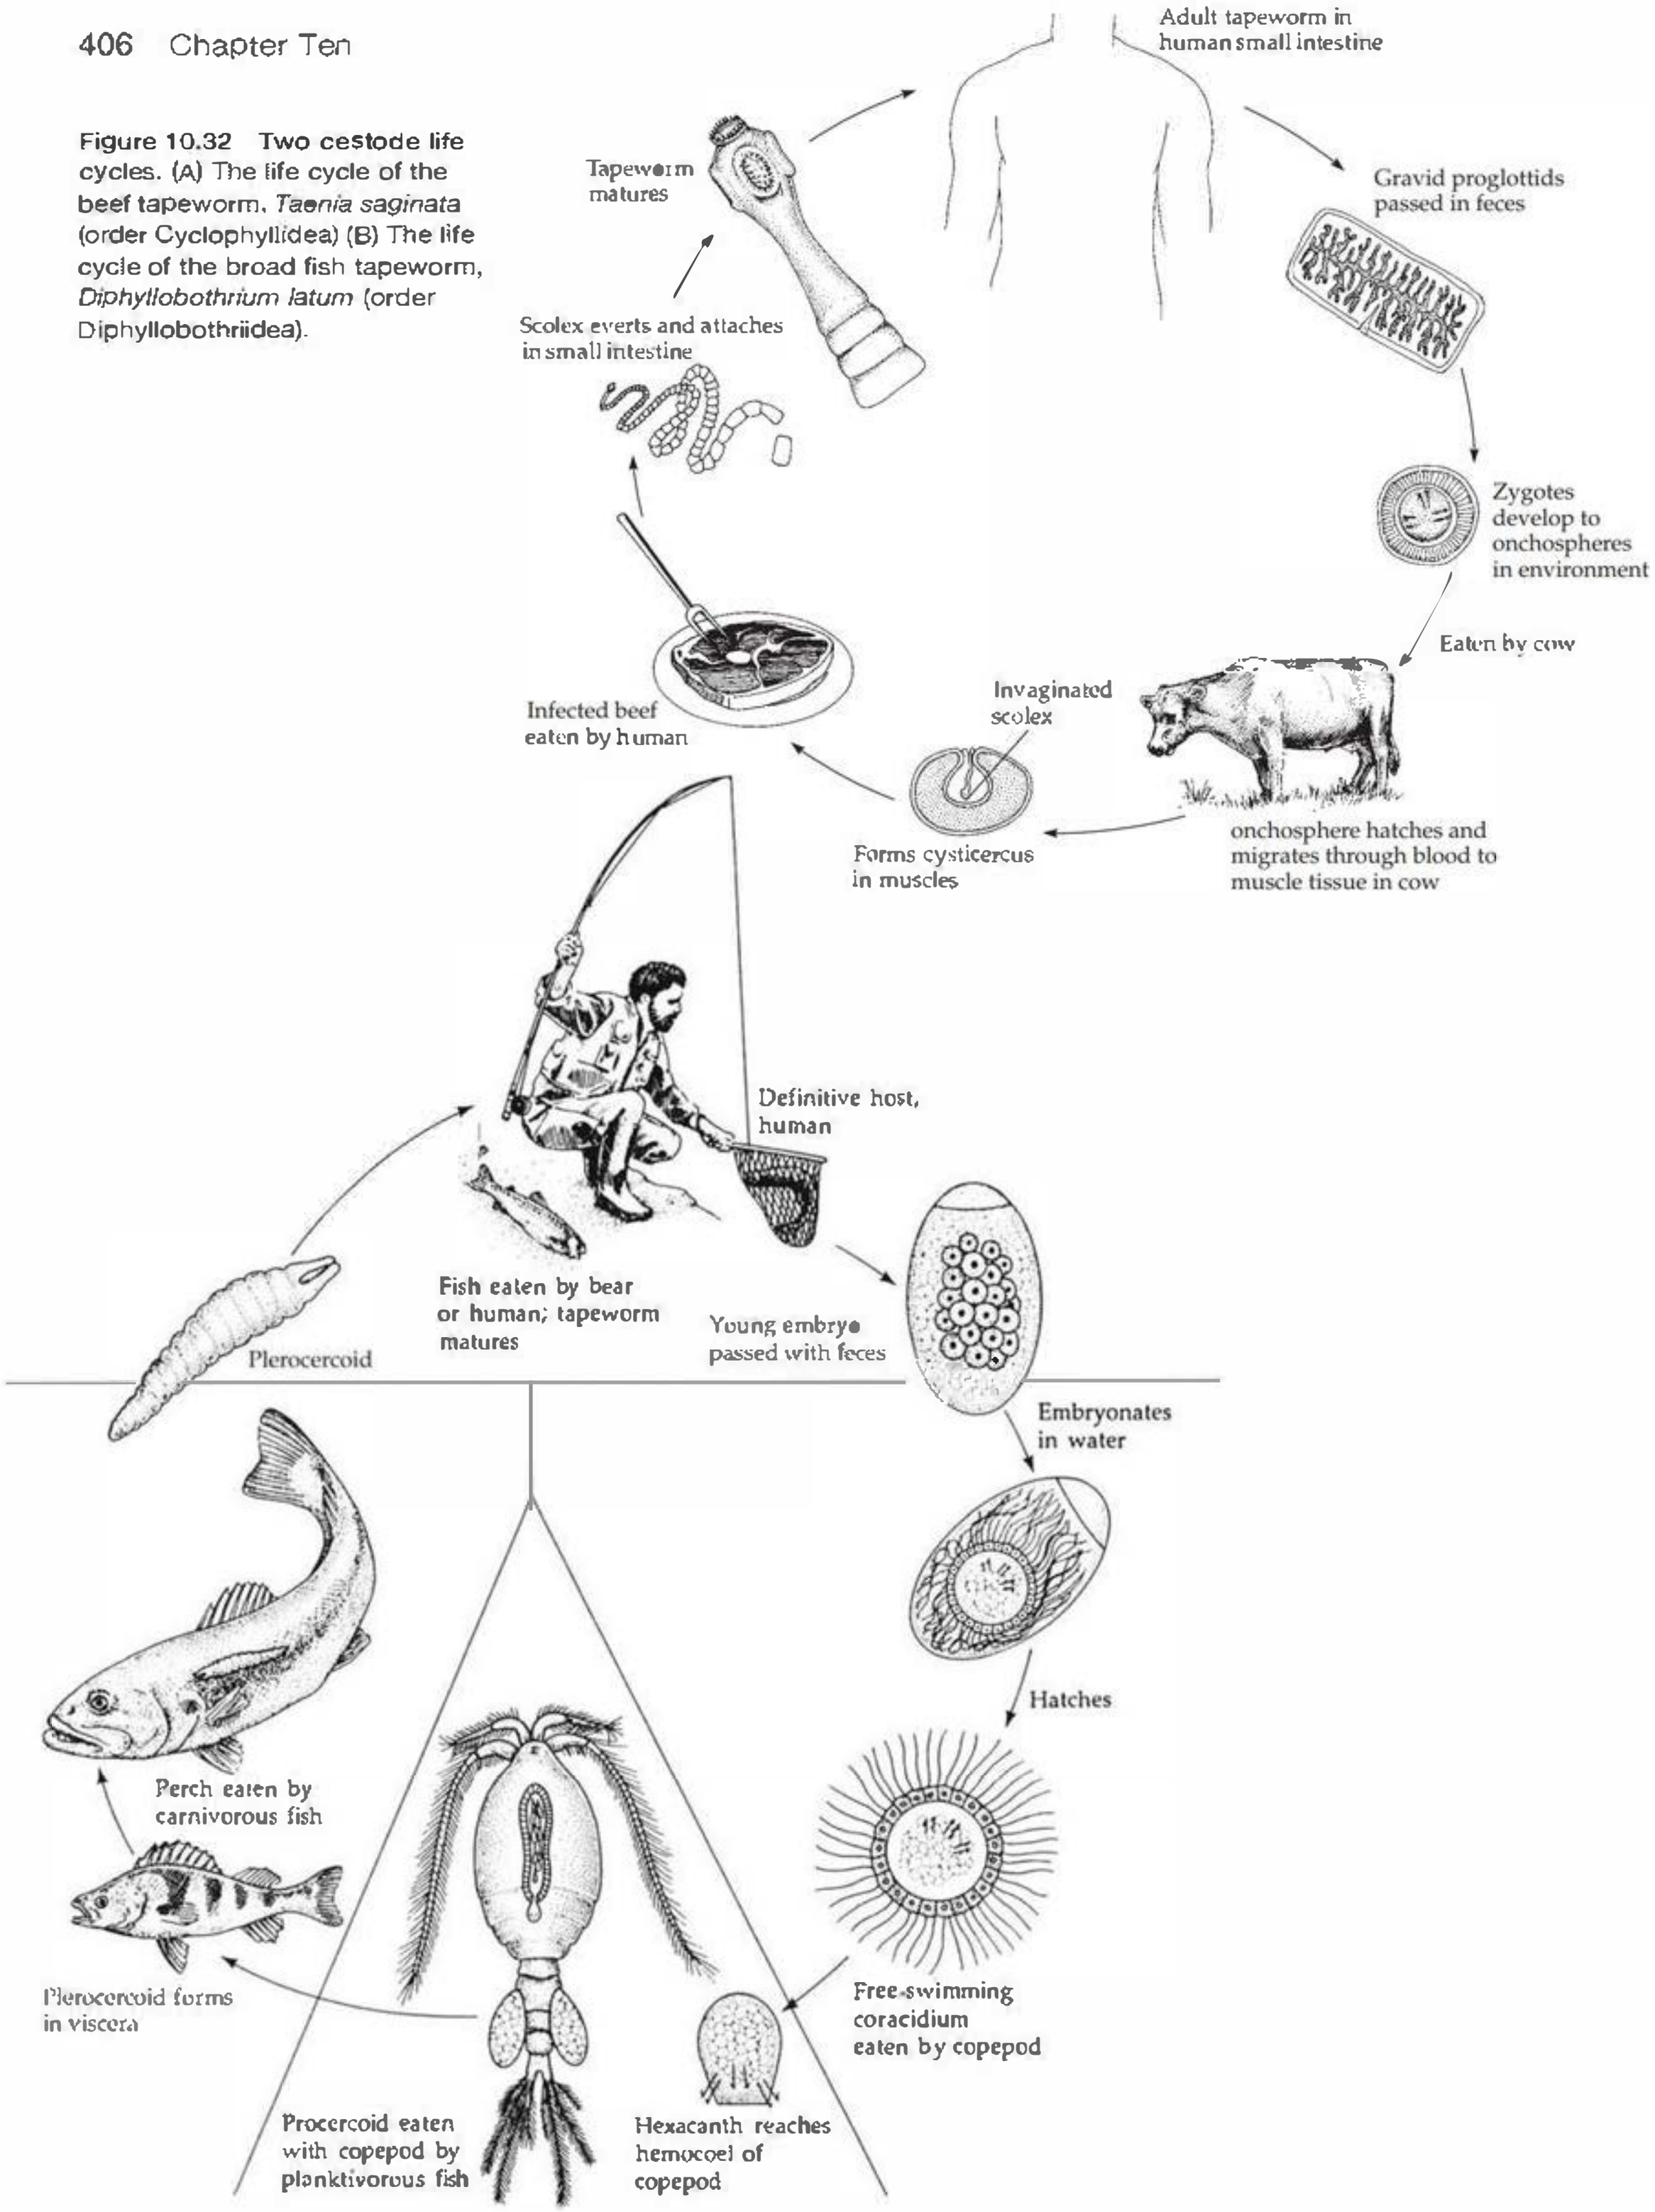

Figure 10.32 Two cestode life cycles. (A) The life cycle of the beef tapeworm, *Taenia saginata* (order Cyclophyllidea) (B) The life cycle of the broad fish tapeworm, *Diphyllobothrium latum* (order Diphyllobothriidea).

from host coprolites, although some trace fossils from the early Paleozoic have been assigned to this phylum.

In the twentieth century, several popular hypotheses concerning the origin of flatworms (or acoels) appeared. The ciliate-to-acoel hypothesis (discussed in Chapter 5 as part of the syncytial theory of Hadzi and Hansen) has been abandoned by most modern zoologists. Another hypothesis was called the ctenophore–polyclad theory, which suggested the ctenophores gave rise to polyclad flatworms. This creative scenario envisioned a flattened ctenophore that assumed a benthic, crawling lifestyle, with the mouth directed against the substratum. By reducing the tentacles and moving them forward along with the apical sense organ, a bilateral condition was achieved. Couple these events with increased gut branching and the formation of a plicate pharynx, and a polyclad body plan is approximated—at least on paper. This hypothesis, too, no longer has much support.

We can safely assume that the original flatworm was free-living, although not necessarily assignable to any extant order. Peter Ax, Tor Karling, and Ulrich Ehlers have presented various versions of this "turbellarian archetype." These hypothetical ancestral flatworms are envisioned as having had a simple pharynx and a saclike gut without diverticula, such as seen in modern Catenulidea and Macrostomorpha (Figure 10.33A,B). There is also general agreement that the primitive flatworm was probably an archoöphoran with endolecithal ova, spiral cleavage, and a single-layered, completely ciliated epidermis.

In 1963, Ax suggested that flatworms might actually be more highly derived (in the protostome line) than previously thought, and that they might represent a series of reductions from a vermiform coelomate ancestor—a case of extreme reduction by paedomorphosis (the retention by adult individuals of traits seen in young), perhaps through neoteny, wherein the somatic development of adults is slowed or delayed. The idea had some support, especially with regards to the acoelomorphs (then included in Platyhelminthes). There was also an idea that platyhelminths arose through progenesis (a type of paedomorphosis in which sexual development of larvae or young is accelerated), from developmental stages of early protostomes prior to the embryonic appearance of the coelomic cavities—that is, rapid maturation of larval or other stages that had solid bodies or still contained the blastocoel. You are probably beginning to see how zoologists have struggled to understand what flatworms "really are"!

Fortunately, modern gene sequence analyses have begun to shed new light on the phylogeny of flatworms, including the removal of the Acoelomorpha (now in the phylum Xenacoelomorpha) and broad acceptance that platyhelminths comprise two major clades, Catenulida and Rhabditophora. Molecular phylogenies also support the monophyly of the

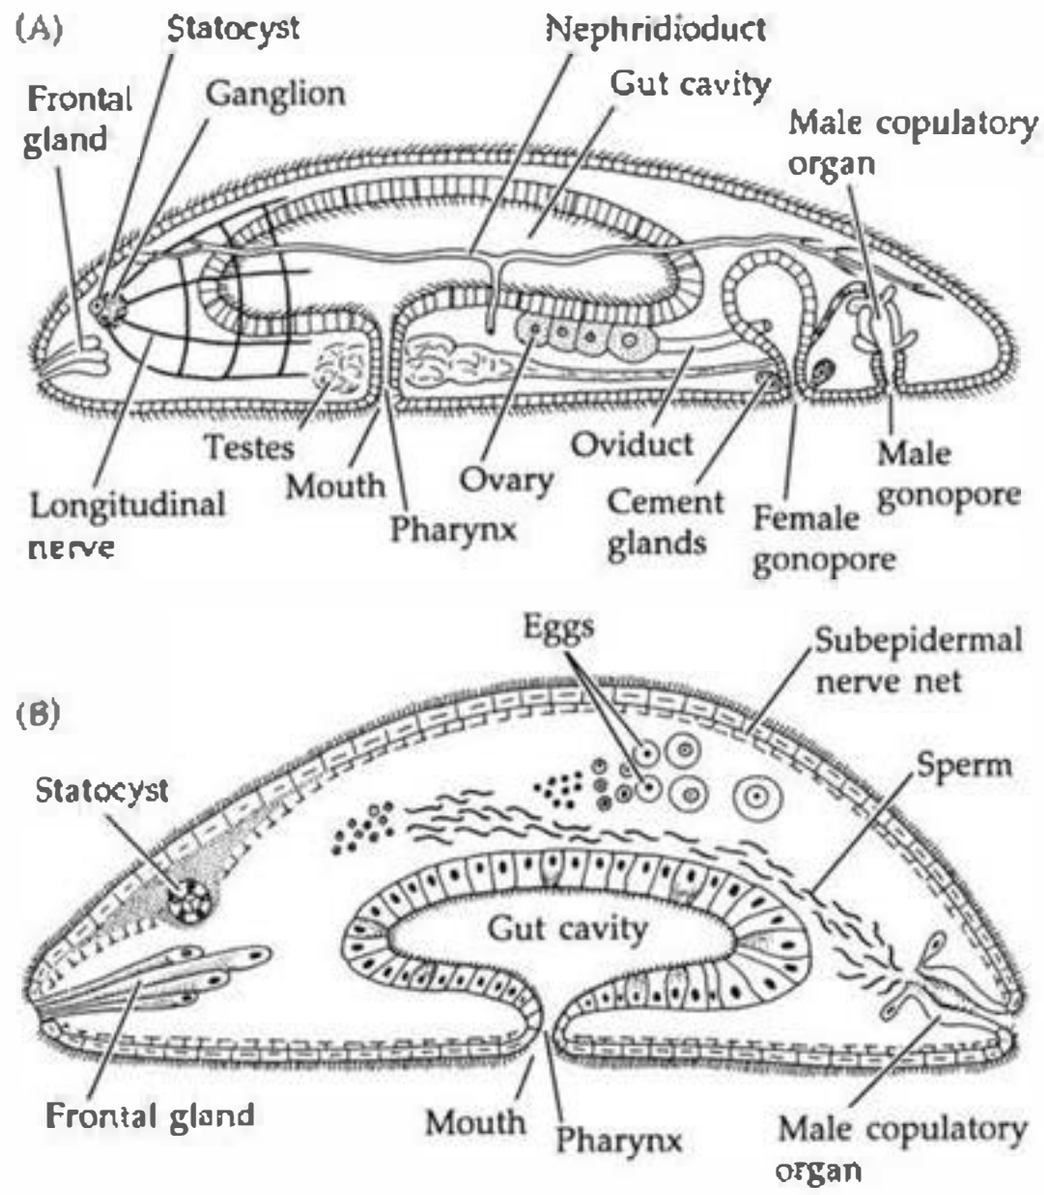

Figure 10.33 Two examples of hypothetical "turbellarian" archetypes. (A) Macrostomid-like archetype suggested by Peter Ax. (B) Archetype proposed by Tor Karling.

Neodermata and also of its three major clades—Trematoda, Monogenea, and Cestoda. Mitochondrial DNA analyses have suggested Monogenea is basal in the Neodermata clade, but 18S rRNA and nuclear "genomic" analyses (and morphology) studies suggest Trematoda is basal, and that Monogenea + Cestoda comprise a sister group. This uncertainty is shown by a trichotomy in our phylogenetic tree (Figure 10.34). Importantly, molecular phylogenies clearly place the flatworms within the protostome clade, and generally position them within the Spiralia. Therefore, while possibly somewhat removed from the base of the bilaterian tree, the morphological simplicity of platyhelminths likely represents an ancestral condition, and is less likely to be due a secondary loss or reduction of complex characters such as the coelom or segmentation.

The availability of genomic datasets for platyhelminths is uneven. High-quality reference genomes exist for some parasites such as *Schistosoma mansoni* and *Echinococcus multilocularis*, and detailed analyses of *S. haematobium* and *Taenia solium* as well as partial genomes of a couple dozen tapeworms, and about the same number for flukes, now exist. However, few if any free-living platyhelminths have been fully sequenced. A draft genome of *Macrostomum lignano* is currently underway, and a genomic compilation of the triclad *Schmidtea mediterranea* has been attempted but is not yet fully published. In the fluke *Schistosoma*, two

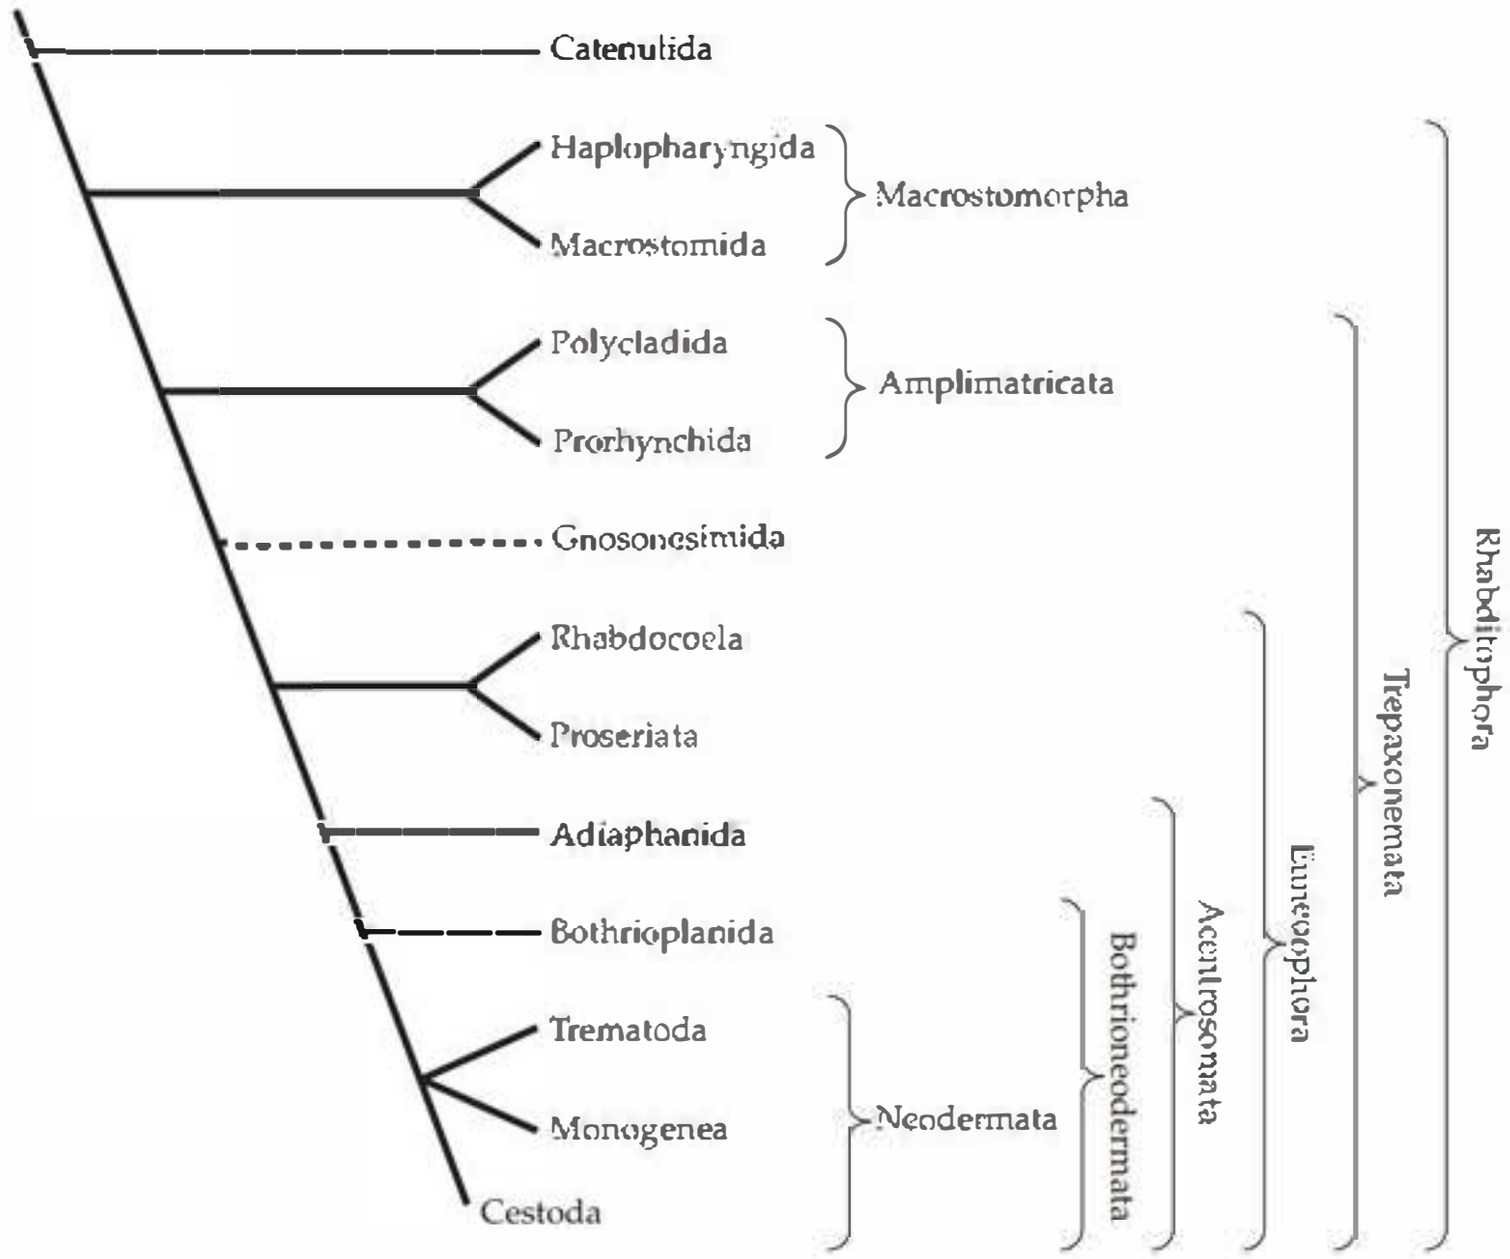

Figure 10.34 An evolutionary tree showing the relationships within Platyhelminthes, based on a consensus of molecular and morphological phylogenetics. Note that the order Proseriata, formerly classified among the Polycladidea, is now removed to the large unresolved clade classified as the polyphyletic subclass Eulecithophora. The relationships of the three Neodermata infraclasses also remain unresolved. See text for further details.

distinct mitochondrial gene orders have been found. However, all other parasitic species that have been examined have a similar gene order. The gene orders in free-living groups are often quite different from one another (and from the gene order of parasitic species). All this means resolution of platyhelminth phylogeny remains challenging.

The phylogeny of Platyhelminthes shown in Figure 10.34 is based primarily on two recent genomic studies (Laumer et al. 2015; Egger et al. 2015). This scheme is subject to revision, as many researchers are currently working to refine our understanding of platyhelminth phylogeny. Although many internal relationships remain largely enigmatic, the Catenulida are now widely viewed to be the most basal platyhelminths, and the sister group to Rhabditophora (the remaining platyhelminths). Catenulids are anatomically simple flatworms, with an unbranched pharynx and gut and a single biflagellate protonephridium. And, they retain the spiral cleavage and endolecithal ova that characterize most phyla in the clade Spiralia. Rhabditophora comprises two clades, Macrostomorpha and Trepaxonemata, the latter being home to the majority of species in the phylum and including some of the best known free-living groups as well as the flukes and tapeworms.

All of the earliest-branching clades of flatworms, Catenulida, Macrostomorpha, and Polycladida share spiral cleavage and endolecithal eggs with other spiralian protostomes. The terrestrial/freshwater group Prorhynchida, a proposed sister group to the mainly marine, diverse and well-known polyclad flatworms (Polycladida), retains spiral cleavage, but has shifted to ectolecithal eggs. Molecular evidence strongly supports the sister group relationship between the endolecithal polyclads and the ectolecithal Prorhynchida (a clade known as Amplimatricata), suggesting that prorhynchids independently developed ectolecithal ova. The discovery that Prorhynchida likely independently evolved ectolecithal ova led to abandonment of the old taxon "Neoophora," which had held *all* the ectolecithal taxa (i.e., Prorhynchida, Rhabdocoela, Proseriata, and Acentrosomata). The latter three groups now comprise the Euneoophora, the most highly derived flatworm lineage. These patterns confirm the basal nature of the archoöphoran plan. Gnosonesimora is likely the sister group to the Euneoophora. Recall that in the neoöphoran plan (seen in the order Prorhynchida and the superclass Euneoophora) there is an ovarian specialization into germinal and vitelline cell producing regions. It has been suggested that this separation of germ-line

and yolk line cells might allow these ectolecithal species to synthesize yolk at a higher rate than their endolecithal ancestors, thereby enhancing fecundity, and possibly allowing multiple embryos to develop within the same egg capsule, also enhancing fecundity by allowing conservation of resources for larval nutrition.

Phylogenetic relationships within the huge and complex Euneoophora lineage are still somewhat unsettled. The Rhabdocoela and Proseriata retain elements of spiral cleavage, suggesting their basal placement within this clade. Molecular analyses also suggest that rhabdocoels could be basal to the Proseriata, and that the latter might be the sister taxon to the Acentrosomata. Acentrosomata is notable for its loss of spiral cleavage. This is thought to be due to the evolutionary loss of three genes associated with centriole formation and function, which has been demonstrated in species of Adiaphanida, Bothrioplanida, and Neodermata. It is this feature that led to their grouping under the name Acentrosomata. Centrioles, of course, play a critical role in the development of spindle fibers during cell division. In some cases, early embryogenesis in acentrosomate species is so chaotic that the blastomeres undergo what has been called dispersive cleavage, wherein they temporarily lose physical contact with one another and "drift" in a matrix of yolk. This process has been given the colorful name blastomere anarchy, and it characterizes Adiaphanida (triclads, prolecithorans and fecampiids) and Bothrioplanida. Bothrioplanids appear to be the last free-living ancestor to the Neodermata. There is no trace of spiral cleavage in neodermatans either, although they are not generally characterized by blastomere anarchy. There seems to be no question about the monophyly of the Neodermata, all of which are ectolecithal, lack spiral cleavage, and have larvae that shed their cilia early in their life cycle (hence the name "neo dermata"). However, there is still debate over relationships among the Monogenea, Cestoda, and Trematoda.

CHAPTER 11

Four Enigmatic Protostome Phyla

Rhombozoa, Orthonectida, Chaetognatha, Gastrotricha

In the 1979 book *The Medusa and the Snail*, Lewis Thomas wrote, "The only solid piece of scientific truth about which I feel totally confident is that we are profoundly ignorant about nature." Despite Dr. Thomas' pessimism, we have actually come a long way since 1979. But, alas, we are still uncertain about where four enigmatic animal phyla fit into the tree of life: Chaetognatha, Gastrotricha, Rhombozoa, and Orthonectida. Well, that's not quite true. Thanks mainly to molecular phylogenetic discoveries of the past decade, we do know that all four of these phyla belong to the Protostomia clade. And there is growing evidence that they could be spiralians, although this is still not certain. Taken together, these four phyla amount to only about 1,000 described species. We cover them together in this chapter not because they are closely related, but because they are, at this point in time, protostomes of uncertain affinity. Our classification in this book includes all but Chaetognatha in the clade Spiralia, even though their phylogenetic positions within Protostomia are still uncertain. Rhombozoans have a very spiralian-like embryogenesis, whereas gastrotrichs have a unique, nonradial and nonspiral embryogenesis; the embryology of orthonectids and chaetognaths is still poorly known. The most recent phylogenetic analyses suggest Chaetognatha may be the sister group to Spiralia, as shown in our tree of Metazoa (Chapter 28), or perhaps basal protostomes.

Each of these phyla is highly specialized for the niche they exploit: chaetognaths mainly inhabit the marine planktonic realm (although numerous species have adopted benthic lifestyles); gastrotrichs are minute species living meiofaunally or in surface detritus; rhombozoans are symbionts in the nephridia of cephalopod molluscs; and orthonectids are parasitic in a variety of invertebrates, including echinoderms, molluscs, nemerteans, free-living flatworms, and polychaete worms. All of these animals have been subjects of taxonomic and phylogenetic controversy since their discovery long ago.

Classification of The Animal Kingdom (Metazoa)

Non-Bilateria*

Panarthropoda
- PHYLUM TARDIGRADA
- PHYLUM ONYCHOPHORA
- PHYLUM ARTHROPODA
  - SUBPHYLUM CRUSTACEA*
  - SUBPHYLUM HEXAPODA
  - SUBPHYLUM MYRIAPODA
  - SUBPHYLUM CHELICERATA

Deuterostomia
- PHYLUM ECHINODERMATA
- PHYLUM HEMICHORDATA
- PHYLUM CHORDATA

*Paraphyletic group

Phylum Chaetognatha has been revised by George Shinn.
Phylum Gastrotricha has been revised by Rick Hochberg.

The rhombozoans and orthonectids were for many years treated as closely related groups, classes, or orders in a taxon of phylum rank: the Mesozoa. They were often allied with the flatworms (Platyhelminthes) because of their complex life cycle and superficially similar appearance to miracidia larvae of digenetic trematodes. At other times they were allied, surprisingly, with ciliate protists. Auguste Lameere (1922) even suggested that the orthonectids might have arisen from echiuran worms, apparently because some echiurans (e.g., *Bonellia*) show extreme sexual dimorphism, with tiny, reduced males. Lameere likened this feature to the dimorphic nature of some orthonectids. Neither the ciliate nor the echiuran hypothesis ever gained much favor. There are no proven fossils of these two groups. Recently, researchers have become convinced that Rhombozoa and Orthonectida are not at all closely related. We agreed with this view and abandoned the name Mesozoa as a formal taxon in the first edition (1990) of this textbook. Since then, molecular and ultrastructural work have supported the idea that these two groups each represent a distinct clade of highly modified parasitic protostomes

Phylum Rhombozoa

Rhombozoans were described and named by A. Krohn in Germany in 1839. But it was not until 1876 that a careful study of these creatures was published by the Belgian zoologist Edouard van Beneden. He was convinced that these odd parasites represented a true link between the protists and the Metazoa, and it was van Beneden who coined the name "Mesozoa" (= middle animals) to emphasize this point of view. Stunkard (1982) considered Rhombozoa as a class of "Mesozoa" comprising the orders Dicyemida and Heterocyemida, and we retain those two subtaxa.[1] Rhombozoans have a simple, solid body construction—there are no body cavities or differentiated organs (e g , chapter opener photo of a vermiform stage). An outer layer of somatic/nutritive cells surrounds an inner core of reproductive cells (or a single reproductive cell, depending on how one views it!). About 70 species have been described.

Recent molecular studies, including sequencing of 18S rRNA, Pax6, and other genes, as well as patterns of Hox (and other gene) expression, suggest that rhombozoans are probably highly reduced and specialized parasitic members of the protostome clade Spiralia. Dicyemids are more common and better understood than are the heterocyemids. Members of both groups are obligate symbionts in the nephridia of cephalopod molluscs.

The Dicyemida

Adult dicyemids are very small, just 0.5 to 3 mm long There are two adult forms, **nematogens** and **rhombogens** that have nearly the same organization but that produce two distinct types of larvae: nematogens produce **vermiform larvae** asexually from an agamete in their body, whereas rhombogens produce **infusoriform larvae** from fertilized eggs.

The body of a nematogen consists of an outer sheath of ciliated somatic cells, the number of which has been constant for most, but not all, species that have been examined.[2] Within the covering of somatic cells lies a single, long axial cell (Figure 11.1A). Eight or nine somatic cells at the anterior end form a distinctive polar cap (or calotte). Immediately behind the polar cap are two parapolar cells. The rest of the 10 to 15 somatic cells are sometimes called trunk cells; the two posterior most cells are the uropolar cells. Altogether, dicyemids have from about 8 to 40 body cells, depending on the species—one of the smallest cell counts among the Metazoa. As in other Bilateria, dicyemids have been shown to have three types of cell–cell junctions: septate, adherens, and gap junctions.

Young dicyemids are motile and swim about in the host cephalopod's urine by ciliary action. The adults, however, attach to the inner lining of the nephridia by their polar caps. There is no conclusive evidence that these animals cause damage to their hosts, but when present in very high numbers they may interfere with the normal flow of fluids through the nephridia. They attach by inserting the "head end" the polar cap into renal tubules or crypts of the host's kidney. Nematogens consume particulate and molecular nutrients from the host's urine by phagocytotic and pinocytotic action of their somatic cells. Once the adult has attached to the host, the somatic cilia might serve to keep fluids moving over the body, bringing nutrients in contact with the surface cells. Although in nature dicyemids appear to be obligatorily associated with cephalopods, they have been successfully maintained in experimental nutrient media.

What we know so far about dicyemid life history is rather bizarre, and the stages of the dicyemid life cycle that occur outside the host are still incompletely known. The host dwelling portion of the life cycle includes both asexual and sexual processes, but without a regular alternation between them. Adult nematogens thus produce two kinds of offspring. One is the vermiform stage, in which the dicyemid exists as a vermiform larva formed asexually from an agamete cell; these grow to become new worms in the renal sac of the host. The other is the infusoriform larva, which develops from a fertilized egg produced around

[1] Some people refer to this phylum as simply "Dicyemida," but this is confusing and suggests that heterocyemids are not included; hence we retain the name Rhombozoa for the phylum.

[2] A constancy in the number of cells (in a given organ, or in the entire body of an animal) is called "eutely" and is a common feature of many microscopic and near-microscopic organisms.

hermaphroditic gonads called infusorigens, and these eventually escape the host to enter the sea. What stimulates production of infusoriform larvae, and how they find their new hosts are unknown. Notably, in sexual reproduction, both fertilization and embryonic development occur within the worm's body.

Asexual reproduction is curious indeed. The cytoplasm of the single axial cell of the nematogen contains numerous tiny cells called **axoblasts**. Immature vermiform organisms are produced asexually by a sort of embryogeny of individual axoblasts within the parent axial cell (Figure 11.2). The first division of an axoblast is unequal and produces a large presumptive axial cell and a small presumptive somatic cell. The presumptive somatic cell divides repeatedly, and its daughter cells move by an epiboly-like process (rapid growth of animal pole ectodermal cells to from a sheetlike cover- ing to the vegetal cells) to enclose the presumptive axial cell, which has not yet divided. When this inner cell finally does divide, it does so unequally, and the smaller daughter cell is then engulfed by the larger one! The larger cell becomes the progeny's axial cell proper with its single nucleus, and the smaller engulfed cell becomes the progenitor of all future axoblasts within that axial cell. The "embryo," which now consists of its own central axial cell surrounded by somatic cells, elongates and the somatic cells develop cilia. The resulting structure is a miniature vermiform organism. The immature vermiform organism leaves the parent nematogen and swims about in the nephridial fluids. Eventually it attaches to the host and enters the adult stage of the life cycle.

The initiation of sexual reproduction in dicyemids may be a density-dependent phenomenon associated with high numbers of vermiform individuals within the host's nephridia. Some workers have suggested that the switch from asexual to sexual processes might be a response to some chemical factor that accumulates in the urine of the host. Other workers suggest that sexual reproduction in dicyemids is brought on by the sexual maturation of the host. In any event, once the vermiform adults become sexually "motivated" they are called rhombogens, and their somatic cells usually enlarge as they become filled with yolky material (Figure 11.3).[3] The axoblast of a rhombogen-stage individual develops into multicellular structures called infusorigens, each consisting of an outer layer of ova and an inner mass of sperm (Figure 11.3B). The infusorigens

[3]Because the reported differences between rhombogens and nematogens are not consistently found, some workers prefer to simply call them sexual and asexual vermiform adults, respectively.

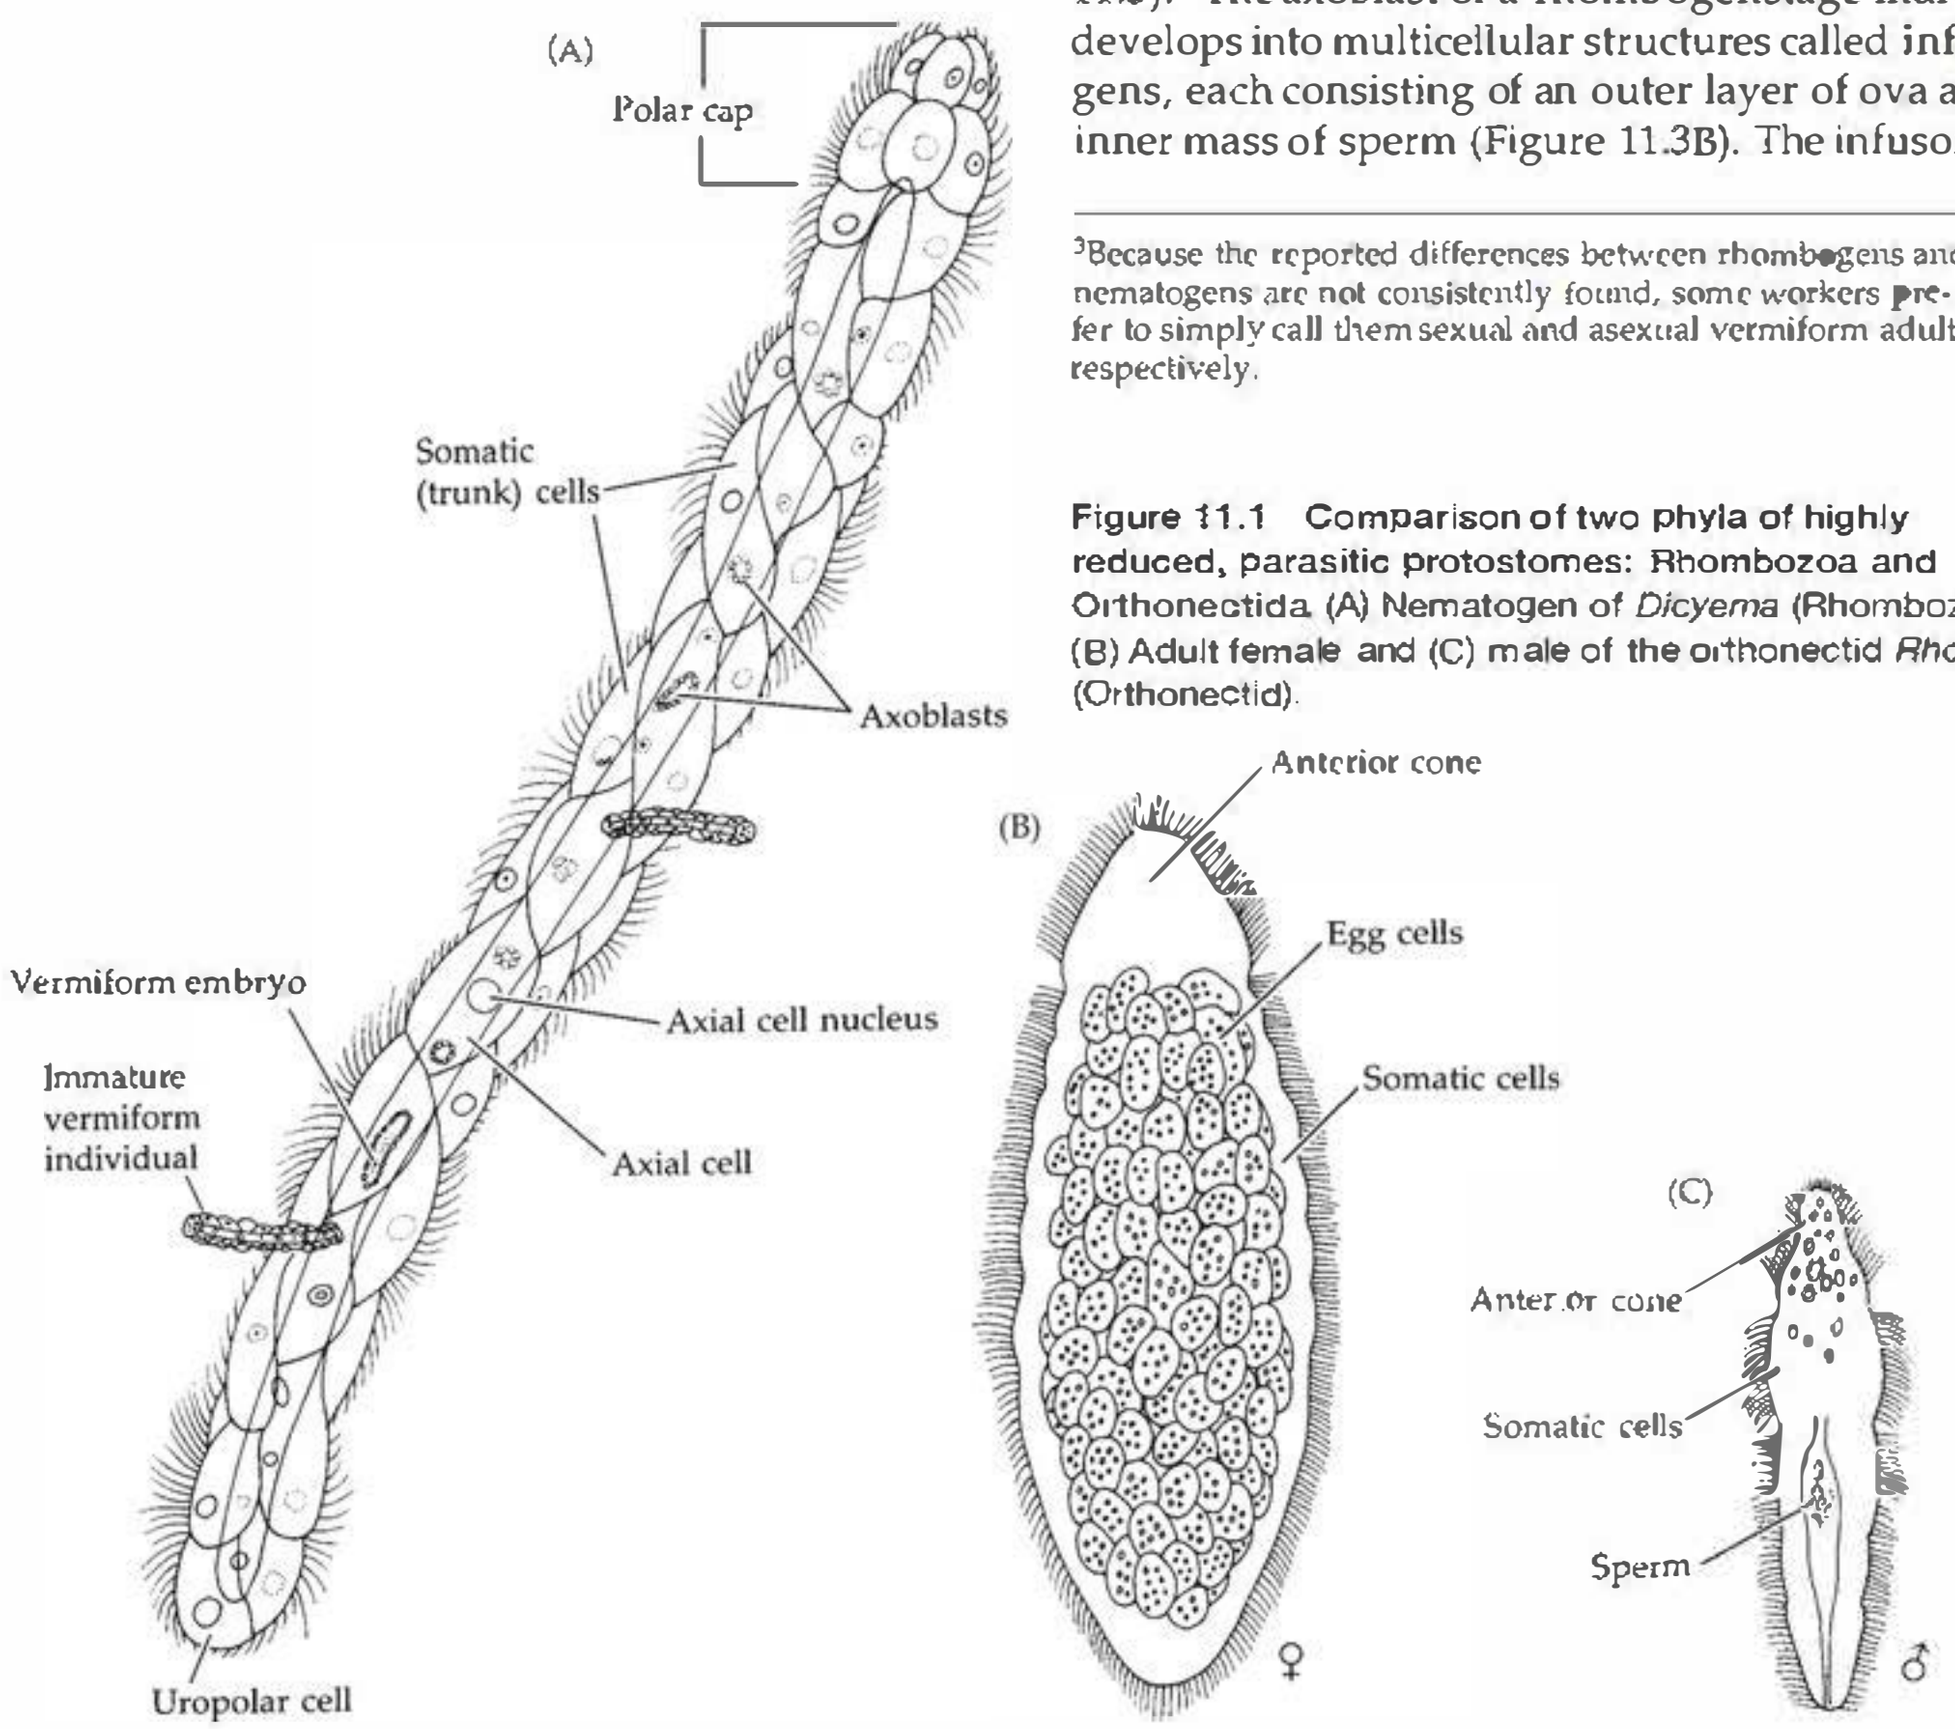

Figure 11.1 Comparison of two phyla of highly reduced, parasitic protostomes: Rhombozoa and Orthonectida. (A) Nematogen of *Dicyema* (Rhombozoa). (B) Adult female and (C) male of the orthonectid *Rhopalura* (Orthonectid).

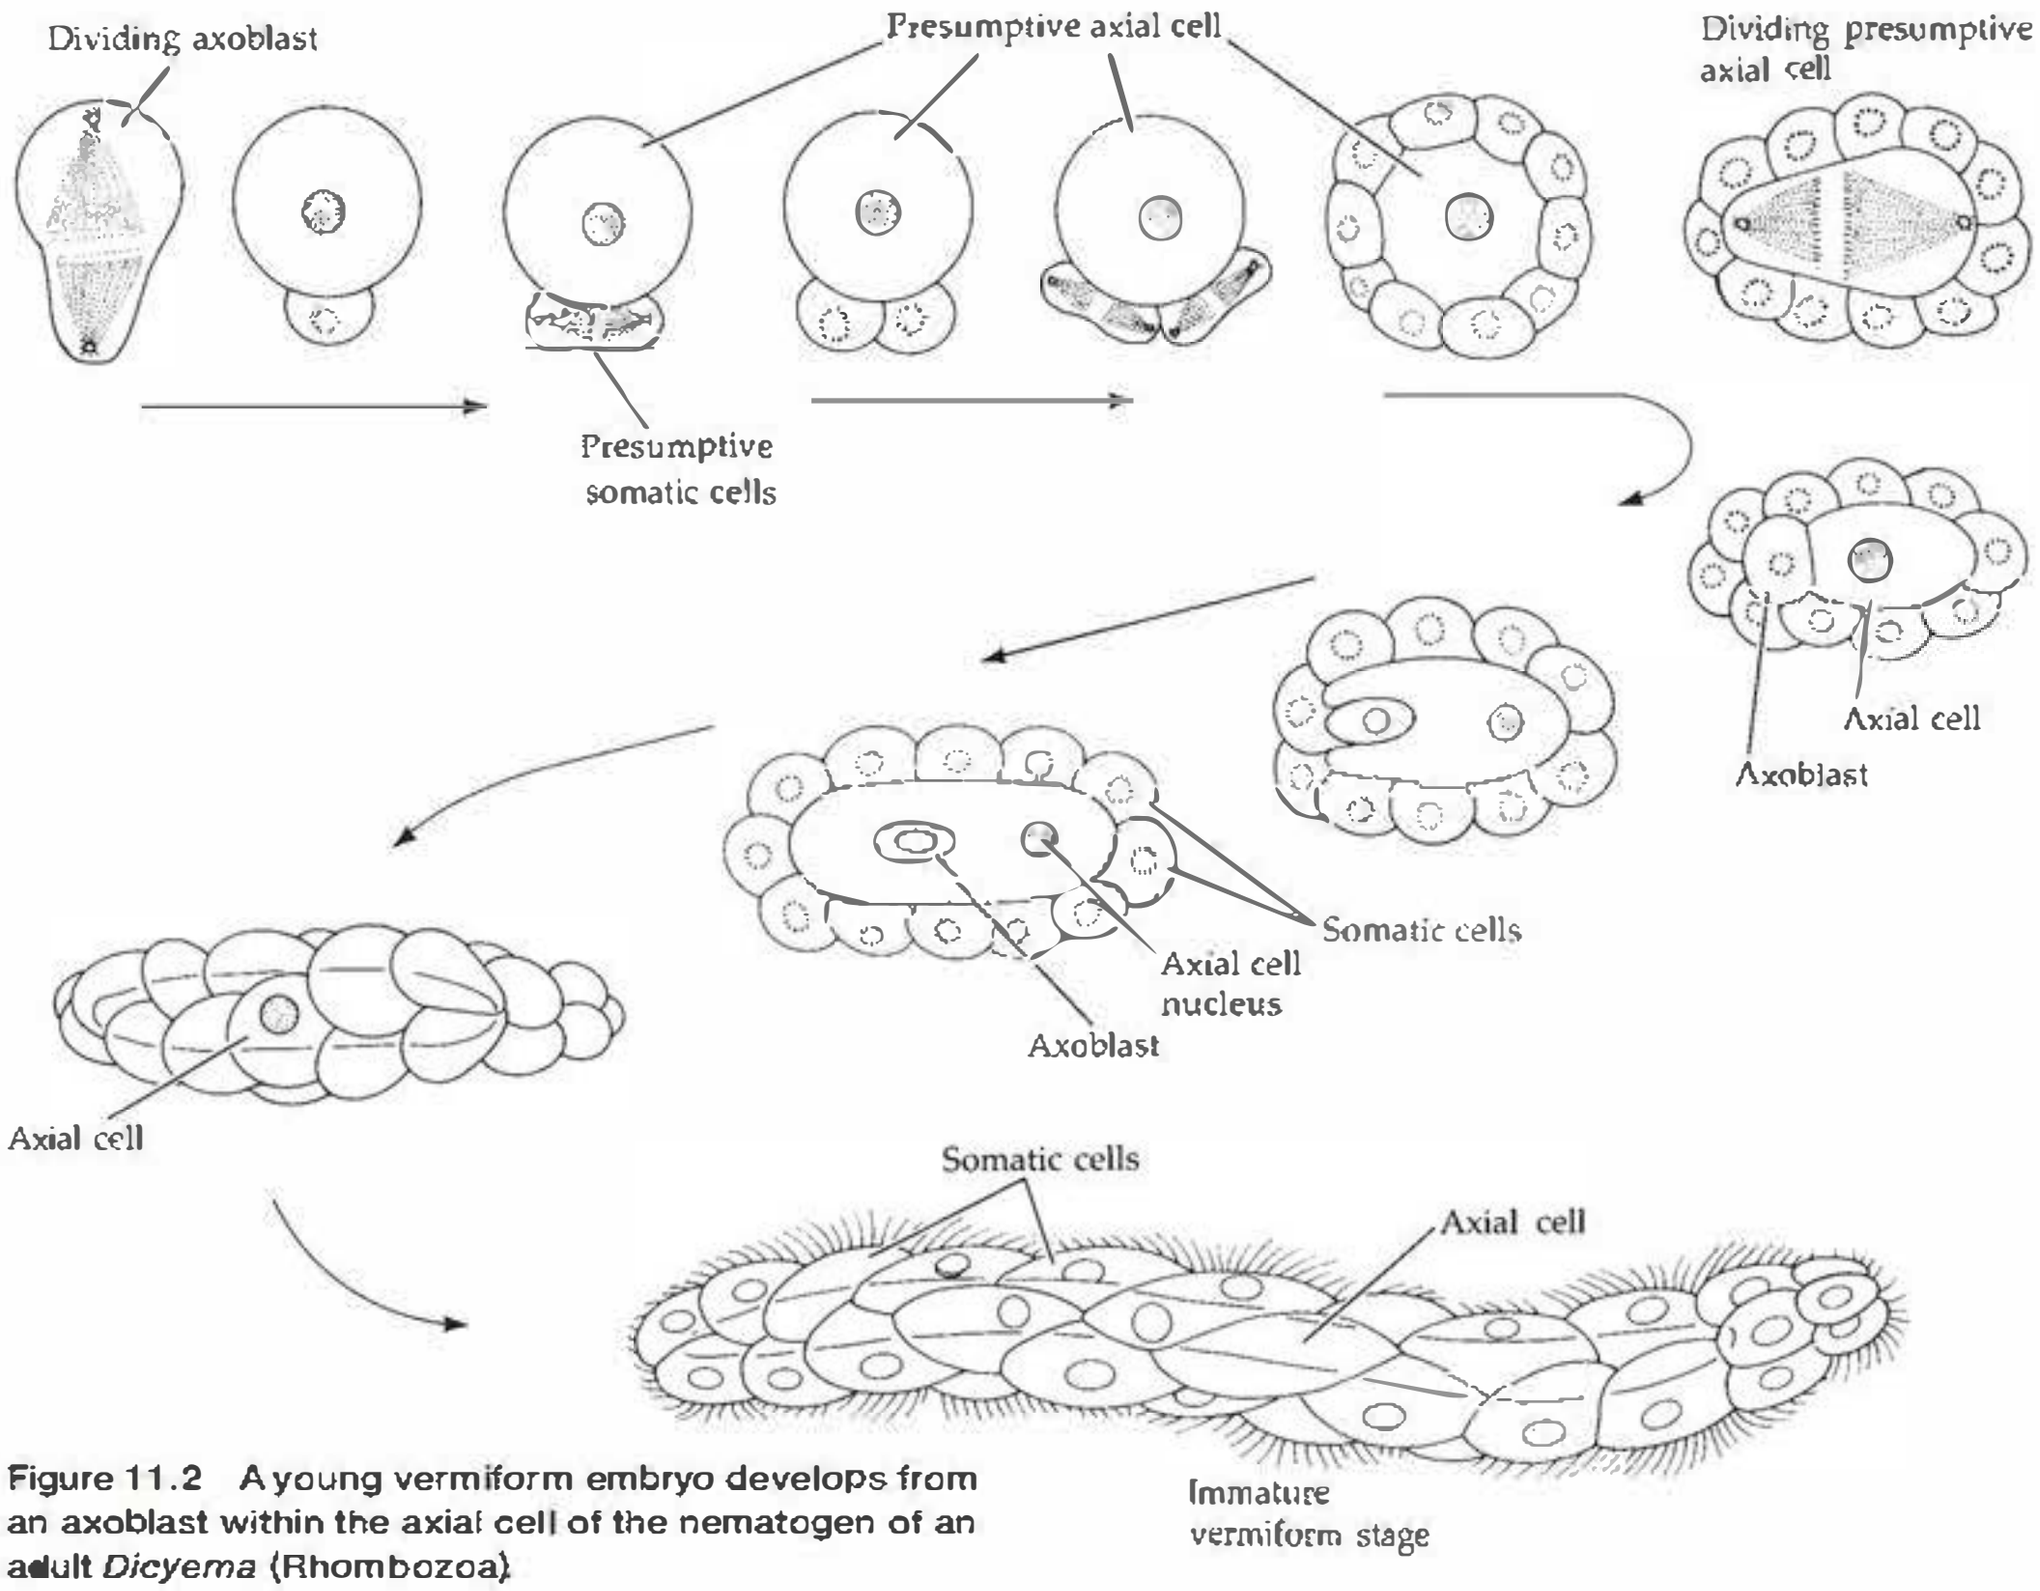

Figure 11.2 A young vermiform embryo develops from an axoblast within the axial cell of the nematogen of an adult *Dicyema* (Rhombozoa).

are retained within a vacuole of the parent's axial cell, and they are functionally hermaphroditic gonads. In each infusorigens, the centrally located sperm fertilize the peripherally arranged ova, each zygote then developing into a ciliated infusoriform larva (Figure 11.3C). This larva has a fixed number of cells; the two anteriormost cells—called apical cells—contain high-density substances within their cytoplasm. The rest of the surface cells are ciliated and form a sheath around a ring of capsule cells, which in turn enclose four central cells. The number of infusorigens, and the larvae they produce, seems to be related to the size of the adult rhombogen. The infusoriform larvae escape from the parent vermiform adult and pass out of the host's body with the urine.

The development of several species has been studied, and there is no clear evidence of germ-layer formation in the development of the infusoriform larva, with a rough distinction only as outer and inner cells. The outer cells occupy the dorsal and caudal surfaces of the embryo, and the inner cells are derived from the blastomeres of the vegetal hemisphere. The innermost germinal cells are derived from the cells that form the vegetal pole. The cleavage pattern of sexually-produced embryos in *Dicyema japonicum* has been described as holoblastic and spiral. A cavity (the urn cavity) appears among the ventral internal cells, but this small space is interpreted to appear secondarily and not to be a blastocoel.

The events of the dicyemid life cycle that occur outside the cephalopod host remain a mystery. Some workers have held to the view that the infusoriform larva enters an intermediate host (presumably some benthic invertebrate), but most of the evidence to date suggests that this is not the case. While much remains to be learned, the following scenario seems plausible. After leaving the host, the infusoriform larva sinks to the bottom of the ocean—the dense contents of the apical cells serving as ballast. The larva, or some persisting part of the larva (perhaps the innermost four cells), enters another cephalopod host. This infectious individual travels through the host, probably via the circulatory system, and enters the nephridia, where it becomes a so-called stem nematogen (Figure 11.3D). The stem nematogen is similar to the vermiform adult except that the former has three axial cells rather than one. Axoblasts within the axial cells of the stem nematogen give rise to more vermiform adults, just as the axoblasts

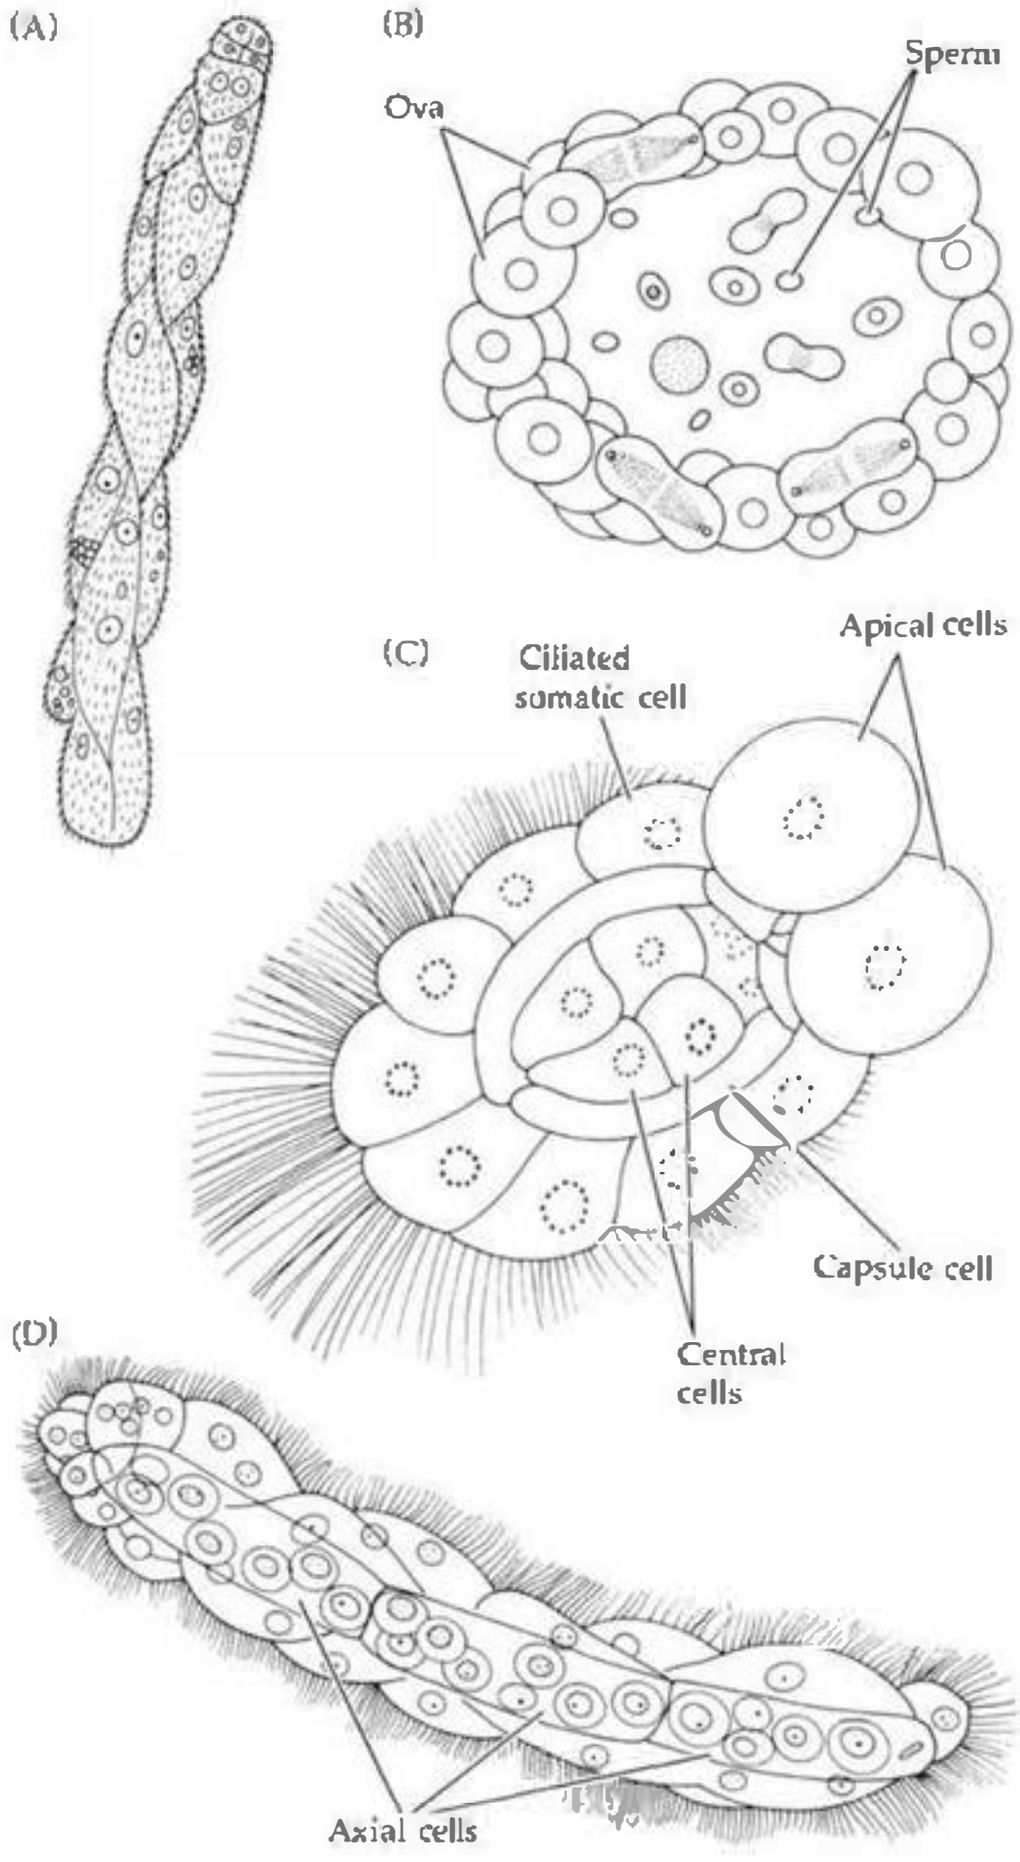

Figure 11.3 Sexual reproduction in dicyemid rhombozoans. (A) Adult, sexual (rhombogen) form. (B) Infusorigen of sperm and ova formed within the axial cell of the adult. (C) Infusoriform larva produced by fertilization. (D) Stem nematogen with three axial cells.

within the adults described earlier did. The vermiform adults produce more individuals like themselves until the onset of sexual reproduction is triggered again, presumably by the high population density. This putative life cycle is schematically represented in Figure 11.4.

The Heterocyemida

Only two species of heterocyemids have been described. *Conocyema polymorpha* lives in the nephridia of octopuses, and *Microcyema gracile* in cuttlefishes of the genus *Sepia*. These two heterocyemids differ from each other in certain respects.

The vermiform adult of *Conocyema* bears a polar cap of four enlarged cells and has a trunk of somatic cells around an inner axial cell; all the cells of the body lack cilia (Figure 11.5 A). The axial cell contains axoblasts, which give rise to ciliated "larvae" that escape from the parent, lose their cilia, and grow into more vermiform adults within the host. The individuals that produce the infusorigens lack a polar cap. They have only a very thin layer of somatic cells surrounding the axial cell, which contains the developing infusorigens (Figure 11.5B). The infusorigens produce infusoriform larvae similar to those of dicyemids. Details of the life cycle of *Conocyema* are lacking.

What little is known about *Microcyema* suggests a complex and distinctive life cycle. The vermiform adult consists of a single inner axial cell surrounded

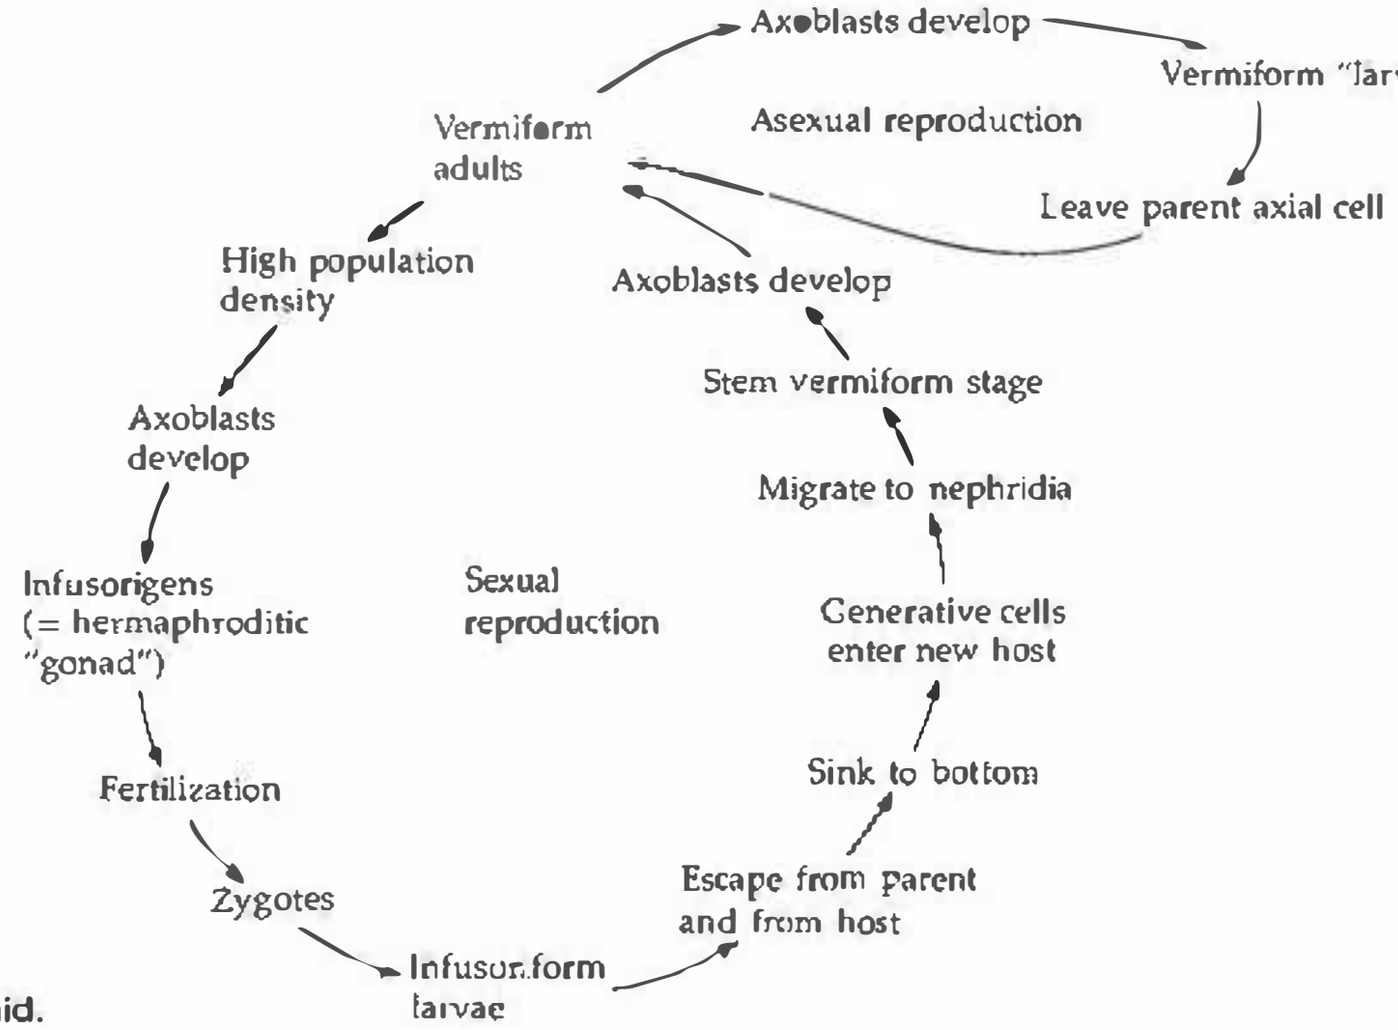

Figure 11.4 Life cycle of a dicyemid.

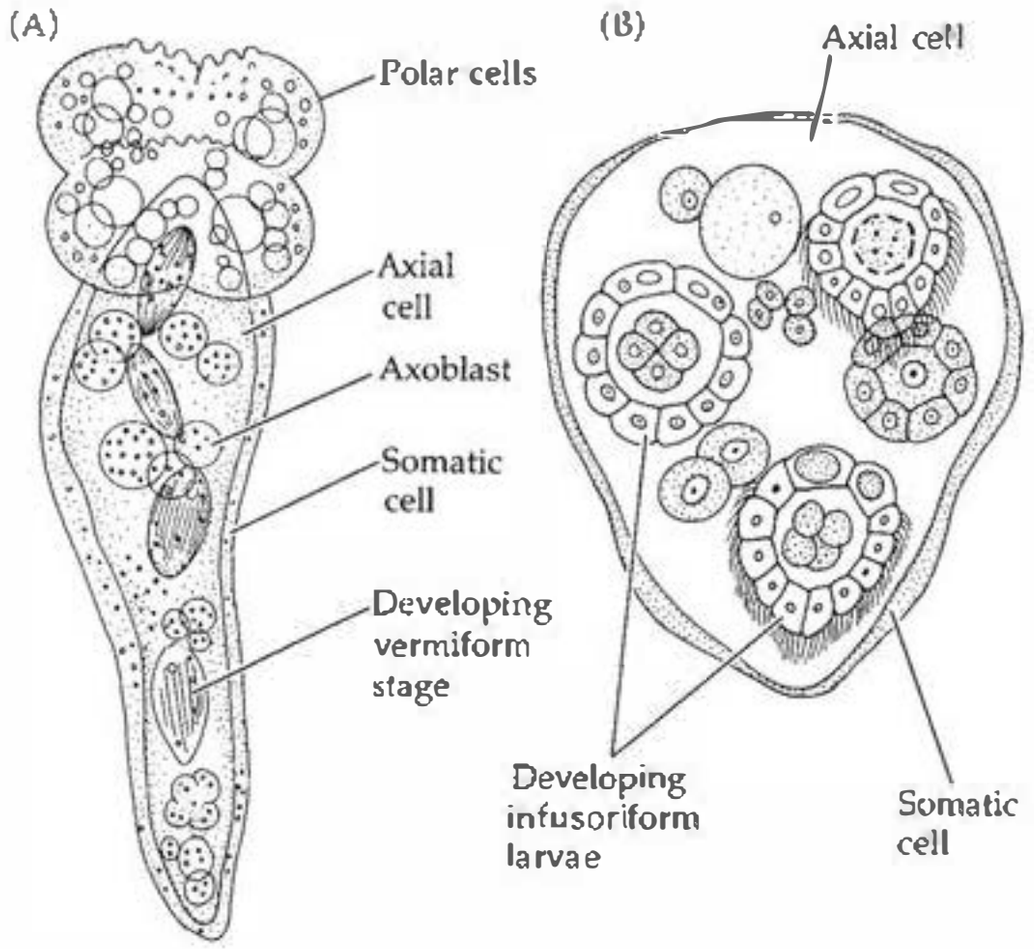

Figure 11.5 The heterocyemid rhombozoan, *Conocyema*. (A) Vermiform adult. (B) During the reproductive phase, infusoriform larvae are formed within the adult's axial cell (cross section).

by a somatic syncytium (Figure 11.6A). The axoblasts within the axial cell produce more vermiform adults by two very different methods. One sequence of events involves the formation of a multicellular "embryo" similar to that seen in dicyemids (Figure 11.6B). As the presumptive somatic cells surround the axial cell precursor, the cell boundaries of the somatic cells break down, resulting in an ameboid individual in which a syncytial mass surrounds the growing axial cell (Figure 11.6C,D). This individual apparently develops into a new vermiform adult. Another asexual process involves the formation of ciliated Wagener's larvae from the axoblasts (Figure 11.6E). These larvae leave the parent, swim about in the host's nephridial fluids, and eventually attach and metamorphose into more vermiform adults. *Microcyema* adults also produce infusorigens and infusoriform larvae much like those of the dicyemids. The infusoriform larvae apparently leave the host via the urine, but nothing is known about the stages of the life cycle outside the host. It is assumed that the infusoriform larva enters a host and matures into a ciliated nematogen, which has three axial cells. Such stem nematogens have been observed in host animals. Eventually, the cilia and the cell boundaries between adjacent somatic cells are lost (Figure 11.6F), and the animal develops into another vermiform adult.

Phylum Orthonectida

First described in 1877, orthonectids, like the rhombozoans, long defied placement in the tree of life. And like Rhombozoa, they have spent time allied with flatworms or viewed as some kind of "transition group" between the lower Metazoa and the Bilateria. Some

Figure 11.6 The heterocyemid rhombozoan, *Microcyema*. (A) Vermiform adult. (B) An embryo develops from an axoblast within the vermiform adult. (C,D) Ameboid phases in development of new individuals. (E) Wagener's larva. (F) A stem nematogen has three axial cells.

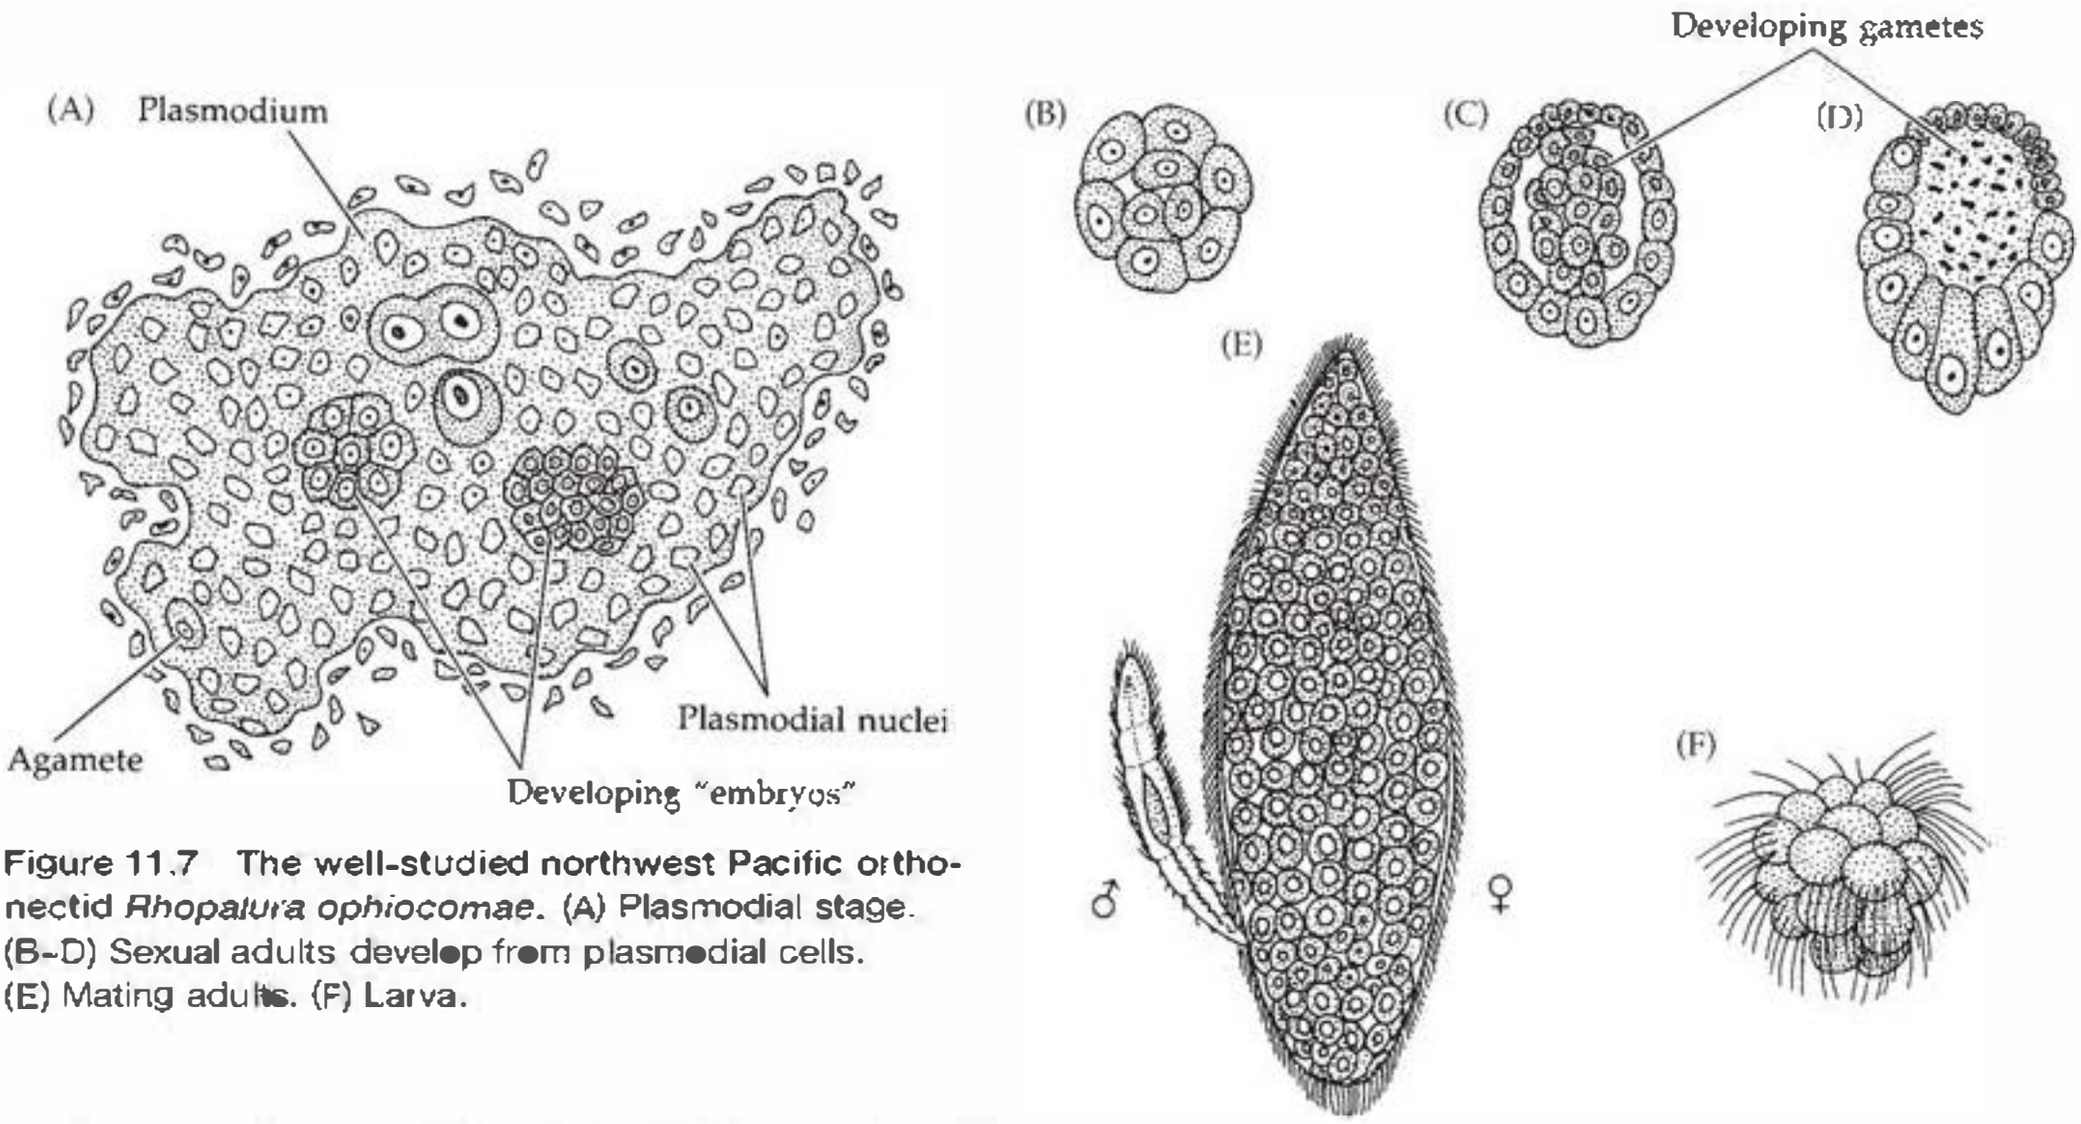

Figure 11.7 The well-studied northwest Pacific orthonectid *Rhopalura ophiocomae*. (A) Plasmodial stage. (B–D) Sexual adults develop from plasmodial cells. (E) Mating adults. (F) Larva.

workers even imagined them to be highly complex ciliate protists. But, preliminary molecular phylogenetic analyses (mainly 18S rDNA sequence data) have now placed them squarely within the Bilateria—not as sister to the Rhombozoa, but somewhere within the Protostomia. Thus they appear to be highly reduced, bilaterian parasites. Only about 21 species are known.

All orthonectids are morphologically simple and, like the Rhombozoa, they lack body cavities or discrete organs; there is no gut or nervous system. They are small, less than 1 mm in length, free swimming, and ciliated. A 2-layered cuticle has been described in one species (*Intoshia linei*). Most species are gonochoristic, but some are hermaphroditic (e.g., *Stoecharthrum*). The outer layer of the body consists of a defined number of cells, arranged more or less in rings. All are parasites of other invertebrates, and they have been reported from nemerteans, free-living platyhelminths, gastropods, bivalves, polychaete annelids, brittle stars, and ascidians.

The life cycles of some orthonectids are known and these differ markedly from those of the rhombozoans. Asexual individuals dominate the life cycle (Figure 11.7A). Some orthonectids cause severe damage to the host. For example, the well-known species *Rhopalura ophiocomae* (in the brittle star *Amphipholis squamata*) and *R. granosa* (in the bivalve mollusc *Heteranomia squamula*) destroy the gonads of their hosts.

The orthonectid *Rhopalura ophiocomae* is a well-studied parasite of the brittle star *Amphipholis squamata*, on the northeast Pacific shores. This orthonectid infects muscle cells underlying the peritoneum, adjacent to the genital bursae and gut of *Amphipholis*. The infected cells grow into large masses that bulge into the body coelom. The mass is enclosed by the coelomic peritoneum, giving it discrete form. These masses were long called "plasmodia" when it was thought that they were part of the orthonectid itself. Eventually, some of the orthonectid cells within the hypertrophied host cells develop into small (< 1 mm) ciliated adults that escape the host and swim free in the surrounding seawater. The organization of these free-living adults—with a central mass of developing gametes surrounded by a layer of ciliated cells—is reminiscent of rhombozoans. However, rhombozoans have a central axial cell within which germ cells (axoblasts) develop into both more worms and what appears to be hermaphroditic gonads, a process quite unlike anything seen in orthonectids. Also, rhombozoans lack free-living sexual forms.

Adult, free-living orthonectids are nonfeeding, ciliated, vermiform organisms that live for a short time in the sea. Females reach about 1 mm in length, males are generally smaller. They are filled with gametes (eggs, sperm, or both). Between the gametes and the outer somatic layer are what appear to be contractile cells, and in some species these have been described as circular and longitudinal muscles. Both males and females have genital pores, usually situated in the middle part of the body in a nonciliated ring of epidermal cells, and this is apparently where sperm is placed, although males lack a specialized copulatory organ. Copulation is very fast—30–40 seconds in *Intoshia variabili*. Sperm (*Rhopalura littoralis*) contain a single mitochondrion, lack an acrosome, and the tail is a simple flagellum with a 9+2 structure. The fertilized eggs develop into minute larvae that are the infective stage, and these larvae exit via the female's genital pore. When a new host is located, and the larvae have entered it, they shed their ciliated outer cells and, in a most remarkable process, the inner cells separate and scatter within the host's tissue spaces. These infective cells are called

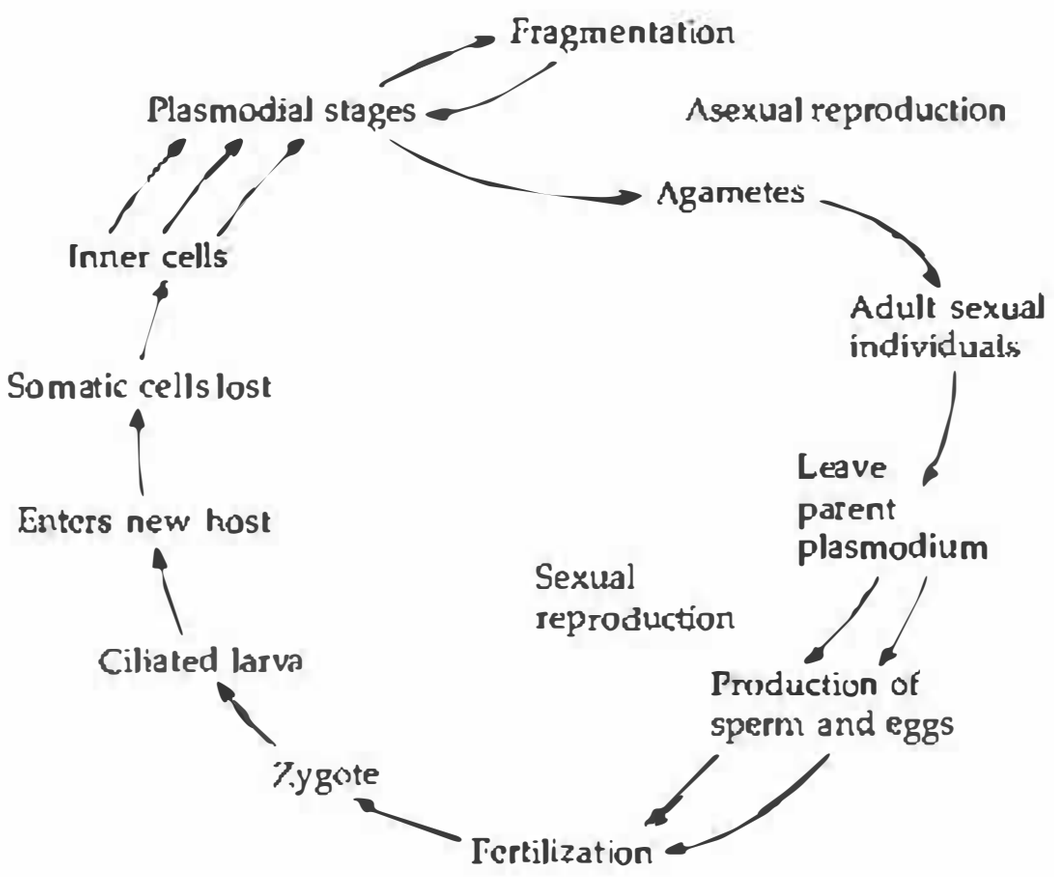

Figure 11.8 Generalized life cycle of an orthonectid.

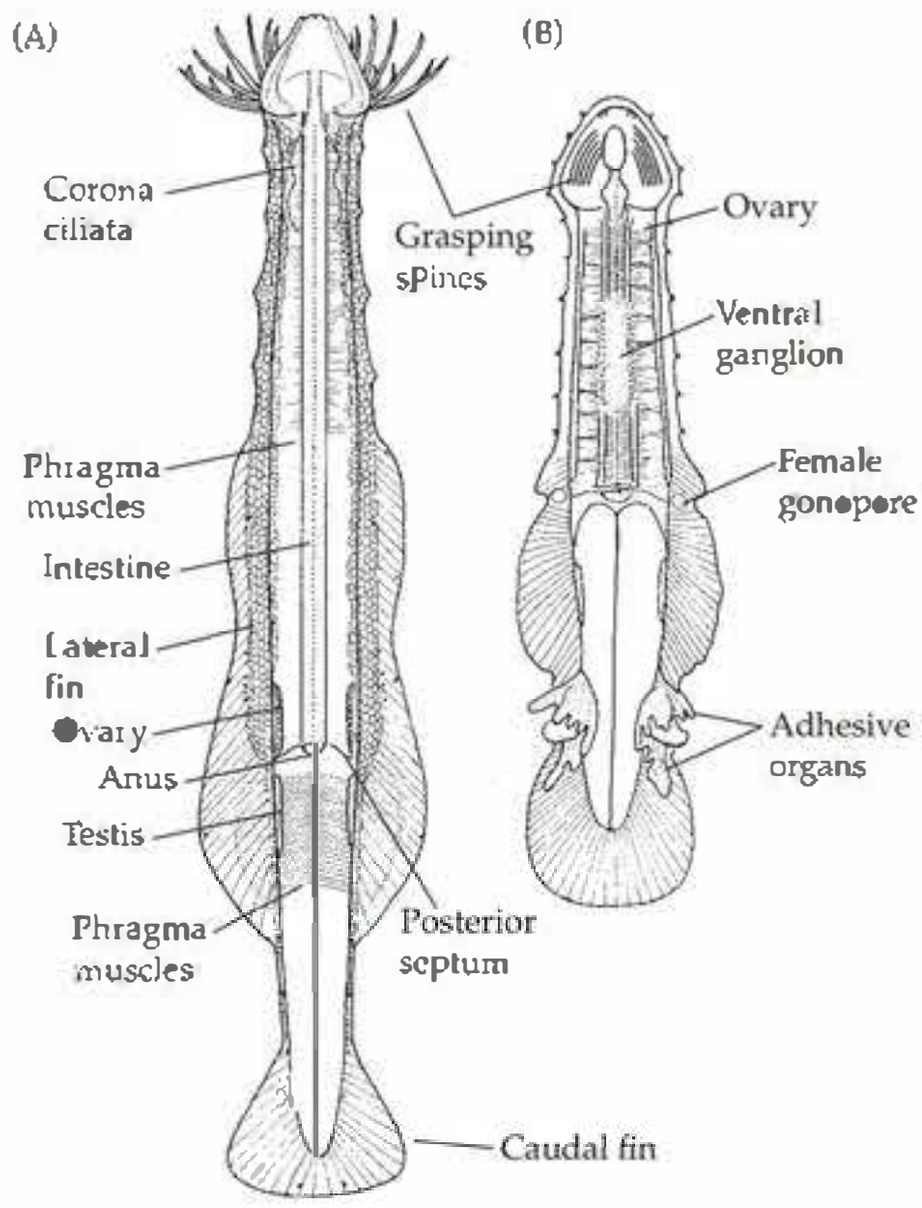
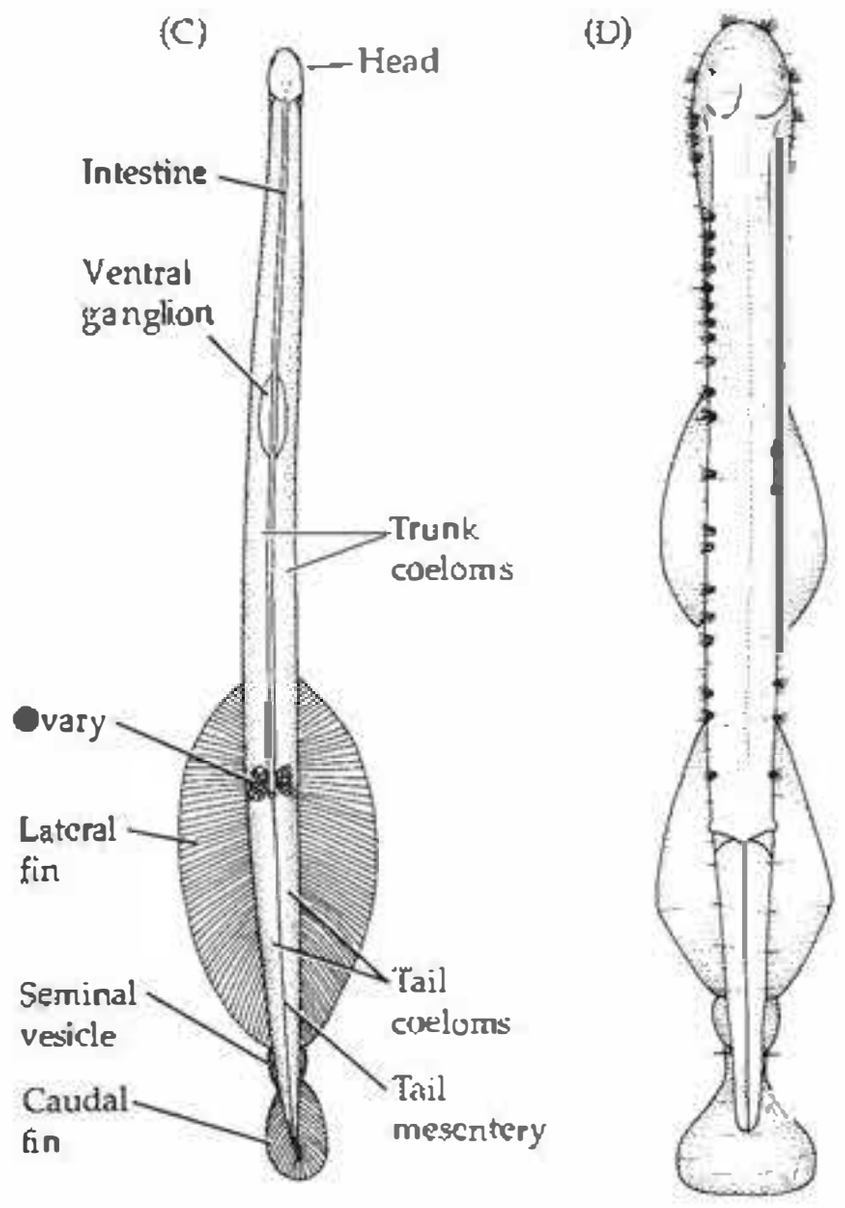


agametes (or "germline cells"). In *R. ophiocomae*, the larvae appear to enter the host brittle star through the genital bursae and gut. The agametes develop to become multicellular sexual forms, both males and females. When fully developed, the adults leave the host as tiny, nonfeeding worms that characteristically swim in straight lines (hence the phylum's name; *ortho*, "straight"; *necta*, "swimming"). Embryonic development has not yet been described for orthonectids. This life cycle is shown in Figure 11.8.



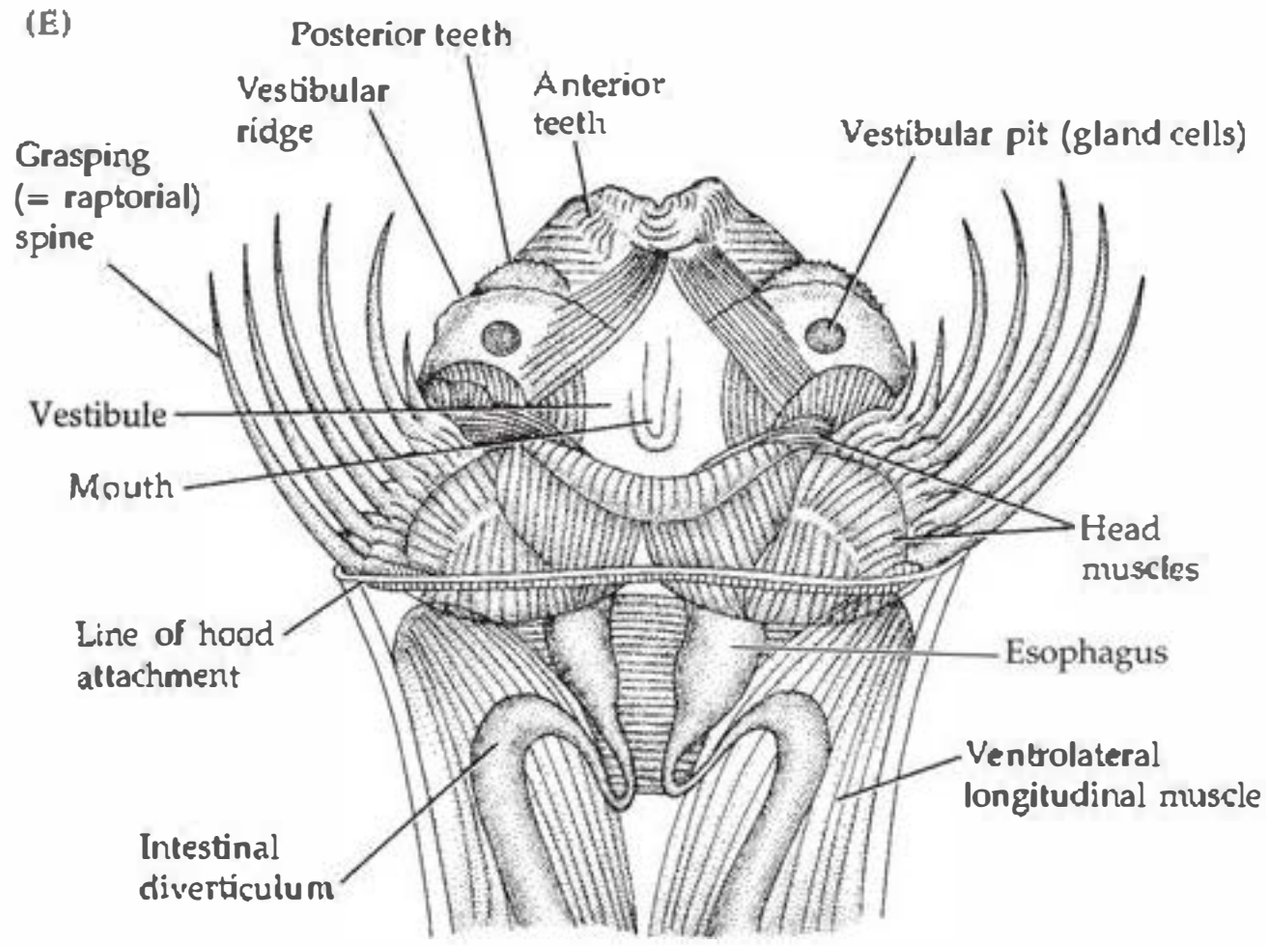


Figure 11.9 This stunning photograph by Eric Thuesen shows the deep-water chaetognath *Eukrohnia fowleri* (order Phragmophora) carrying its developing embryos in two temporary gelatinous pouches on either side of the body.

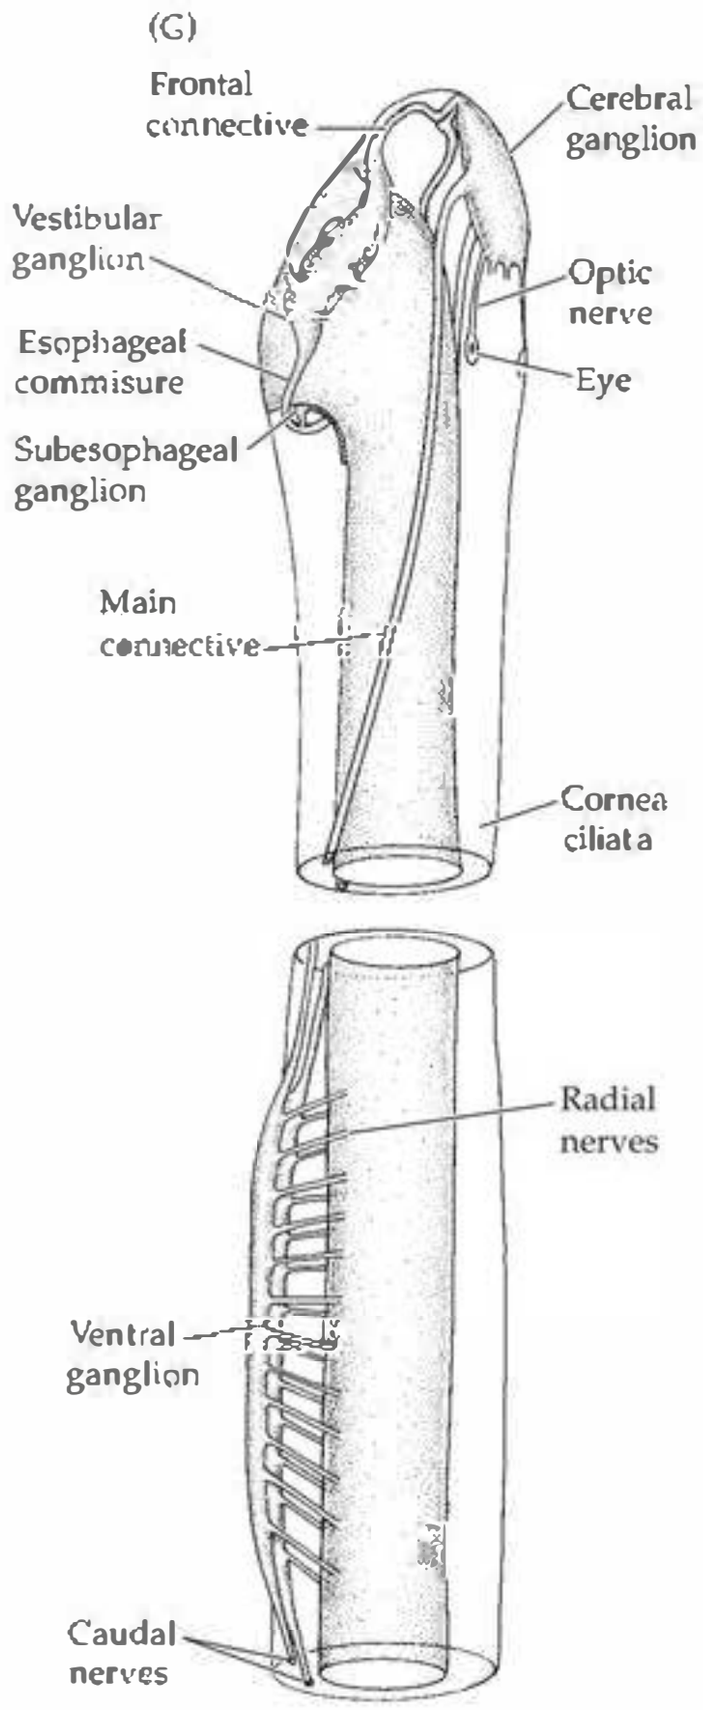
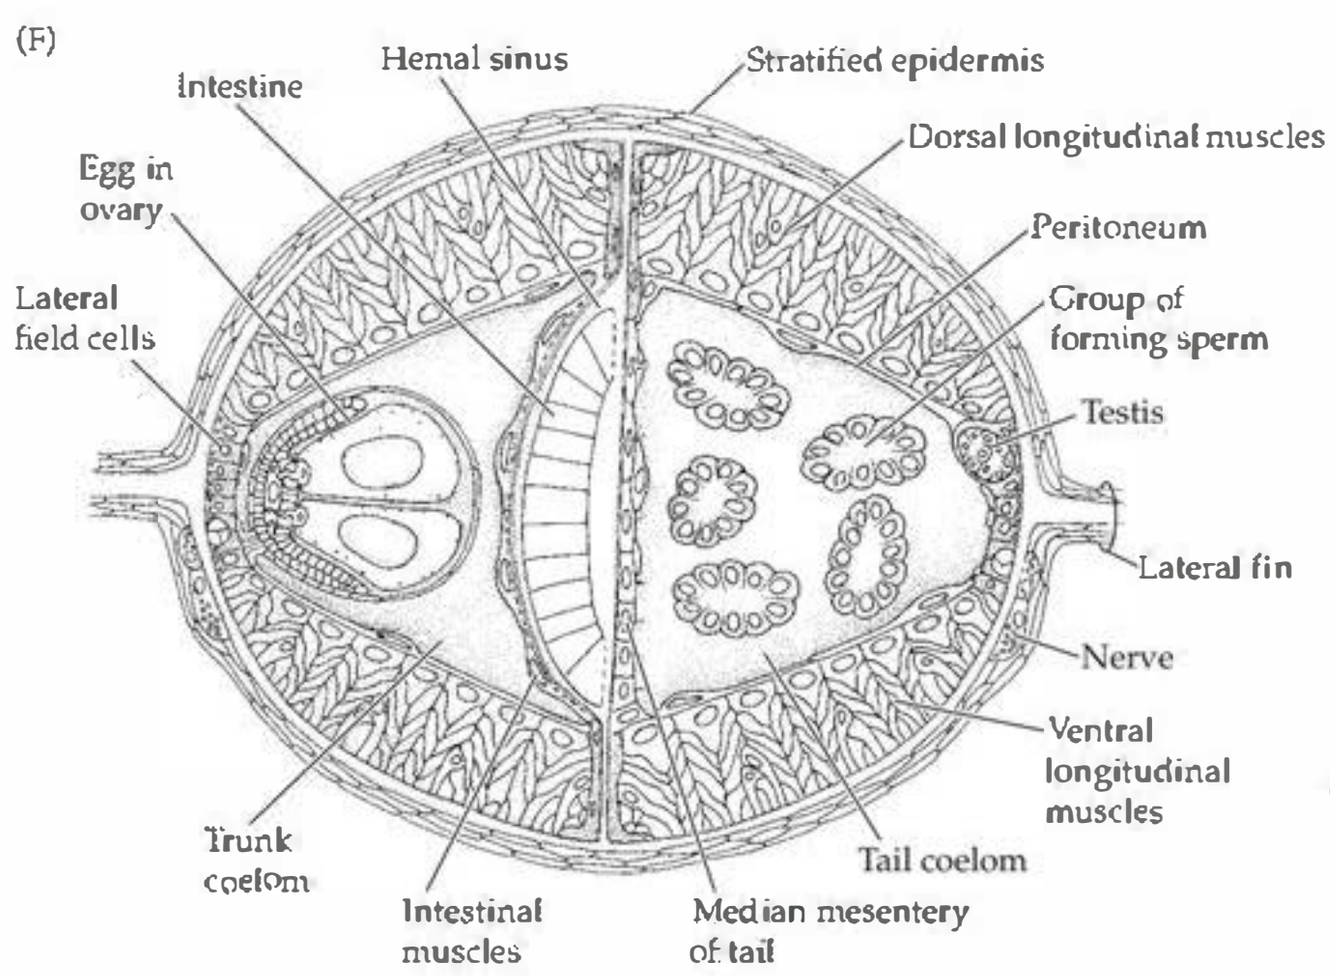


Phylum Chaetognatha



The chaetognaths, or arrow worms, comprise about 130 species of marine, mainly planktonic, voraciously predatory invertebrates (Figures 11.9 and 11.10). They are of moderate size, ranging from about 0.5 to 12 cm in

length. Arrow worms are distributed throughout the world's oceans and occur in some estuaries; they are ecologically important as consumers of copepods and other small zooplankton. Arrow worms often occur in very high numbers and sometimes dominate the biomass in mid-water plankton tows. Some species (e.g., *Spadella*) are epibenthic in shallow water. Special collection methods, such as use of submersibles, are turning up new species at great ocean depths and many of these live just off the deep ocean floor (e.g., *Heterokrohnia* and *Archeterokrohnia*). At least two deep-water species, *Caecosagitta macrocephala* and *Eukrohnia fowleri*, are bioluminescent, releasing luminous particles that form glowing clouds in the water (although their luciferin/luciferase-based luminescent organs are located in different parts of the body). Only two definitive fossil chaetognaths have been described, one from the Carboniferous (*Pancijacutum samanithion*) and one from the Lower Cambrian, about 520 million years ago (*Eognathacantha ercainella*), although it has been suggested that some of the Cambrian protoconodonts could be grasping spines of arrow worms.

Chaetognath Classification

The first record of a chaetognath was made by the Dutch naturalist Martinus Slabber in 1775, and the group name was first proposed by Leuckart in 1854. The systematic position of the group has been hotly debated ever since. Arrow worms have been at times allied with the catchall group Vermes, the molluscs, the arthropods, and certain blastocoelomates (particularly nematodes). For many years chaetognaths were considered deuterostomes, based on developmental features and their tripartite body coeloms. Although the question of chaetognath phylogenetic affinities is still somewhat unsettled, modern research is beginning to resolve some of the longstanding issues. For example, arrow worms are, without doubt, coelomate animals. This was revealed by early embryological studies, but it took electron microscopy to demonstrate that the adult body cavities are completely lined by mesodermally derived tissues.

Molecular phylogenetic methods consistently reveal that chaetognaths are neither deuterostomes nor a close sister group to the deuterostomes. Recent phylogenomic analyses have strongly suggested protostome affinities, branching near or at the base of that line. This is consistent with them having typical protostome ventral mid-body ganglia and circumesophageal fibers. The possibility of arrow worms being sister to all other protostomes is intriguing because it might explain their mix of protostome and deuterostome like features. Thus, the enterocoelous formation of body cavities and the secondary appearance of the mouth, once considered to be their defining deuterostome attributes, may be ancestral (plesiomorphic) bilaterian features. Similarly, the enzyme GAMT (guanidinoacetate N-methyltransferase), which occurs in cnidarians, deuterostomes, and chaetognaths but not other protostomes, may represent a remnant ancestral feature of arrow worms that was lost in the rest of the protostome line.

Comparative morphologists have not yet identified any clear synapomorphies that unite chaetognaths with other protostome phyla. However, many unique features reveal the phylum status of arrow worms, including the moveable cuticular grasping spines on the head, a multilayered epidermis over most of the body, horizontal fins on the sides and posterior end, and closed seminal vesicles on the tail. Major characteristics of the group are listed in Box 11A.

BOX 11A Characteristics of the Phylum Chaetognatha

1. Bilateral protostomes, with streamlined, elongate, trimeric body comprising head, trunk, and tail region; single head coelom, and paired trunk and tail coeloms separated by transverse septa
2. Epidermis mostly stratified, with cuticle on ventral side of head; body with lateral and caudal fins, supported by "rays" consisting of elongate cytoskeletonrich epidermal cells; nonmolting
3. Mouth surrounded by sets of long moveable grasping spines and short teeth used in prey capture; mouth set in ventral vestibule; anterolateral fold of body wall forms retractable hood that can enclose grasping spines
4. Longitudinal muscles of unusual type, arranged in quadrants; weak circular musculature consists of myoepithelial cells
5. No discrete gas exchange or excretory systems
6. Hemal system restricted to trunk, consisting of narrow peri-intestinal sinuses and larger sinuses in dorsal mesentery and posterior septum
7. Complete gut; anus ventral, at trunk–tail junction
8. Centralized nervous system with large dorsal (cerebral) and ventral (subenteric) ganglia connected by circumenteric connectives; ciliary fence receptors for detection of water borne disturbances; anterior ciliary loop (= corona ciliata) of uncertain function. Inverted pigment cup ocelli
9. Hermaphroditic, with internal fertilization and direct development. Cleavage equal, holoblastic, and perhaps modified spiral. Mesoderm and body cavities form by enterocoely. Although blastopore denotes posterior end of body, both mouth and anus form secondarily, subsequent to closure of the blastopore.
10. Strictly marine; raptorial carnivores; largely planktonic, but some benthic species are known

Morphological uniformity within the phylum has resulted in few features that can be used to establish genera and families, or to determine systematic relationships within the phylum. The features that are used may be subject to homoplasy. The following classification based on morphology is only partially corroborated by molecular systematic studies.

Order Phragmophora With ventral transverse muscles (phragma) in trunk or tail. Three families with about 60 species: Spadellidae (e.g., *Paraspadella*, *Spadella*), Eukrohniidae (*Eukrohnia*), Heterokrohnidae (*Archeterokrohnia Heterokrohnia*, *Xenokrohnia*).

Order Aphragmophora Without ventral transverse muscles (phragma). Six families with about 70 species: Sagittidae (e.g., *Caecosagitta*, *Ferosagitta*, *Parasagitta*, *Sagitta*), Krohnittidae (*Krohnitta*), Pterosagittidae (*Pterosagitta*), Bathybelidae (*Bathybelos*), Krohnittellidae (*Krohnittella*), and Pterokrohnidae (*Pterokrohnia*).

The Chaetognath Body Plan

Externally, arrow worms are streamlined, with virtually perfect bilateral symmetry. Internally, transverse septa divide the coelomate body into a head, a trunk, and a tail. The head bears a ventrally placed mouth, set in a depression called the **vestibule**. The entire head region is elegantly adapted to a predatory life style. Lateral to the mouth are long moveable grasping spines, or "hooks," and in front of the mouth are short **cuticular teeth**—both used in prey capture and ingestion (Figures 11.10E and 11.11). The dorsolateral margins of the head possess a muscularized fold of the body wall called the **hood**. Except during prey capture, this is drawn ventrally around the sides of the head, thereby enclosing the grasping spines and streamlining the head. A pair of small, pigmented photoreceptors lie dorsally on the head. Also dorsally is a distinctive ring of innervated ciliated cells, the **corona ciliata**, of unknown function. The trunk bears one or two pairs of lateral fins and the tail bears a single horizontal tail fin. Chaetognath fins are simple epidermal folds enclosing a thick sheet of supportive extracellular matrix; certain elongate epidermal cells form fin rays. The body surface bears many **ciliary fence receptors**, which are short rows of nonmotile cilia serving as mechanoreceptors for detecting disturbances in the water. The trunk contains the intestine, which terminates ventrally at the trunk–tail junction, and two ovaries. The female gonopores are located laterally at the posterior end of the trunk. The male reproductive system occupies the tail, which is commonly filled with masses of differentiating sperm. Paired seminal vesicles protrude laterally, between the lateral and caudal fins.

The chaetognath body plan couples structural simplicity with a high degree of specialization. We tend to view the specialized features of arrow worms as adaptations to a planktonic predatory life style but, with nowhere to hide, pelagic arrow worms must also be adept at avoiding their own predators. Most chaetognaths are as transparent as glass and spend much of their time suspended motionlessly in the water, both features that minimize detection by visual predators such as fish. A chaetognath's sensitivity to water-born disturbances is equally useful for detecting prey and approaching predators, and the ability to move quickly enables both prey capture and escape from potential predators.

Body wall, support, and movement

Over most of the body, the epidermis is a stratified epithelium. Flattened surface cells produce a thin layer of secretion over the body, much like in fish. Underlying epidermal cells are filled with cytoskeletal tonofilaments (supportive cytoskeletal microfilaments). The epidermis on the ventral and lateral parts of the head consist of a single layer of cuticularized cells. The cuticle is not molted. On all parts of the body, a thick basement membrane joins the epidermis to underlying tissues. Four large groups of striated longitudinal muscle dominate the body wall of the trunk and tail (Figure 11.10F). These are separated from the body cavities by a thin layer of squamous peritoneum (noncontractile peritoneal cells). In addition, a weak circular musculature exists in the form of myoepithelial "lateral field cells" and dorsomedial and ventromedial cells. In the Phragmophora, sheets of transverse muscle extend obliquely from the lateral body wall to the ventral midline. In all arrow worms, the head musculature is complex (Figure 11.10E).

The body cavities are true coeloms. The single head cavity is reduced by the elaborate cephalic musculature. In the trunk and tail, longitudinal mesenteries separate the coelomic space into left and right compartments and in the tail incomplete lateral mesenteries partially subdivide each tail compartment. The 1:2:2 tripartite arrangement of the coelom resembles the coelomic arrangement of deuterostomes and lophophorates, but this similarity may represent convergent evolution. It has even been suggested that the posterior-most transverse septum is not a embryological homologue to that seen in other deuterostomes, and that it forms later, in connection with the development of the gonads. The coelomic fluid is colorless in life, but it stains intensely, which suggests an abundance of dissolved organic molecules. Circulation of coelomic fluids in both trunk and tail is caused by ciliated peritoneal cells in the lateral body wall. Coelomocytes are lacking

Body support in chaetognaths is provided by the hydrostatic quality of the coelom, crossed helical arrangement of collagen fibers in the basement membrane, and tonus of the body wall musculature. Locomotion of both pelagic and epibenthic species involves forward

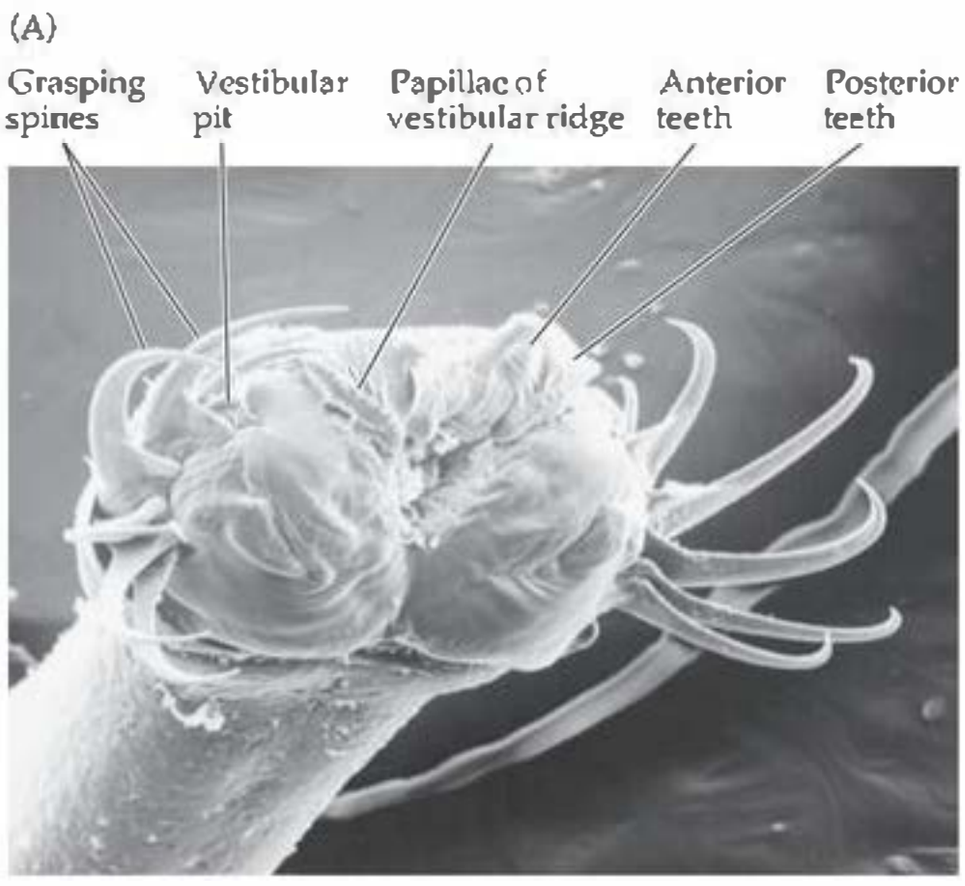

Figure 11.11 (A,B) Heads of chaetognaths. (A) *Zonosagitta pulchra*. Note the well-developed raptorial structures. (B) *Zonosagitta bedoti*, from the eastern Pacific. The hooks are clearly visible on either side of the head surrounding the exceptionally large number (17–20) of long, narrow, posterior teeth. The shorter anterior teeth lie just above the mouth. The vestibular ridge with its pores is partially visible behind the left set of posterior teeth. (C) The chaetognath in this photo, *Flaccisagitta hexaptera*, has partially swallowed a fish larva (probably an anchovy). A single anterior tooth projects down below the second hook on the left side of the photo, and two posterior teeth can be seen between the first and second hooks. The circular organ just below the first hook is the vestibular pit. (D) Diagram of a grasping spine of *Parasagitta elegans*.

darting motions caused by rapid alternating contractions of the dorsal- and ventral-longitudinal muscles. The fins are not used as propelling surfaces but are placed so that they slice through the water and serve as stabilizers. In pelagic species, brief swimming bursts alternate with quiescent periods, when the animals may slowly sink. This "hop-sink swimming," common among small planktonic invertebrates, probably constitutes a prey search behavior. Because swimming tends to be upward it helps the animals maintain their level in the water column. The fins increase resistance to sinking between swimming bursts. Species that make pronounced diurnal vertical migrations—up at night and down during the day—are presumably capable of extended bouts of swimming. Some species of arrow worms are neutrally buoyant due to hypertrophied intestinal cells or vacuolated epidermal cells that contain fluids less dense than seawater. The ventral transverse muscles in benthic chaetognaths (e.g., *Spadella*) might aid posturing or epibenthic movement.

Feeding and Digestion

Chaetognaths prey upon a variety of small pelagic animals, especially copepods. They can consume prey that

are nearly as large as themselves, including small fish and other arrow worms! The complex musculature of the head operates the grasping spines and retraction of the hood during feeding Both planktonic and benthic species are ambush predators, using ciliary receptors scattered over the body to detect movements of nearby prey. A chaetognath can determine both the direction and distance of potential prey at close range. Prey are ingested whole The release of luminescent clouds in deep sea species might serve to startle potential prey into movement, which can then be detected by the chaetognaths to facilitate predation. The luminescent cloud might also provide a means of escaping from predators.

Benthic forms, such as *Spadella*, feed while affixed to a substratum by adhesive secretions. As prey swim within reach, the anterior end is raised, and grasping spines flared. The prey is captured by a quick downward flex of the head while the rest of the body remains firmly attached. The grasping spines close around and manipulate the prey, orienting it for ingestion. Planktonic chaetognaths feed on prey approaching the body from all sides Laterally positioned prey are captured by rapid flexure of the body and a short forward hop can be executed to grab prey located in front

The grasping spines on left and right sides can be moved simultaneously or alternately, resulting in a surprising degree of dexterity during manipulation of prey. When rigid prey such as small crustaceans are captured, the chaetognath positions the victim longitudinally for swallowing. The spines and teeth contain α chitin, hardened at their tips by silicon in the two species so far examined closely. While superficially resembling setae of arthropods or chaetae of annelids, each tooth and grasping spine is a complex structure produced by a group of specialized epidermal cells. The grasping spines of some species bear serrations. Teeth are commonly cuspidate, a shape that may aid in the penetration of prey, including the exoskeletons of small crustaceans. Some, if not most, species of arrow worms use a fast-acting neurotoxin, tetrodotoxin, to quell prey. Tetrodotoxin blocks sodium transport across cell membranes. Many marine bacteria synthesize tetrodotoxin, and in chaetognaths the toxin is probably produced by commensal bacteria (*Vibrio*) inhabiting the head or gut of the arrow worm. The toxin is presumably incorporated into the very sticky secretions produced by vestibular glands and, possibly, the esophageal glands.

The gut is a relatively simple straight tube extending from the mouth in the vestibule to the ventral anus at the trunk tail junction (Figure 11.10A,C,I). The mouth leads to a short pharynx, which is equipped with mucus secreting cells. Swallowing is accomplished by well-developed pharyngeal muscles aided by lubricants from the mucous cells. The gut narrows where it passes through the head trunk septum, and it extends posteriorly as a long intestine. A short rectum joins the posterior intestine to the anus. Most digestion occurs extracellularly in the posterior intestine and can be extremely rapid. Orange carotenoid pigments derived from the prey are incorporated into the otherwise transparent tissues of some deep-water chaetognaths.

Circulation, Gas Exchange, and Excretion

A simple hemal system exists in chaetognaths, but it is easily overlooked because the blood is colorless and transparent. The hemal system consists of thin sinuses situated between the intestinal epithelium and surrounding myoepithelial peritoneum. Larger hemal sinuses exist in the dorsal mesentery, trunk/tail septum, ovaries, and body wall near the ventral ganglion. Transport through the hemal system is probably driven by the intestinal musculature. Even when the gut is empty, posteriorly directed peristalsis alternates with anteriorly directed peristalsis. The nutritive demands of various tissues in the tail are probably met by ultrafiltration across the tail side of the posterior septum, from the hemal sinus in the trunk/tail septum to the tail coelom. Gas exchange and excretion are apparently by diffusion through the body wall.

Nervous System and Sense Organs

Of paramount importance to the success of chaetognaths as active predators are features of the nervous system and associated sensory receptors. As we have seen in other groups, a body plan that emphasizes cephalization is usually an integral factor in adapting to a predatory lifestyle. The central nervous system of chaetognaths includes a large dorsal cerebral ganglion in the head. From this, paired nerves extend posteriorly to the eyes and corona ciliata, and two pairs of circumenteric connectives extend ventrally. Small anterior frontal connectives innervate the head muscles and gut Larger main connectives extend posteroventrally to join a large ventral ganglion located in the trunk epidermis (Figure 11.10G). From the ventral ganglion, numerous peripheral nerves radiate to all parts of the trunk and tail, branching to form an elaborate intraepidermal nerve plexus. The ventral ganglion receives sensory input from the ciliary fence receptors on the body, and it controls swimming and other behaviors caused by the body wall musculature.

The ciliary fences are stereotypically arranged and are oriented either parallel or transversely relative to the long axis of the body, such that the entire body functions as an "antenna" for reception of nearby disturbances. Each ciliary fence contains 50–300 cells. Although chemoreceptors have yet to be positively identified in chaetognaths, they almost certainly exist. Candidates include the aforementioned corona ciliata, the pore-bearing vestibular ridges located just behind the teeth, and other tiny pores flanking the mouth.

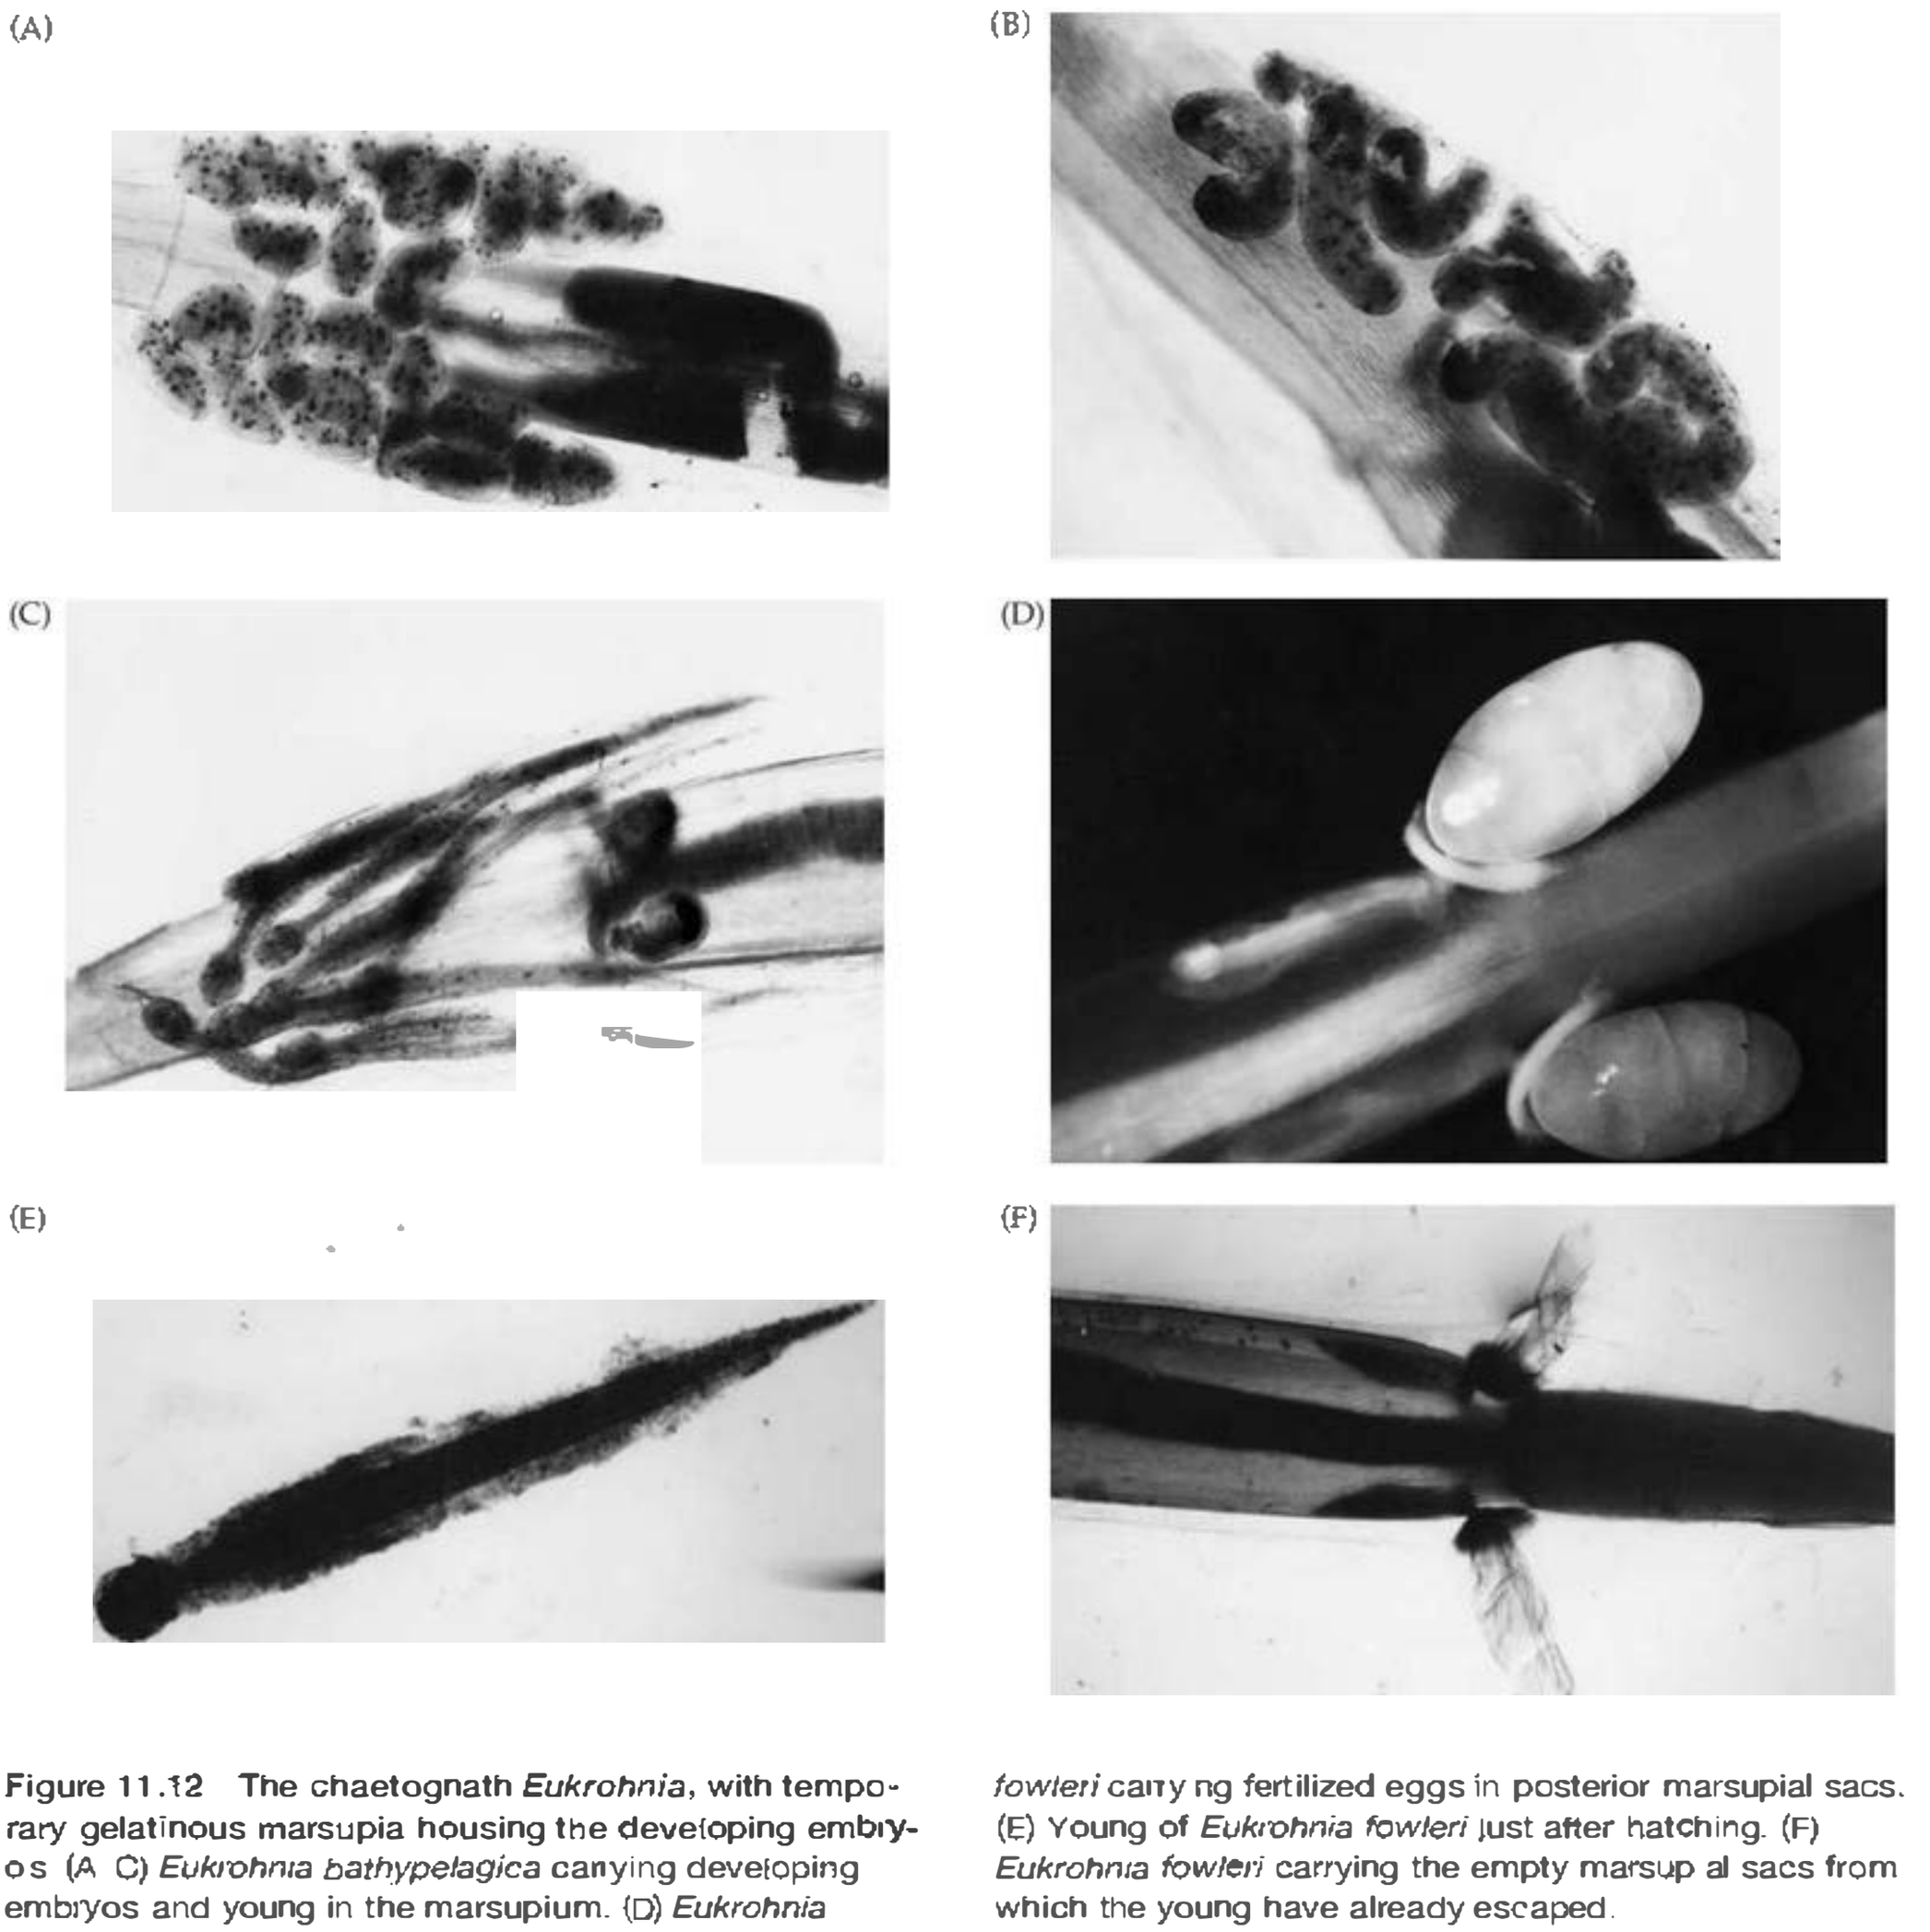

Figure 11.12 The chaetognath *Eukrohnia*, with temporary gelatinous marsupia housing the developing embryos (A–C) *Eukrohnia bathypelagica* carrying developing embryos and young in the marsupium. (D) *Eukrohnia fowleri* carrying fertilized eggs in posterior marsupial sacs. (E) Young of *Eukrohnia fowleri* just after hatching. (F) *Eukrohnia fowleri* carrying the empty marsupial sacs from which the young have already escaped.

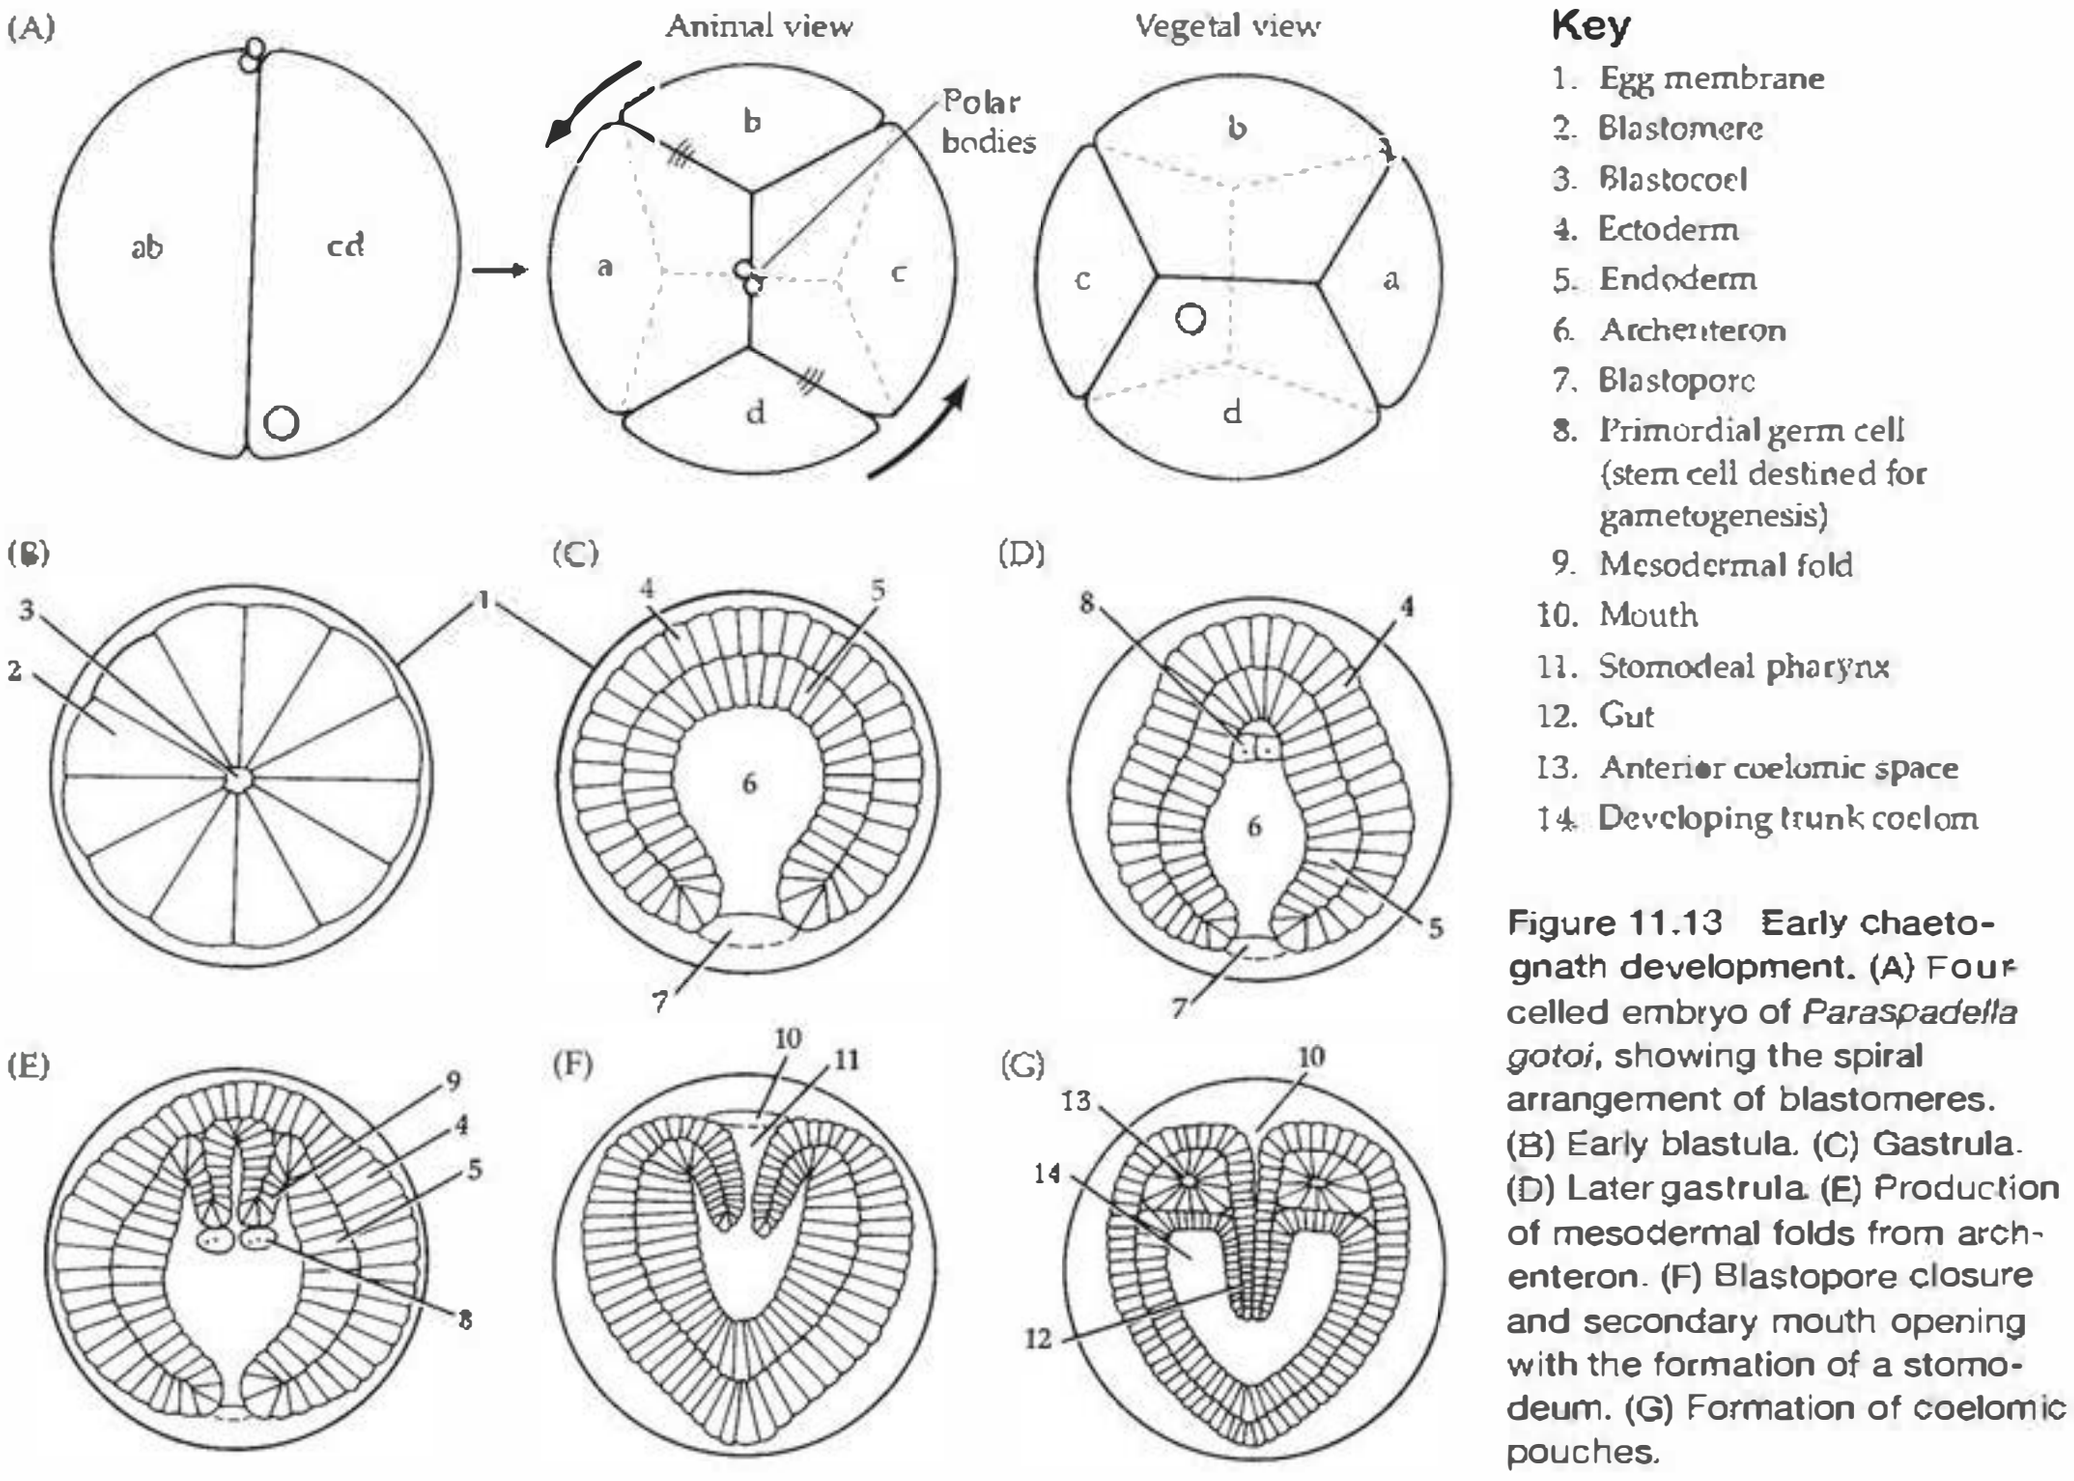
Most arrow worms possess a pair of eyes on the dorsal surface of the head. Typically, each eye has a large central pigment cell, indented to form seven cups containing the light sensitive parts of the ciliary receptor cells (Figure 11.10H). We can infer from their structure that chaetognaths have a nearly uninterrupted visual field enabling them to orient to light direction and intensity. The eyes of deep-water arrow worms are variously modified in ways that presumably increase sensitivity to light. For example, in certain species of *Eukrohnia*, the photoreceptor cells are directed outward, and each is capped by a transparent "lens." The eyes probably do not form images but are used for orientation during vertical migration.

Reproduction and Development



Arrow worms are hermaphroditic, with paired ovaries in the trunk and paired testes in the tail (Figure 11.10I). Groups of spermatogonia are released from the testes to the tail coeloms, where they circulate as the sperm mature. The filiform sperm are picked up by open ciliated funnels and conveyed down the sperm ducts to a pair of seminal vesicles, which bulge from the sides of the tail. In some species, gland cells secrete a spermatophore wall around the enclosed sperm. When filled with sperm, the seminal vesicles are conspicuously white. Release of sperm involves rupture of the seminal vesicles during mating. This can lead to self-fertilization in some species, but happens during

mating in most species. Each ovary bears along its side an oviduct that leads to a genital pore just in front of the trunk–tail septum. Eggs develop within the ovaries where they are bathed in a nutritive fluid derived from the posterior hemal sinus. Fertilization occurs prior to ovulation as sperm received during mating pass from the oviduct through specialized accessory fertilization cells to the attached eggs. Immediately after fertilization, zygotes move into the oviduct for release to the environment.

Mating has been most extensively studied in some benthic spadellids (e.g., *Spadella cephaloptera*, *Paraspadella gotoi*) and the neritic *Ferosagitta hispida*. After a rather elaborate mating "dance," sperm from a seminal receptacle are deposited as a mass onto the mate's body. In *Paraspadella gotoi*, the sperm mass is precisely placed at the female gonopore, but in the others sperm masses are attached more anteriorly and columns of sperm stream over the epidermis of the recipient to enter the female gonopores. Benthic chaetognaths (e.g., *Spadella*) tend to deposit fertilized eggs on algae or other suitable substrata. Planktonic species typically shed floating embryos to the sea. *Pterosagitta draco* encloses the embryos in a large floating gelatinous mass and species of *Eukrohnia* carry developing embryos in gelatinous masses, one on either side of the body near the tail, until the young are ready to swim (Figure 11.12). *Ferosagitta hispida* descends and attaches developing eggs to stationary benthic objects. When food is abundant, new batches of sperm and eggs can be produced in daily succession.

Development is direct, lacking any larval stage or metamorphosis. The transparent eggs contain little yolk, and cleavage is holoblastic and equal. Both classical and modern studies have suggested a modified spiral pattern of cleavage, with unmistakable animal and vegetal cross-furrow cells, but this is easily overlooked because animal-pole cells ("micromeres") and vegetal-pole cells ("macromeres") are similar in size, and cleavage of arrow worms has been incorrectly described in the past as being radial. However, while a spiralian-like tetrahedral 4-cell embryo is derived via a levotropic blastomere displacement in the second cleavage, subsequent cleavage stages have not yet been documented and further research is needed to understand the nature of cleavage in these animals. The coeloblastula consists of pyramidal cells arranged around a small blastocoel (Figure 11.13).

Gastrulation (germ layer formation) occurs by invagination of the presumptive endoderm, leaving no blastocoel. The blastopore marks the eventual posterior end of the animal—both mouth and anus form secondarily,

thus giving chaetognaths a deuterostome-like developmental pattern. Coelom formation has been described as a modified form of enterocoely. Starting at the future anterior end, vertical epithelial folds of endoderm grow posteriorly through the archenteron, separating the future lateral coelomic cavities from the medial gut cavity (Figure 11.13). Early formation of the head–trunk septum results in the early isolation of the head coeloms. As development continues, embryos elongate and the body cavities become compressed, but the surrounding mesodermal cells retain their epithelial morphology. The coeloms re expand later in development and then persist as true coeloms into adulthood. Interestingly, all organs and tissues of mesodermal origin, including body wall musculature, intestinal musculature, and somatic reproductive tissues derive entirely from the peritoneum of the embryonic coeloms. It seems that coelom and mesoderm formation in chaetognaths is neither fully enterocoelous nor schizocoelous, and Kapp (2000) proposed the name **heterocoely** for the unique mode of coelom formation in this group.

Development from zygote release to hatching as a juvenile chaetognath is rapid, about 48 hours. Parental investment per embryo is small, the eggs contain little yolk, and they are abandoned soon after fertilization (except in brooding forms). The rapid development to a feeding juvenile is essential to the success of this life history strategy

Phylum Gastrotricha: The Gastrotrichs

The phylum Gastrotricha (Greek *gasteros*, "stomach"; *trichos*, "hair") comprises about 800 species of marine, brackish, and freshwater Metazoa. Most species are less than 1 mm long, although a few reach 3 mm in length. Many gastrotrichs bear a superficial resemblance to flatworms and rotifers, but are easily distinguished by their adhesive tubes and cilia restricted to the ventral surface. Under high magnification the tiny gastrotrichs appear to be very charismatic invertebrates, with their "whiskered" faces and spiny or scaled, often bowling pin-shaped bodies. Figure 11.14 illustrates some of the

BOX 11B Characteristics of the Phylum Gastrotricha

1. Triploblastic, bilateral, unsegmented, acoelomate
2. Microscopic, body elongate or bowling pin-shaped
3. Bilayered cuticle, smooth or with scale or spine like elaborations; with exocuticle covering entire body including all cilia; cuticle is not molted
4. Duo-gland adhesive tubes
5. Epidermis cellular or partly syncytial; epidermal cells monociliate or multiciliate; locomotory cilia on ventral surface only
6. Myoepithelial pharynx with triradiate lumen; complete gut
7. One pair or more of protonephridia, without special circulatory or gas exchange structures
8. Hermaphroditic, parthenogenetic, or hermaphroditic and parthenogenetic
9. Complex reproductive organs
10. Embryonic development poorly studied
11. Direct development

body forms within this phylum and some features of their external anatomy, and Box 11B lists the distinguishing features of this group. Marine gastrotrichs are meiofaunal and live in the interstitial spaces between sand grains from the intertidal zone to abyssal depths (> 2,500 m). Freshwater species are found in surface detritus or among the filaments of aquatic plants and plantlike protists; a few are semiplanktonic. They are sometimes abundant when found.

The gastrotrich body is typically divisible into a head and a trunk (Figures 11.14B,C and 11.15A), though many species lack such an obvious distinction. Externally, gastrotrichs possess a cuticle that surrounds all aspects of the body and is often smooth in appearance but may be elaborated into spines, bristles, scales, and/or plates (Figure 11.14). Adhesive tubes, a diagnostic character of most gastrotrichs, are also derived from the cuticle and generally contain a pair of glands that secrete adhesive and releaser substances (the duo gland adhesive system). These tubes may be abundant (Macrodasyida) or sparse to absent (most Chaetonotida).

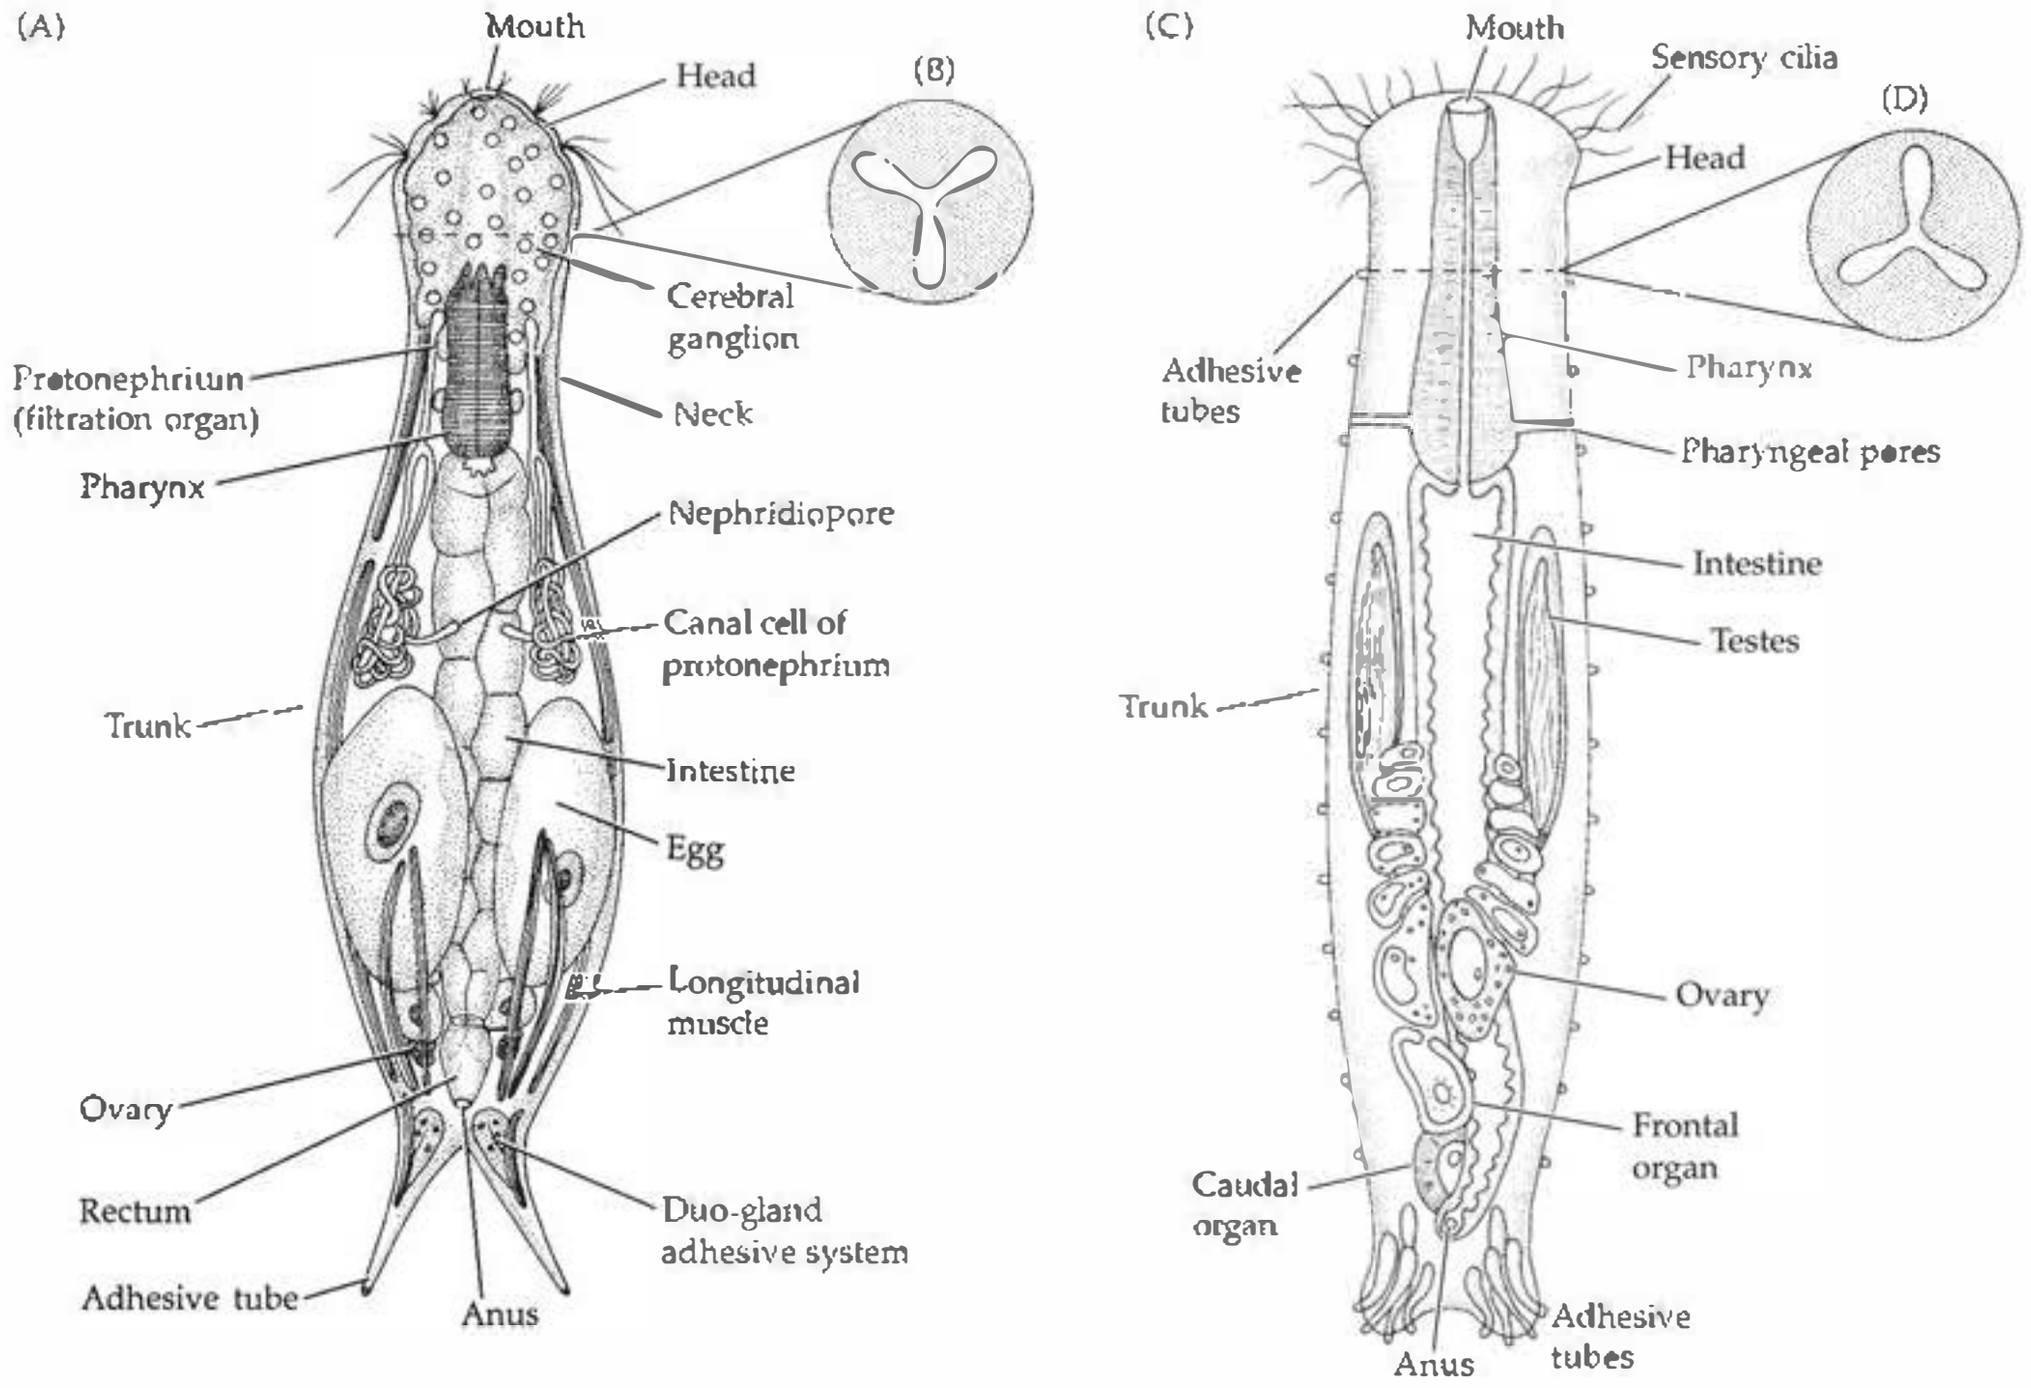
The gastrotrich head bears a terminal or subterminal mouth with stiff cilia or other cuticular elaborations. A ring of motile cilia often encompasses the head dorsally while other ciliary elaborations such as pits and tentacles are present on the sides (Figure 11.14F). A neck-like constriction behind the head is present in many but not all gastrotrichs. The gastrotrich trunk (the main part of the body) is generally vermiform (Macrodasyida, *Neodasys*) or bowling pin-shaped (Chaetonotida), and it contains most of the organ systems. The trunk terminates in a rounded, bilobed, tailed, or forked caudum that bears adhesive tubes

The most recent molecular phylogenetic studies place gastrotrichs squarely within the protostome bilaterians and close to the base of the Spiralia, where they seem to arise near the Platyhelminthes or the Gnathifera (Gnathostomulida, Micrognathozoa, and Rotifera). Anatomically, however, gastrotrichs are more similar to Nematoida and Scalidophora clades because of their circumpharyngeal brain, bilayered cuticle, and myoepithelial pharynx.

Gastrotrich Classification

Order Chaetonotida (Figure 11.14A-C). Primarily freshwater, but also some marine, estuarine, and semiterrestrial (freshwater microhabitats) species; smooth or complex cuticle with a variable number of adhesive tubes (most with only two on caudal furca); pharynx with Y-shaped lumen, pharyngeal pores absent; one or more pair of protonephridia present; hermaphroditic, parthenogenetic, or a combination of hermaphroditic and parthenogenetic.

Suborder Multitubulatina Marine; strap-shaped body with smooth cuticle and anterior, posterior, and lateral adhesive tubes; hermaphroditic. Monogeneric: *Neodasys*, with two known species.



Suborder Paucitubulatina Mostly freshwater species but with many marine representatives; bowling pin-shaped body often covered by elaborate cuticle, usually with two terminal adhesive tubes on caudal furca; hermaphroditic, parthenogenetic, or both (e.g., *Aspidiophorus, Chaetonotus, Dasydytes Lepidodermella*).

Order Macrodasyida (Figures 11.14D–F). Mostly marine and estuarine gastrotrichs with only a single freshwater genus (*Redudasys*); with smooth or elaborately sculptured cuticle, usually bearing numerous adhesive tubes along the head (ventral), and trunk (lateral, ventral, sometimes dorsal); pharynx with inverted Y shaped lumen, pharyngeal pores present in all except species of *Lepidodasys*; usually with several pairs of protonephridia; hermaphroditic with complex reproductive organs; some may be parthenogenetic (e.g., *Dactylopodola, Macrodasys, Turbanella, Urodasys, Xenodasys*).

The Gastrotrich Body Plan

Body Wall

A gastrotrich's body is encased in a bilayered cuticle of varying thickness and complexity. It is never molted. The outer portion or exocuticle contains one or more lamellae that cover all external surfaces including locomotory and sensory cilia (Figure 11.15E); the inner portion or endocuticle is thick and fibrous and produces the spines, scales, and adhesive tubes (Figure 11.14). The epidermis may be cellular as in Macrodasyida or

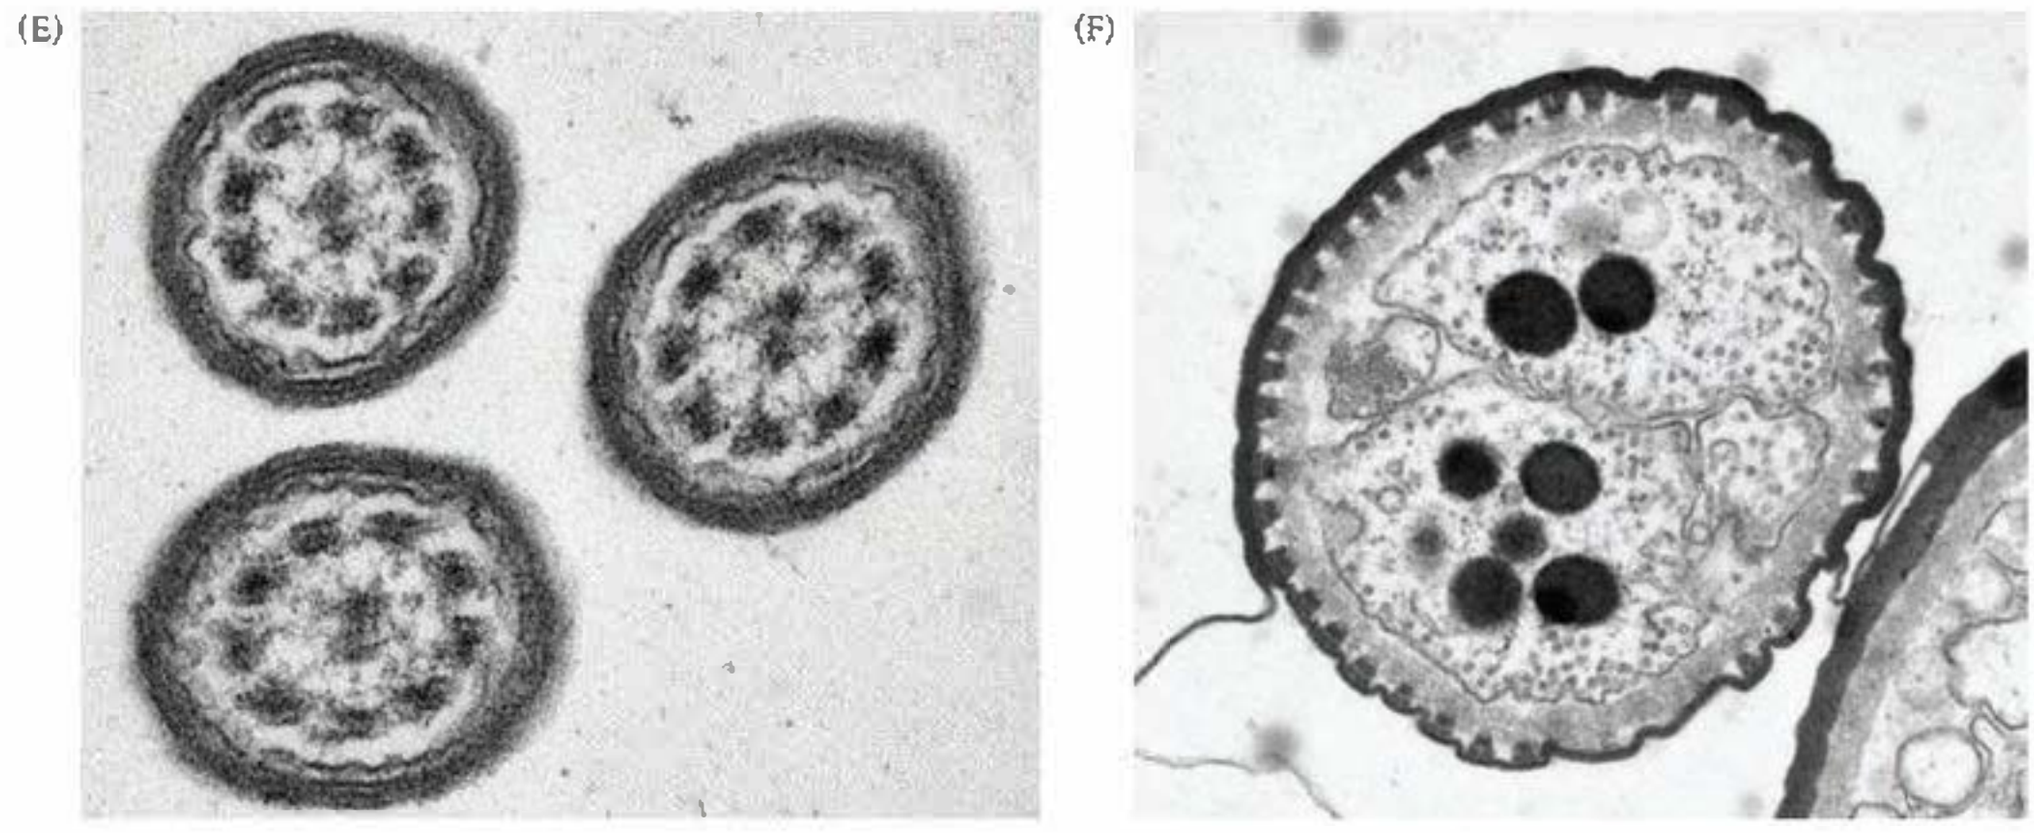


Figure 11.15 Anatomy of gastrotrichs. (A) Representative of Chaetonotida, *Paucitubulatina*. (B) Cross section through pharynx showing Y-shaped pharyngeal lumen. (C) Representative of Macrodasyida and (D) cross section through pharynx showing inverted Y-shaped pharyngeal lumen. (E–F) Transmission electron micrographs of (E) a cross section through locomotory cilia and (F) an adhesive tube.

partly syncytial as in most Chaetonotida; only ventral epidermal cells bear locomotory cilia (thus the derivation of the phylum name: "hairy belly"). Most species possess multiciliate epidermal cells, however some species possess monociliate cells. Duo-gland adhesive organs, consisting of at least one adhesive gland and one releaser gland (which are critical for rapid grip and release from sand grains in the interstitial environment), are present in all species and form cuticle covered neck-like tubes to the outside (Figure 11.15F).

Internal to the epidermis are connective tissues such as a basal lamina (absent in many species) or in some

cases large vacuolar Y cells (some Macrodasyida and *Neodasys*) that function in hydrostatic support; hemoglobin has been detected in the Y cells of *Neodasys* and may be present in others. Muscles are present as circular, helicoidal, and longitudinal bands that insert on the cuticle via an intervening epithelial cell; dorsoventral and other muscle orientations may also be present.

Support and Locomotion

The cuticle and compact (acoelomate) body plan provide hydrostatic support while the complex array of muscles produce the bending and twisting movements characteristic of gastrotrich locomotion, and essential for life between sand grains (which are "boulder size" for millimeters long gastrotrichs). Most animals are highly flexible and in some genera such as *Megadasys* (Figure 11.14D) can stretch their already elongate bodies to nearly twice gliding length or contract into a tight ball. The adhesive tubes play a significant role during these activities. Some semi-planktonic freshwater gastrotrichs such as species of Dasydytidae (Chaetonotida) have moveable spines that permit a form of saltatory swimming.

Feeding and Digestion

Most gastrotrichs feed by pumping small food items into the gut by action of the pharynx, a myoepithelial tube that is surrounded by complex layered muscles. The pharyngeal lumen is either Y-shaped (Chaetonotida) or inverted Y-shaped (Macrodasyida) (Figures 11.15B,D). In most macrodasyidans, a pair of pharyngeal pores connects the pharyngeal lumen to the outside, thereby permitting the release of excess water imbibed with the food (Figure 11.15C). Gastrotrichs feed on nearly any organic material, alive or dead, of appropriately small size (bacteria, detritus, protists, unicellular algae)

The mouth is terminal or subterminal and often surrounded by a ring of stiff cilia or cuticular spines that may aid in food capture A short buccal cavity connects the mouth to the elongate muscular pharynx lined with cuticle (a stomodaeum) (Figure 11.14). In species of Chaetonotida, a pharyngeal "valve" may be present at the junction of the pharynx and intestine (midgut). The endodermally derived portion of the gut is a straight tube that narrows posteriorly and leads to a ventral anus. The anus is preceded by a cuticlelined hindgut in Chaetonotida, while in most Macrodasyida a hindgut is absent and the anus is presumably permanent or temporary. Digestion and absorption occur in the intestine, which is comprised of cuboidal cells with a brush border; motile cilia may be present in some species and aid in food passage.

Circulation, Gas Exchange, Excretion, and Osmoregulation

Circulation and gas exchange occur by diffusion through the body wall. Some gastrotrichs are capable of anaerobic respiration when environmental conditions require it Protonephridia are the primary excretory organs in gastrotrichs. Marine species such as most macrodasyidans and *Neodasys* possess multiple pairs of protonephridia that function solely in the removal of metabolic wastes. Their protonephridia are generally mono- or bicellular filtration organs each with a single flagellum; they connect to the outside by way of a single ciliary canal cell and nephridiopore cell. In species that live in a hypoosmotic environment like most freshwater chaetonotidans, the single pair of protonephridia also function in osmoregulation. Their protonephridia are bicellular organs that lead to an elongate and convoluted canal cell (Figure 11.15A). The extra length of the canal cell in freshwater species is hypothesized to function for increased reabsorption of necessary salts and minerals from the primary urine before elimination.

Nervous System and Sense Organs

The central nervous system consists of a dorsal brain and one or more pairs of longitudinal nerve cords. The brain consists of numerous cells that sit atop a ring-like commissure around the anterior region of the pharynx (Figure 11.15A). Cerebral neurons innervate the head and pharynx. The nonganglionated nerve cords arise from the brain and are interconnected by thin commissures; they unite at the posterior end.

Sensory receptors are ciliary in structure and concentrated in the head region but may be distributed over the entire body. Ciliary pits and tentacles on the heads of some species are likely chemosensory, while stiff, bristlelike cilia on the head and trunk probably have a tactile function. Several species possess pigmented (red) ocelli that indicate probable photoreceptive capabilities; experiments have shown that species lacking ocelli still have spectral sensitivity. One species, *Pleurodasys helgolandicus*, possesses an unusual pair of drumstick like organs that are hypothesized to function as gravity receptors

Reproduction and Development

Most species of gastrotrichs are hermaphroditic or a combination of hermaphroditic and parthenogenetic Strict parthenogenesis is rare and known from only a few species. The hermaphroditic reproductive system is best studied in Macrodasyida and often contains gametes and organs of sperm transfer and storage (Figure 11.15C). The male system comprises one or two testes with associated sperm ducts that lead to a single or paired ventral gonopores. A caudal organ that presumably functions in the transfer of sperm is present in most species, but only in Macrodasyidae and Thaumastodermatidae is it directly connected to the sperm ducts; some species bear a sclerotized stylet within the caudal organ.

The female system includes one or two ovaries in the posterior body region. Other reproductive organs may include a frontal organ (seminal receptacle) as in

Macrodasyida and *Neodasys*, or an X organ as in most Chaetonotida. The ovaries are generally compact or somewhat diffuse. Oocytes mature anteriorly in most species and become positioned above the intestine and in proximity to the frontal organ when present; oviducts are rare but some species do have a distinct uterus. Yolk is produced within the oocyte itself. Mutual cross-fertilization leads to the direct exchange of sperm or spermatophores (via hypodermic impregnation or some other mechanism) in all species, but sperm is stored in the frontal organ of most macrodasyidans. The X-organ in chaetonotidans is a bilobed syncytial organ in the posterior trunk that develops during the sexual phase and is thought to play a role in reproduction, although its function has never been demonstrated. Fertilization is always internal and precedes the production of an eggshell by the egg itself. Oviposition is through the body wall of most species, and it might occur through a temporary or perhaps permanent pore, or in some cases via rupture of the body wall.

Historically, most freshwater chaetonotidans were assumed to be strict parthenogens until small packets of rodlike sperm were discovered next to their midgut. The sperm develop after the production of the parthenogenetic ova and in synchrony with the meiotic (sexual) ova, suggesting they are not vestigial male gametes; such a condition is referred to as **post-parthenogenetic hermaphroditism**. Cross fertilization has never been observed in these species. Two forms of parthenogenetic eggs are produced: the first few eggs (tachyblastic) hatch quickly and are important for rapid population growth, while the last egg (opsiblastic) may overwinter before hatching. A third and more rare type of egg, called the plaque bearing egg, is thought to be the result of sexual reproduction, but its development has never been followed.

Few embryological studies have been conducted on gastrotrichs and those that have detailed the main cleavage events are somewhat contradictory. In general, cleavage is holoblastic and adequal (i.e., the blastomeres are of approximately equal size), however, after the initial equatorial division, there is an apparent divergence in cleavage patterns between the two orders. The second cleavage plane of the posterior blastomere is meridional in macrodasyidans but equatorial in chaetonotidans, which leads to different fates for the developing tissues. In neither case is a spiral like cleavage pattern evident. By the fifth division, a bilaterally symmetric embryo has developed. Gastrulation occurs by invagination followed by epiboly of the secondary ectoderm over presumptive mesoderm. A stomodaeum forms in both orders but a proctodeum has been noted only for chaetonotidans. The U-shaped embryo continues to grow and elongate in the eggshell for several hours (to several days) prior to hatching.

Development is direct and juveniles are small versions of adults, though without noticeable reproductive organs and with fewer adhesive tubes (in Macrodasyida). Maturation is rapid and the animals usually are sexually mature within a few days after hatching. Individuals of most species probably live only a few weeks.

CHAPTER 12

Phylum Nemertea

The Ribbon Worms

Members of the phylum Nemertea (Greek, "a sea nymph") or Rhynchocoela (Greek *rhynchos*, "snout"; *coel*, "cavity") are commonly called ribbon worms. Figure 12.1 illustrates a variety of body forms within this taxon and the major features of their anatomy. These unsegmented vermiform animals are usually flattened dorsoventrally and are moderately cephalized; they possess highly extensible bodies. Many ribbon worm species are rather drab in appearance, but others are brightly colored or distinctively marked (e.g., the tropical eastern Pacific species *Baseodiscus punnetti*, above).

There are about 1,300 accepted, described species of nemerteans. They range in length from a few mm to several meters. Many can stretch easily to several times their contracted lengths (one specimen of *Lineus longissimus* reportedly measured 60 m in length). They are predominately benthic marine animals. A few, however, are planktonic, and some are symbiotic in molluscs, ascidians, or other marine invertebrates. A few freshwater and terrestrial species are known, the latter having some species of nearly cosmopolitan distribution.

Many features of the nemertean body plan (Box 12A) are similar to the conditions seen in flatworms (Platyhelminthes), and historically the two taxa were often grouped together as triploblastic acoelomate Bilateria. However, we now understand that nemerteans are truly coelomate, and that they are closely related to annelids, molluscs, and the lophophorate phyla. The similarities with the flatworms are reflected in the overall architecture of the nervous systems, the types of sense organs, and the protonephridial excretory structures. However, in other respects ribbon worms are more similar to the abovementioned spiralian phyla. Nemerteans possess a through gut with an anus (a complete, one-way digestive tract), a closed circulatory system that is coelomic in nature, and an eversible proboscis surrounded by a hydrostatic cavity called the rhynchocoel. The circulatory system and the rhynchocoel are both coelomic cavities. The structure of

This chapter has been revised by Gonzalo Giribet.

the proboscis apparatus is unique to nemerteans and represents a novel synapomorphy that distinguishes the Nemertea from all other invertebrate taxa.

Taxonomic History and Classification

The earliest report of a nemertean was that of William Borlase (1758), who described his specimen as "the sea long worm" and categorized it "among the less perfect kind of sea animals." For nearly a century, most authors placed the ribbon worms with the turbellarian flatworms, although other writers suggested that they were allied to annelids (including sipunculans), nematodes, and even molluscs and insects. It was during this period that Georges Cuvier (1817) described a particular ribbon worm and called it *Nemertes*, from which the phylum name was eventually derived. However, it was not until 1851 that substantial evidence for the distinctive nature of the ribbon worms was published by Max Schultze, who described the functional morphology of the proboscis, established the presence of nephridia and an anus, and discussed many other features of these animals. Schultze even proposed the basis for classifying these worms, which is still largely employed today by most authorities. Interestingly, he persisted in considering them to be turbellarians, but he coined the names Nemertina and Rhynchocoela. Charles Minot separated the nemerteans from the flatworms in 1876, but it was not until the mid twentieth century that the unique combination of characters displayed by the ribbon worms was fully accepted. Since that time they have been treated as a valid phylum. It was in the mid-1980s that James M. Turbeville, studying their ultrastructure, determined that nemerteans are more closely related to the coelomate protostomes than to platyhelminths, a result later corroborated by molecular sequence data and by the mode of development.

Classification

Since the publication of Schultze's classic accounts, the primary effort of nemertean taxonomists has been to refine the details of his scheme, which has generated surprisingly few controversies. The classification scheme used here is mostly based on the traditional one established by Wesley Coe in 1943 and refined with molecular phylogenetic analyses.

For most of the last 100 years, the traditional classification system of nemerteans has largely followed that of Gerarda Stiasny-Wijnhoff (1936), which accepted as classes Schultze's (1851) division of nemerteans into the classes Anopla and Enopla. Stiasny Wijnhoff divided Anopla into Palaeonemertea and Heteronemertea, and Enopla into Hoplonemertea and Bdellonemertea. Hoplonemertea was further subdivided into Monostilifera and Polystilifera. Recent accounts of the systematics of Nemertea found a division between Palaeonemertea and Neonemertea, with Hubrechtidae as the sister group of Heteronemertea, constituting the clade Pilidiophora (see classification that follows). Furthermore, all molecular analyses have contradicted the ordinal status of Bdellonemertea, which is deeply nested within Hoplonemertea.

We therefore follow a system in which the phylum is subdivided into two main clades, Palaeonemertea and Neonemertea, the latter divided into Pilidiophora (including the traditional order Heteronemertea and the family Hubrechtidae) and Hoplonemertea (= Enopla of older classifications). The principal anatomical features used to distinguish between these clades include proboscis armature, mouth location relative to the position of the cerebral ganglion, gut shape, layering of the body wall muscles, position of the longitudinal nerve cords, and several larval features.

BOX 12A Characteristics of the Phylum Nemertea

1. Marine, freshwater, or terrestrial
2. Triploblastic, coelomate, bilaterally symmetrical unsegmented worms
3. Digestive tract complete, with an anus
4. With protonephridia (a few deep-sea pelagic species lack excretory systems)
5. With bobed cerebral ganglion that surrounds proboscis apparatus (not the gut), and two or more longitudinal nerve cords connected by transverse commissures
6. With two or three layers of body wall muscles arranged in various ways
7. With a unique proboscis apparatus lying dorsal to the gut and surrounded by a coelomic hydrostatic chamber called the rhynchocoel
8. With a closed circulatory system; some species with hemoglobin
9. Most are gonochoristic; cleavage holoblastic; early development typically spiral, and either direct or indirect
10. Asexual reproduction by fragmentation is not uncommon

PHYLUM NEMERTEA (= RHYNCHOCOELA)

CLASS PALAEONEMERTEA Unarmed nemerteans (Figure 12.1B). Proboscis not armed with stylets and not morphologically specialized into three regions. Mouth separate from proboscis pore and located directly below or somewhat posterior to cerebral ganglion. Two or three layers of body wall muscles, from external to internal either

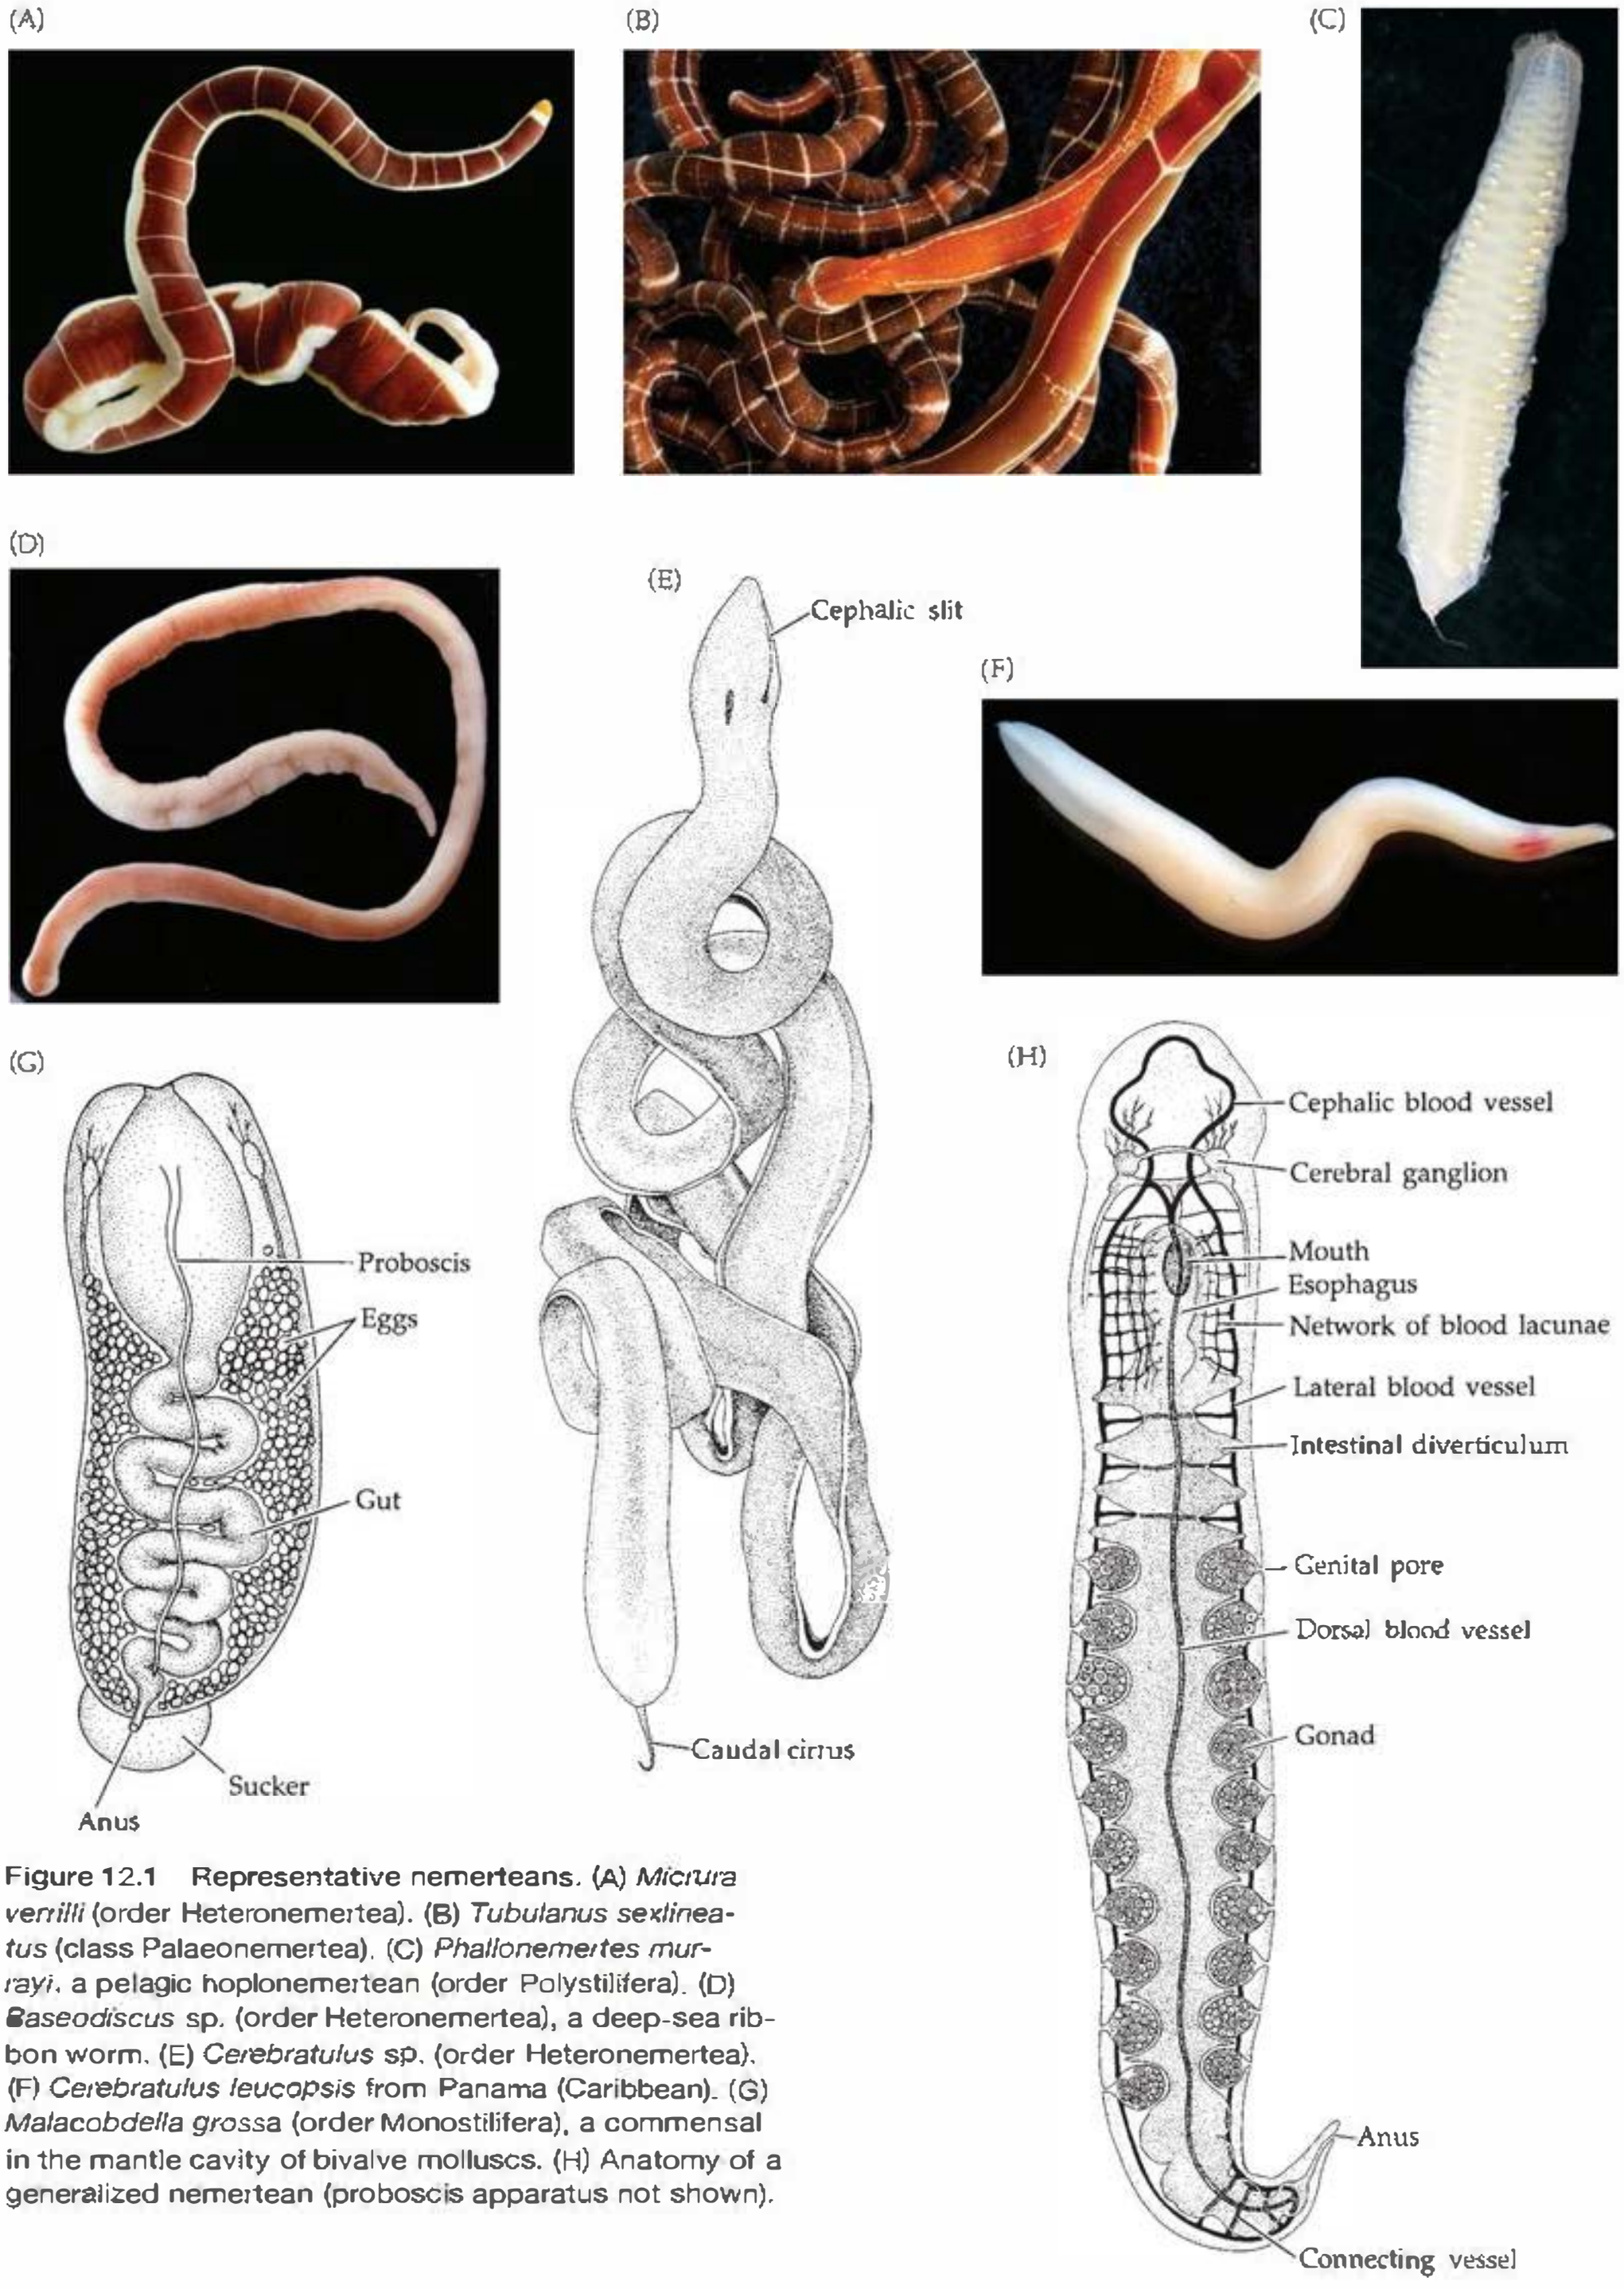

Figure 12.1 Representative nemerteans. (A) *Micrura verrilli* (order Heteronemertea). (B) *Tubulanus sexlineatus* (class Palaeonemertea). (C) *Phallonemertes murrayi*, a pelagic hoplonemertean (order Polystilifera). (D) *Baseodiscus* sp. (order Heteronemertea), a deep-sea ribbon worm. (E) *Cerebratulus* sp. (order Heteronemertea). (F) *Cerebratulus leucopsis* from Panama (Caribbean). (G) *Malacobdella grossa* (order Monostilifera), a commensal in the mantle cavity of bivalve molluscs. (H) Anatomy of a generalized nemertean (proboscis apparatus not shown).

circu ar- ongitudina or circular longitud nal-c rcular; dermis thin and gelatinous, or absent; longitudinal nerve cords epidermal, derma, or intramuscu ar within the longitudinal layer; cerebra organs and ocelli frequently ack ng. Pa ae-onemer :eans are mar ne, primarily l ttora forms. (e g., *Carr noma*, *Cephalothr:x*, *Tubulanus*)

CLASS NEONEMERTEA Unarmed or armed nemerte-ans w th separate or fused mouth and proboscis pores. Because Hubrecht dae was former y placed in Pa aeone mer:ea. most characters w thin Neonemertea are variable.

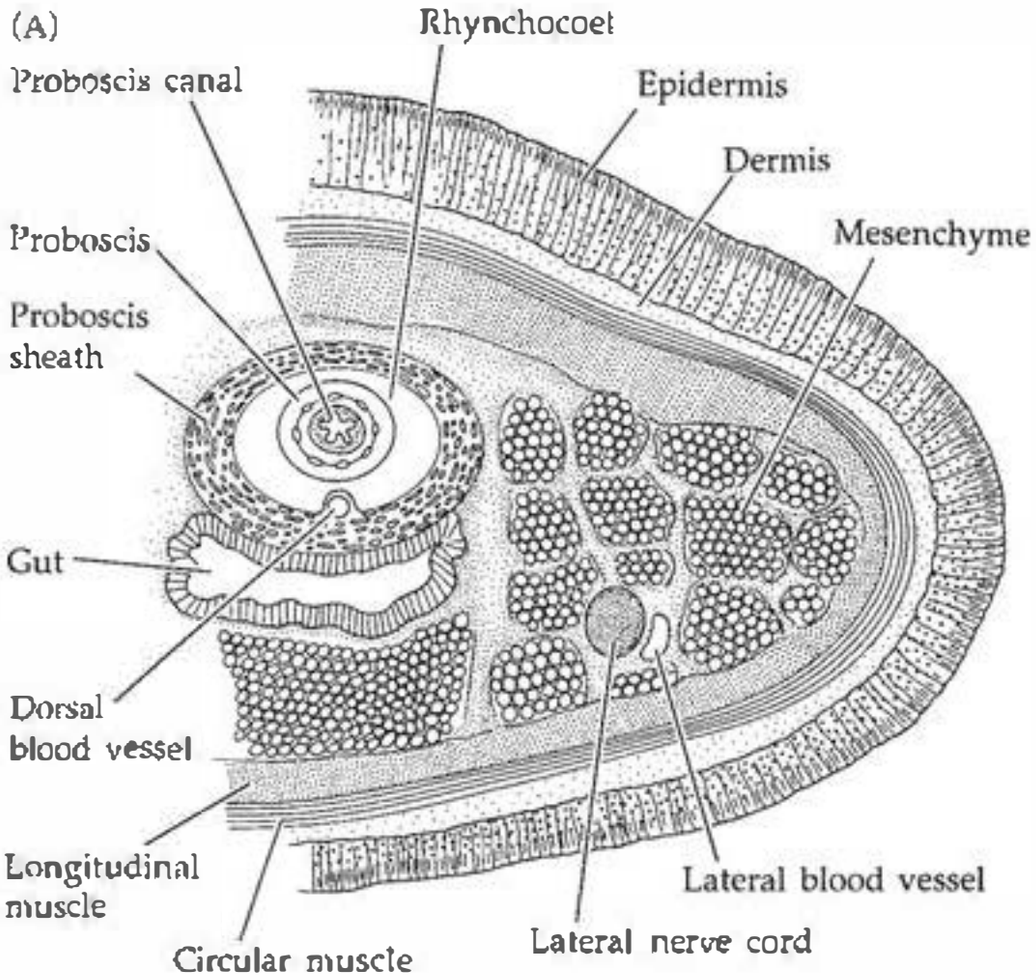
SUBCLASS PILIDIOPHORA Nemer:eans w th a pi id um larva (when present) and the probosc s musculature b - ateral y arranged.

ORDER HUBRECHTIDA Unarmed nemerteans w th separate mouth and probosc s pores. The brain and ateral nerve chords are s tuated below the ep dermis n the connect ve tissue, whereas the cerebra sensory organ occupies a position re at ve to the bra n and atera b ood vessel s milar to that of heteronemer teans. Histor:cally, hubrechtiids were regarded as a "transitiona stage" between palaeonemerteans and basal heteronemer :eans All mar ne. (e.g., *Hubrechtia*, *Hubrechtella*)

ORDER HETERONEMERTEA Three layers of body wall muscles, from external to nterna longitudina -cir-cu ar longitud nal; derm s usual y thick, par : y fibrous; ongitud nal nerve cords intramuscu ar, between outer ongitudina and midd e circu ar layers; cerebra organs and ocel usual y present; development ndirect. These nemerteans are primar ly mar ne littora forms, but a few freshwater spec es are known (Figure 12.1A D-F). (e.g., *Baseodiscus*, *Cerebratulus*, *Lineus*, *Micrura*, *Nemertoscolex*, *Paralineus*)

SUBCLASS HOPLONEMERTEA (= ENOPLA) Typically armed nemerteans (Figure 12.1C,G). Proboscis usually armed w th d st nct stylets and morpho ogically special-zed into three regions (except n *Bdellonemertea*); mouth and proboscis pore usually un ted into a common aper ture; mouth located anterior to cerebral gangl on; longi-tudinal nerve cords w th n mesenchyme, interna to body wal muscles. With marine, freshwater and terrestrial spec es; many mar ne spec es symbiot c with or parasitic upon other invertebrates

ORDER POLYSTILIFERA Sty et apparatus cons sts of many small stylets borne on a basa shield. All spe-c es are marine, e ther benth c or pe agic. (e.g., *Hu brechtonemertes Nectonemertes Pelagonemertes*, *Phallonemertes*)



ORDER MONOSTILIFERA Stylet apparatus consists of a sngle ma n stylet and two or more sacs hous ng access ory (repla ement) stylets; probosc s apparatus is unarmed and opens into foregut in *Malacobdella*, which has a trunk with a large poster or sucker and a convoluted gut that acks lateral d verticu a. Most spec es are mar ne and benthic, but freshwater, ter restr a , and paras t c forms are known: *Malacobdella* species are commensal in the mantle cavit es of m a r ne biva ves and, in one spec es, a freshwater gastro-pod. (e g., *Amphiporus*, *Annulonemertes*, *Carcinone mertes* *Emplectonema*, *Geonemertes*, *Malacobdella*, *Ovicides*, *Paranemertes*)

The Nemertean Body Plan

The nemertean body plan is especially interesting, since it presents characteristics of both coelomates (the closed circulatory system and rhynchocoel) and acoe lomates (the parenchyma and protonephridial system). In Chapters 4 and 10 we discussed some of the limita-tions of the acoelomate body plan, and we have seen the results of these constraints in our examination of the flatworms. It might be said that the ribbon worms have made the best of a rather difficult situation. Even though it is now clear that nemerteans have true coelo-mic cavities, these worms have relatively solid bodies. Thus they are at least functionally acoelomate. Recall that many of the problems inherent in acoelomate ar-chitecture are related to restricted internal transport capabilities. The presence of a circulatory system in nemerteans has largely eased this problem, and the functional anatomy of many other systems is related directly or indirectly to the presence of this circulatory mechanism For example, nemertean protonephridia are usually intimately associated with the blood, from which wastes are drawn, rather than with the mesen-chymal tissues as are flatworm protonephridia.

The increased capabilities for internal circulation and transport have allowed a number of developments that would otherwise be impossible. First, the circula-tory system provides a solution to the surface-to vol-ume dilemma, and as a result nemerteans tend to be much larger and more robust than flatworms, having been largely relieved of the constraints of relying on diffusion for internal transport and exchange. Second, the digestive tract is complete and somewhat region-ally specialized. With a one way movement of food materials through the gut, and a circulatory system to absorb and distribute digested products, the anterior region of the gut has been freed for feeding and inges-tion. Third, since the animal does not have to rely on diffusion for transport through a loosely organized mesenchyme, that general body area is freed for the d e velopment of other structures, notably the well devel-oped layers of muscles. In summary, the presence of a circulatory system in concert with these other changes has resulted in relatively large, active animals, capable of more complex feeding and digestive activities than seen in most acoelomate metazoans.

This general body plan is enhanced by the presence of the unique proboscis apparatus (which usually func tions in prey capture), the distinctly anterior location of the mouth, and well-developed cephalic sensory or-gans for prey location. Thus, while variation exists, the

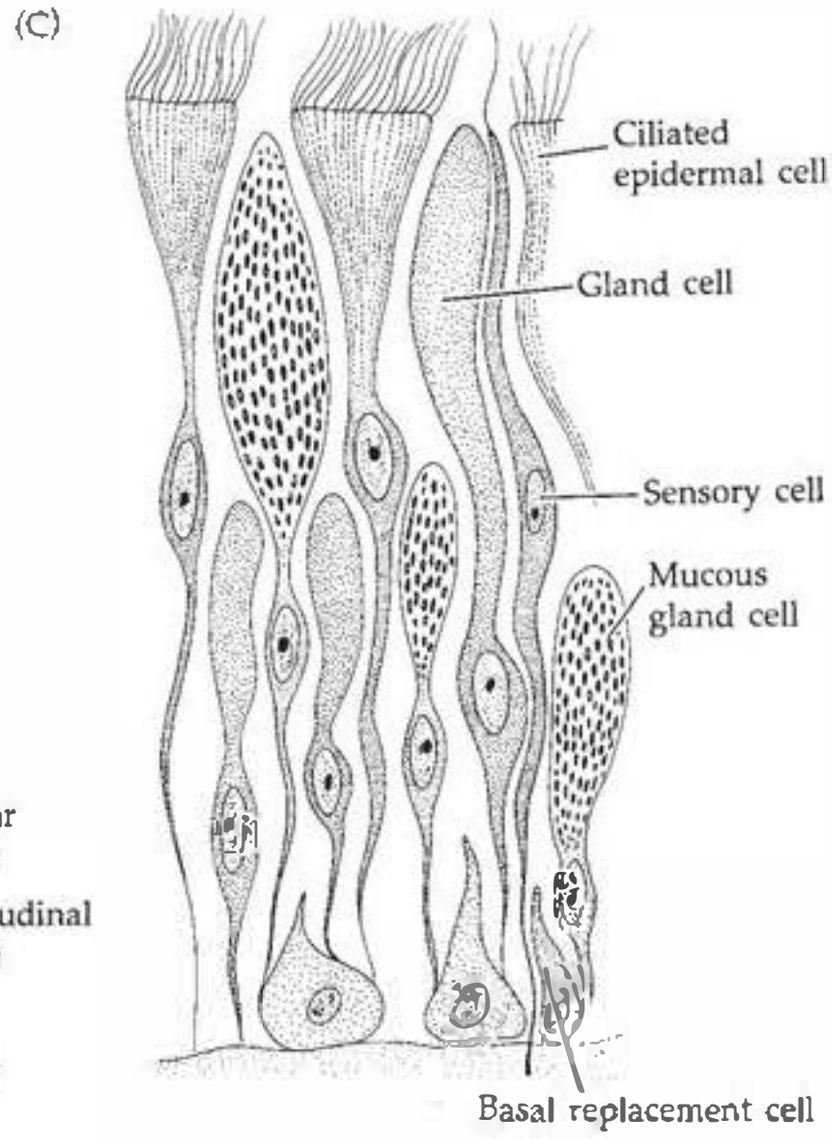


Figure 12.2 Organization of the nemertean body wall. (A) A hoplonemertean (cross section). (B) The anterior end of a palaeonemertean (longitudinal section). (C) Epidermal cells.

"typical" nemertean may be viewed as an active benthic hunter/tracker that moves among nooks and crannies preying on other invertebrates or even on some vertebrate prey and vertebrate remains.

Body Wall

The body wall of nemerteans comprises an epidermis, a dermis, relatively thick muscle layers surrounding the gut and other internal organs, and a mesenchyme of varying thickness (Figure 12.2). The epidermis is a ciliated columnar epithelium (Figure 12.2C). Mixed among the columnar cells are sensory cells (probably tactile), mucous gland cells, and basal replacement cells that may extend beneath the epidermis. Below the epidermis is the dermis, which varies greatly in thickness and composition. In some ribbon worms (e.g., the palaeonemerteans) the dermis is extremely thin or composed of only a homogeneous gel-like layer; in others (e.g., the heteronemerteans), it is typically quite thick and densely fibrous and usually includes a variety of gland cells. Beneath the dermis are well-developed layers of circular and longitudinal muscles. The organization of these muscles varies among taxa and may occur in either a two- or three-layered plan (Figure 12.3). The layering arrangement may also vary to some degree along the body length of individual animals. Internal to the muscle layers is a dense, more or less solid mesenchyme, although in some nemerteans the muscle layers are so thick that they nearly obliterate this inner mass. The mesenchyme includes a gel matrix and often a variety of loose cells, fibers, and dorsoventrally oriented muscles. Figure 12.3 depicts cross-sectional views of representatives of the two classes, showing mesenchyme thickness, muscles, placement of longitudinal nerve cords, major longitudinal blood vessels, and other features.

Support and Locomotion

In the absence of any rigid skeletal elements, the support system of nemerteans is provided by the muscles

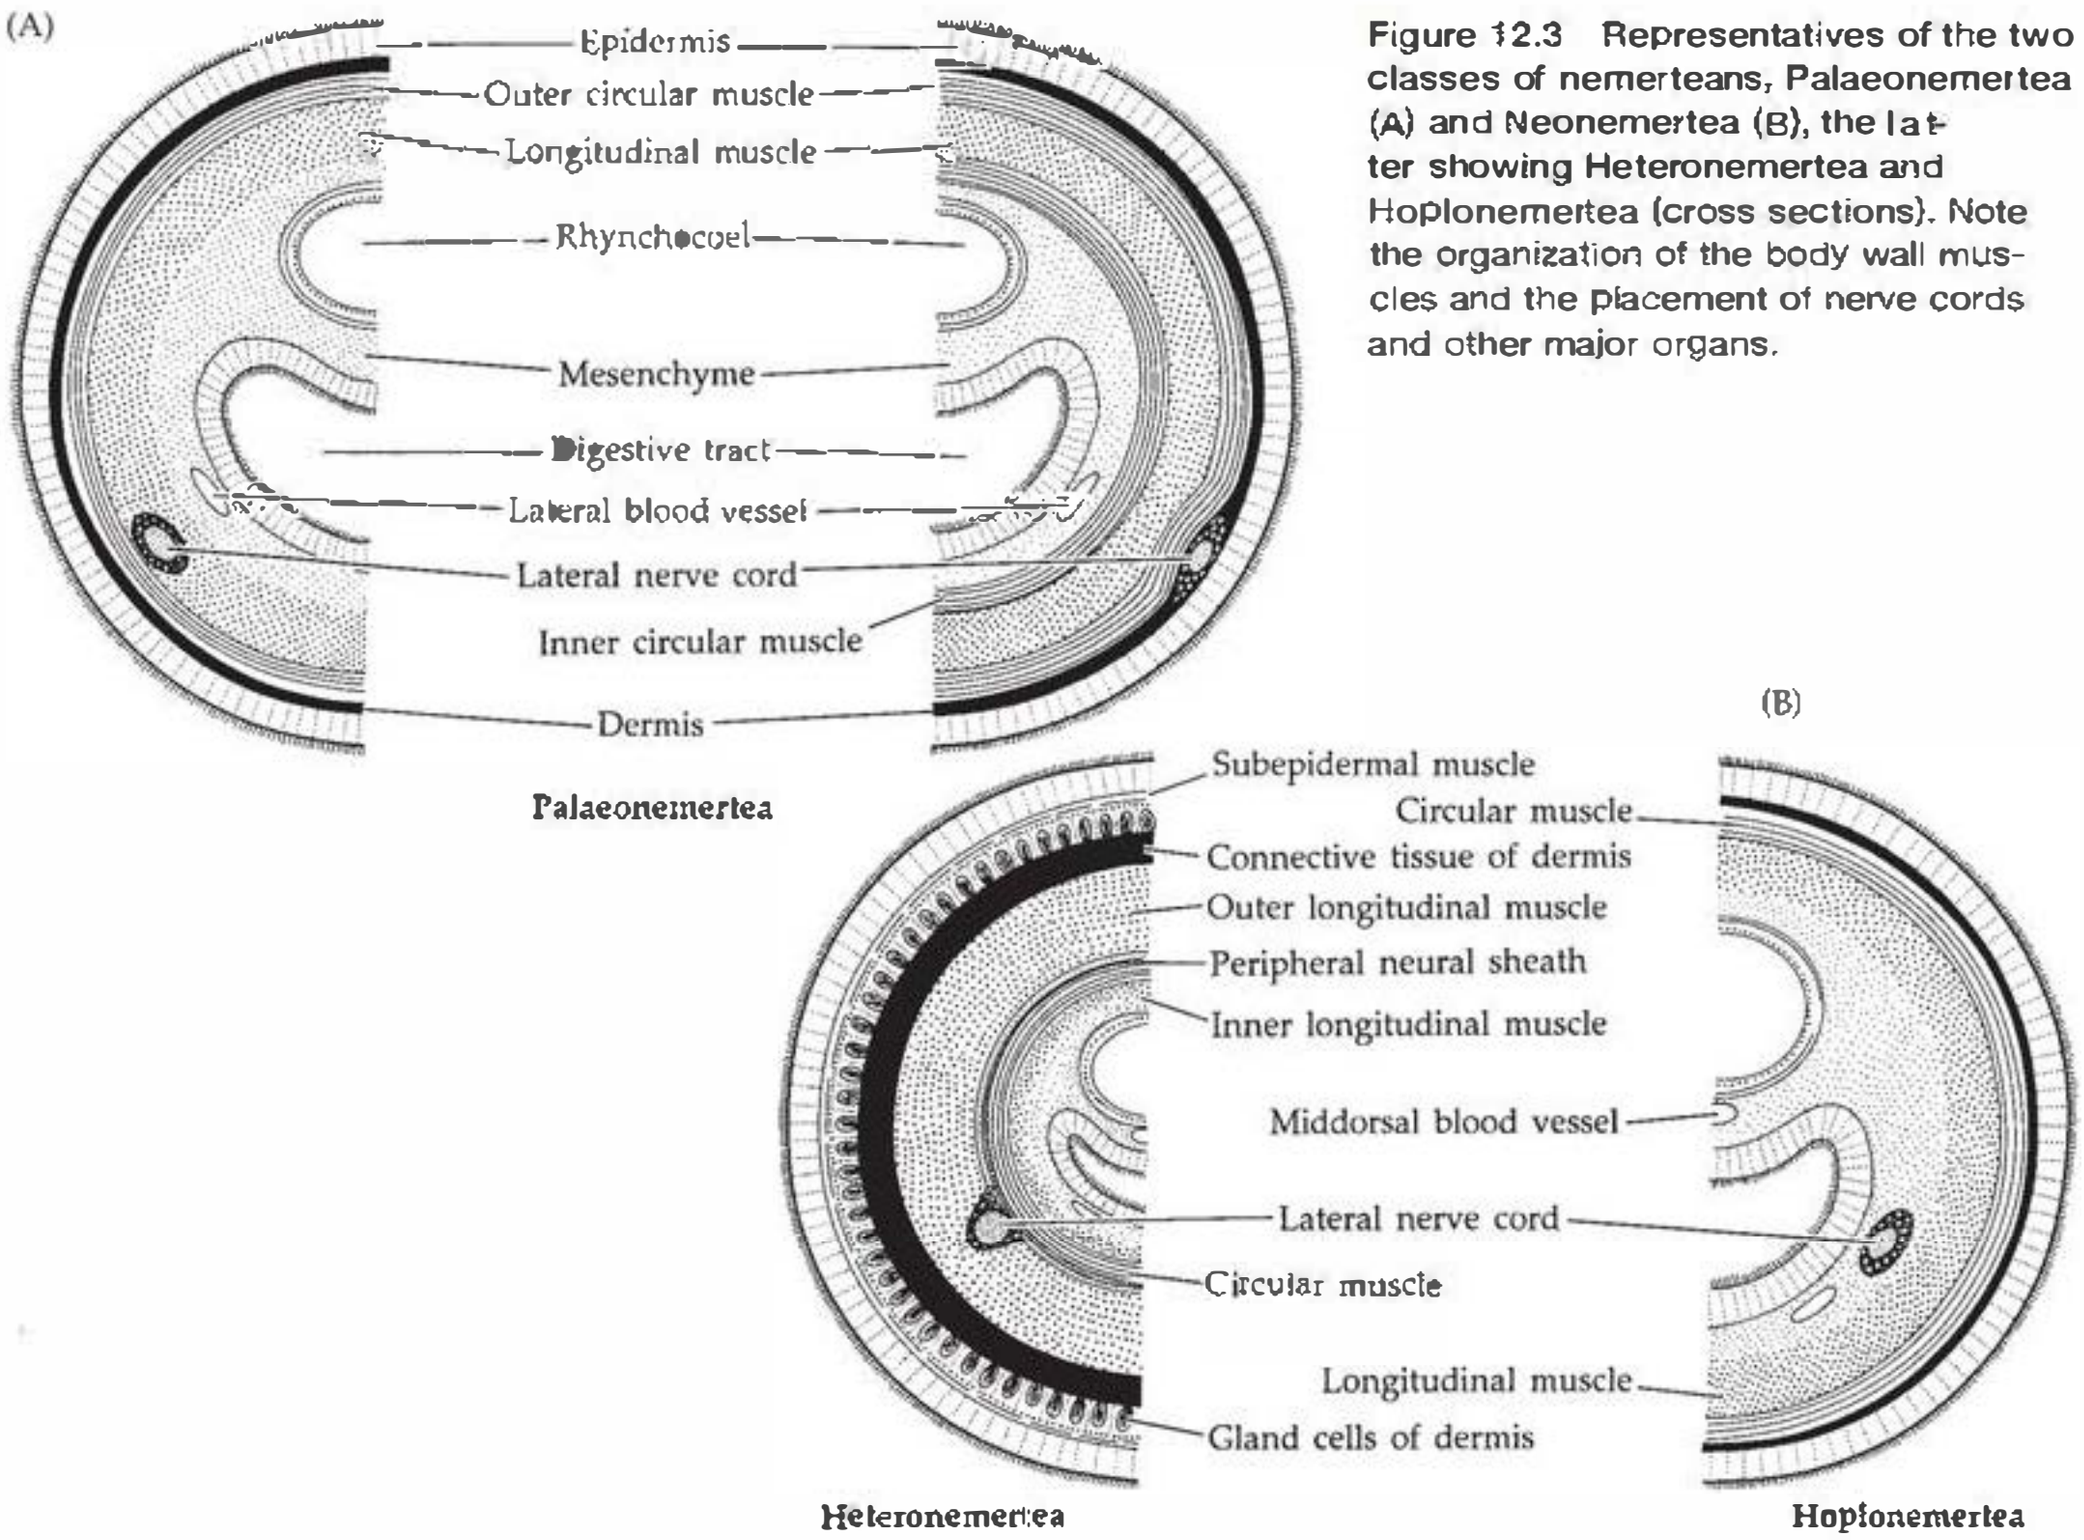

Figure 12.3 Representatives of the two classes of nemerteans, Palaeonemertea (A) and Neonemertea (B), the latter showing Heteronemertea and Hoplonemertea (cross sections). Note the organization of the body wall muscles and the placement of nerve cords and other major organs.

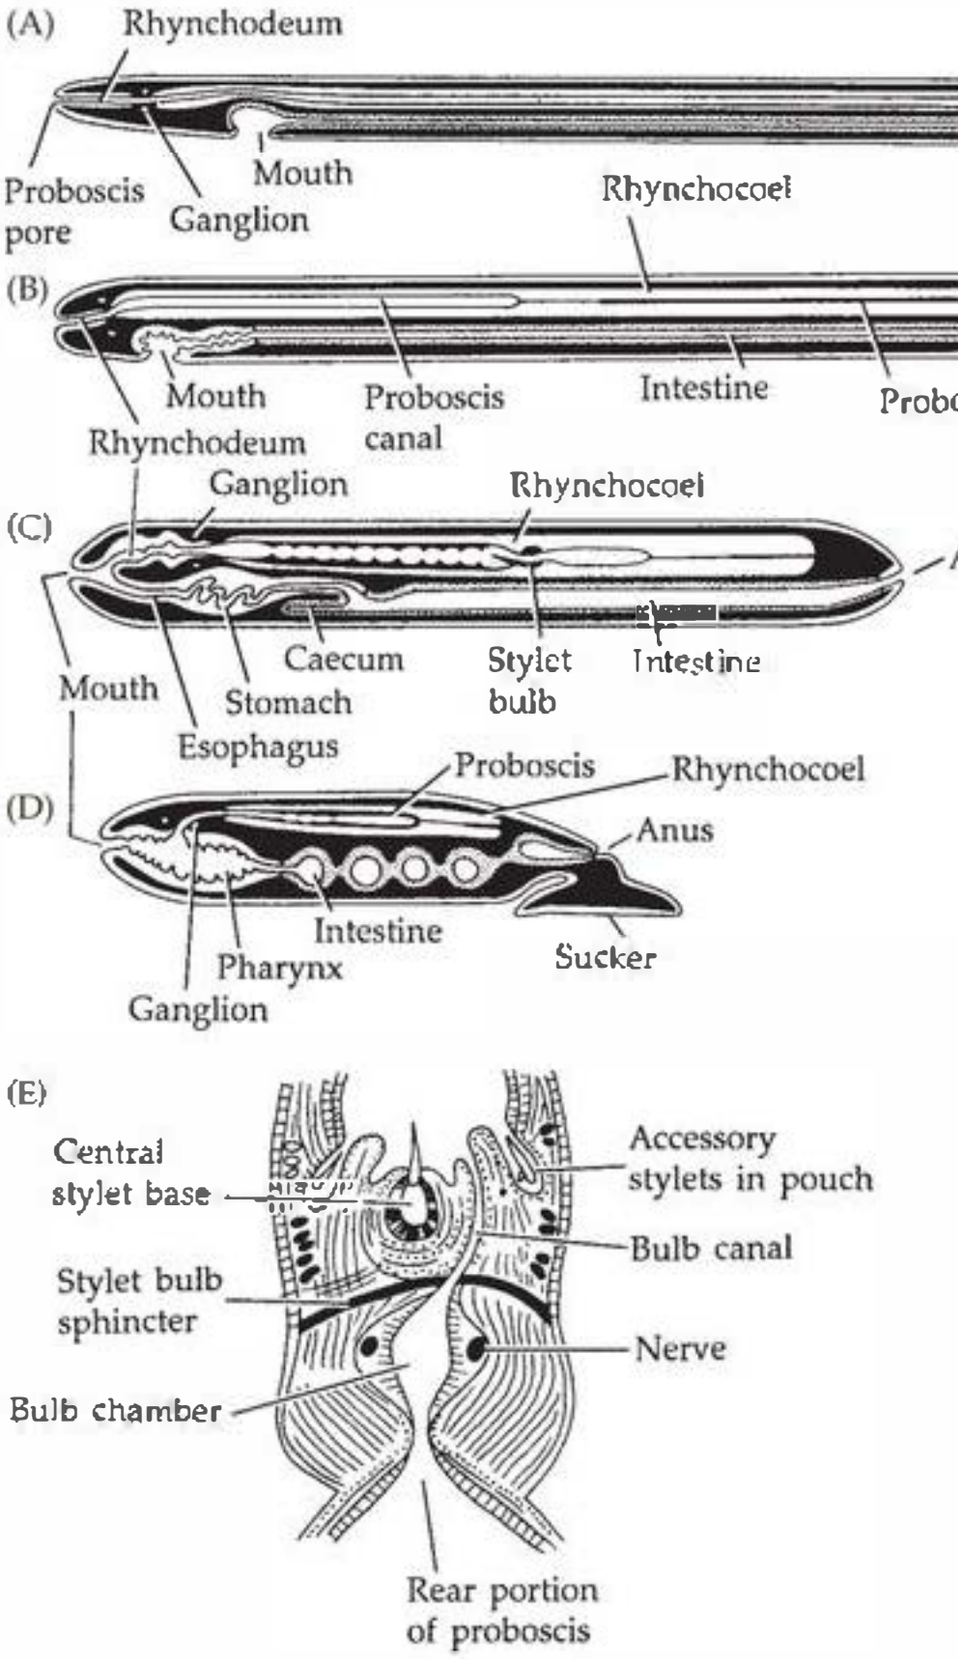
and other tissues of the body wall and by the hydrostatic qualities of the mesenchyme. These features permit dramatic changes in both length and cross-sectional shape and diameter, characteristics that are closely associated with locomotion and accommodation to cramped quarters. Most very small benthic ribbon worms are propelled by the action of their epidermal cilia. A slime trail is produced by the body wall mucous glands and provides a lubricated surface over which the worm slowly glides. Small nemerteans commonly live among the interstices of filamentous algae, under tidepool rocks, or in the spaces of other irregular surfaces such as those found in mussel beds and sand, mud, or pebble bottoms. Larger epibenthic ribbon worms and most of the burrowing forms employ peristaltic waves of the body wall muscles to propel them over moist surfaces or through soft substrata. Some of the larger forms (e.g., *Cerebratulus*) use undulatory swimming as a secondary means of locomotion, and perhaps as an escape reaction to benthic predators. Fully pelagic nemerteans (certain polystiliferan hoplonemerteans) generally drift or swim slowly. Some of the terrestrial forms produce a slime sheath through which they glide by ciliary action, and some use their proboscis for rapid escape responses.

Feeding and Digestion

Most ribbon worms are active predators on small invertebrates, but some are able to capture live fish, or even active invertebrates like cephalopods. Some are scavengers, feeding on all sorts of decaying animal matter, including large vertebrates, and yet others feed on plant material (at least under laboratory conditions). There is evidence to suggest that species of the commensal genus *Malacobdella*, which inhabit the mantle cavity of bivalve molluscs, feed largely on phytoplankton captured from their host's feeding and gas exchange currents. Field observations indicate that the diets of predatory forms may be either extremely varied or quite restricted, depending on the species. Some species are capable of tracking prey over long distances, whereas others must locate food by direct contact. Distance prey location and assessment of food acceptability are almost certainly chemotactic responses. Ribbon worms that actually hunt and track can recognize the trails left by potential prey, and they fire their proboscis along the trail ahead of them to capture food (Figure 12.4). Similar reactions are elicited when infaunal nemerteans encounter burrows in which potential prey might be located. Surface hunters that live in intertidal areas generally forage during high tides or

Figure 12.4 *Paranemertes peregrina* (order Hoplonemertea) capturing a nereid polychaete. The proboscis is coiled around the polychaete.



at night, and thus avoid the threats of desiccation and visual predators. However, members of some marine genera (e.g., *Tubulanus, Paranemertes, Amphiporus*) may frequently be seen during low tides on foggy mornings, gliding over the substratum in search of prey. The rapid expulsion of their proboscis and successful prey capture can be a memorable moment of high drama for tidepool enthusiasts.

The behavior involved in the capture and ingestion of live prey is significantly different from that associated with scavenging on dead material. In predation, the proboscis is employed both in capturing prey and in moving it to the mouth for ingestion. The proboscis is everted and wrapped around the victim (Figure 12.4). The prey is not only physically held by the proboscis but may be subdued or killed by its toxic secretions. In the Pacific species *Paranemertes peregrina*, which feeds primarily on nereid polychaetes, the glandular epithelium of the everted proboscis secretes a potent neurotoxin. Nemerteans with an armed proboscis (Hoplonemertea) actually use the stylets to pierce the prey's body (often numerous times) to introduce the toxin. Once captured, the prey is drawn to the mouth by retraction and manipulation of the proboscis; it is usually swallowed whole. The mouth is expanded and pressed against the food, and swallowing is accomplished by peristaltic action of the body wall muscles aided by ciliary currents in the anterior region of the gut Scavenging, in contrast, usually does not involve the proboscis. The worm simply ingests the food directly by muscular action of body wall and foregut. In some predatory hoplonemerteans (those in which the lumen of the proboscis is connected with the anterior gut lumen), the foregut itself may be everted for feeding on animals too large to be swallowed whole. In such cases, fluids and soft tissues are generally sucked out of the prey's body. Polychaete worms and amphipod crustaceans seem to be favorite food items for many predatory nemerteans.

Species of the hoplonemertean genus *Carcinonemertes* are ectoparasites (egg predators) on brachyuran crabs. Different species inhabit different regions of the host's body, but all migrate to the egg masses on gravid female crabs and feed on the yolky eggs. In high numbers, these egg predators can kill all of the embryos in the host's clutch. Some studies have reported up to 99% infestation rates of *Carcinonemertes errans* on the commercially important Pacific Dungeness crab (*Cancer magister*), with up to 100,000 worms per host. This parasite has been implicated in past collapses of the central California Dungeness crab fishery. Several species of *Ovicides* (Carcinonemertidae) live on the abdomens of hydrothermal vent crabs in the Pacific, and *Nemertoscolex parasiticus* (Heteronemertea) lives in the coelomic fluid of the echiuran *Echiurus echiurus*.

The proboscis apparatus The proboscis apparatus is a complex arrangement of tubes, muscles, and hydraulic systems (Figure 12.5). The proboscis itself is an elongate, eversible, blind tube, and either is associated with the foregut or opens through a separate proboscis pore. The proboscis, which may be branching in some species, may be regionally specialized and bears stylets in various arrangements (Figures 12.5E H). Nemertean stylets are nail-shaped structures that typically reach lengths of 50–200 μm. Each calcified stylet is composed of a central organic matrix surrounded by an inorganic cortex composed of calcium phosphate. The stylets are formed within large epithelial cells called styletocytes. Because growing ribbon worms must replace their stylets with new larger ones, and because they often lose the stylet during prey capture, new stylets are continuously produced in reserve stylet sacs and stored until needed, whereupon they are transported and affixed in their proper position

The basic structure and action of the proboscis are most easily described where the apparatus is entirely separate from the gut. As shown in Figures 12.5A and B, the proboscis pore leads from the outside directly into the anterior proboscis lumen, called the rhynchodeum, the lining of which is continuous with the epidermis. Posterior to the rhynchodeum, the lumen continues as the proboscis canal that is surrounded by the muscular wall of the proboscis itself; these muscles are derived from the muscles of the body wall. The proboscis is surrounded by a closed, fluid filled, coelomic space called the rhynchocoel, which in turn is surrounded by additional muscle layers. The inner blind end of the proboscis is connected to the posterior wall of the rhynchocoel by a proboscis retractor muscle. In a few taxa (e.g., *Gorgonorhynchus*), there is no retractor muscle, and eversion and retraction are accomplished hydrostatically.

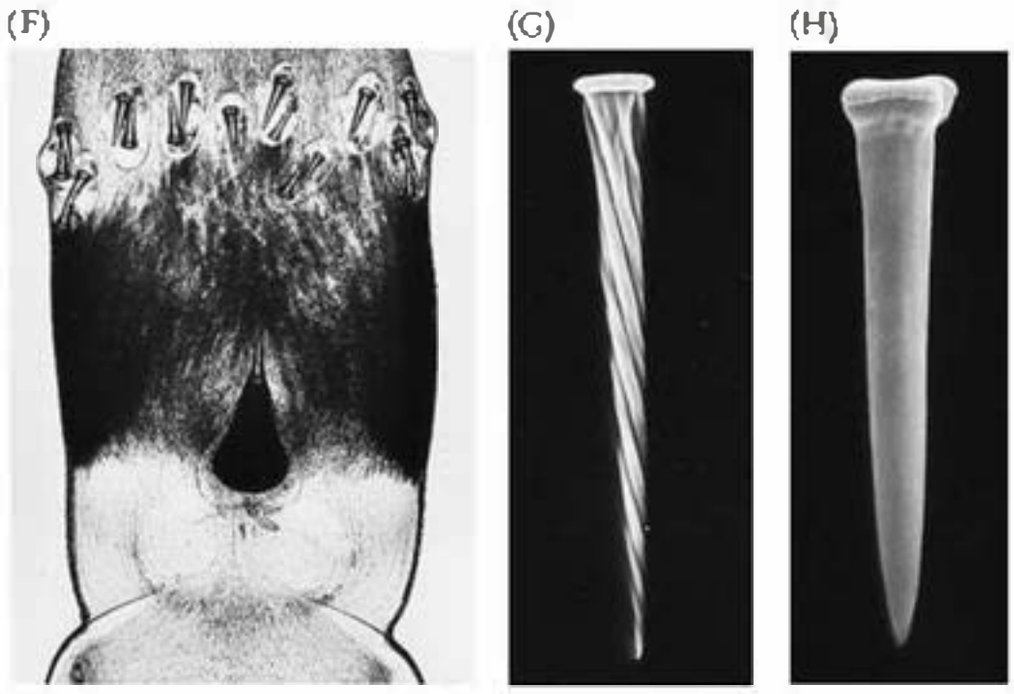


Figure 12.5 (A–D) The arrangements of the proboscis apparatus and digestive tube in the (A) Palaeonemertea (B) Heteronemertea, (C) Hoplonemertea, and (D) the highly modified hoplonemertean *Malacobdella*. (E) Stylet apparatus in the proboscis of *Prostoma graecense* (Monostilifera). (F) Stylet apparatus of *Amphiporus formidabilis* (Monostilifera). (G) Stylet from *Paranemertes peregrina* (scanning electron micrograph). (H) Stylet from *Amphiporus bimaculatus* (scanning electron micrograph).

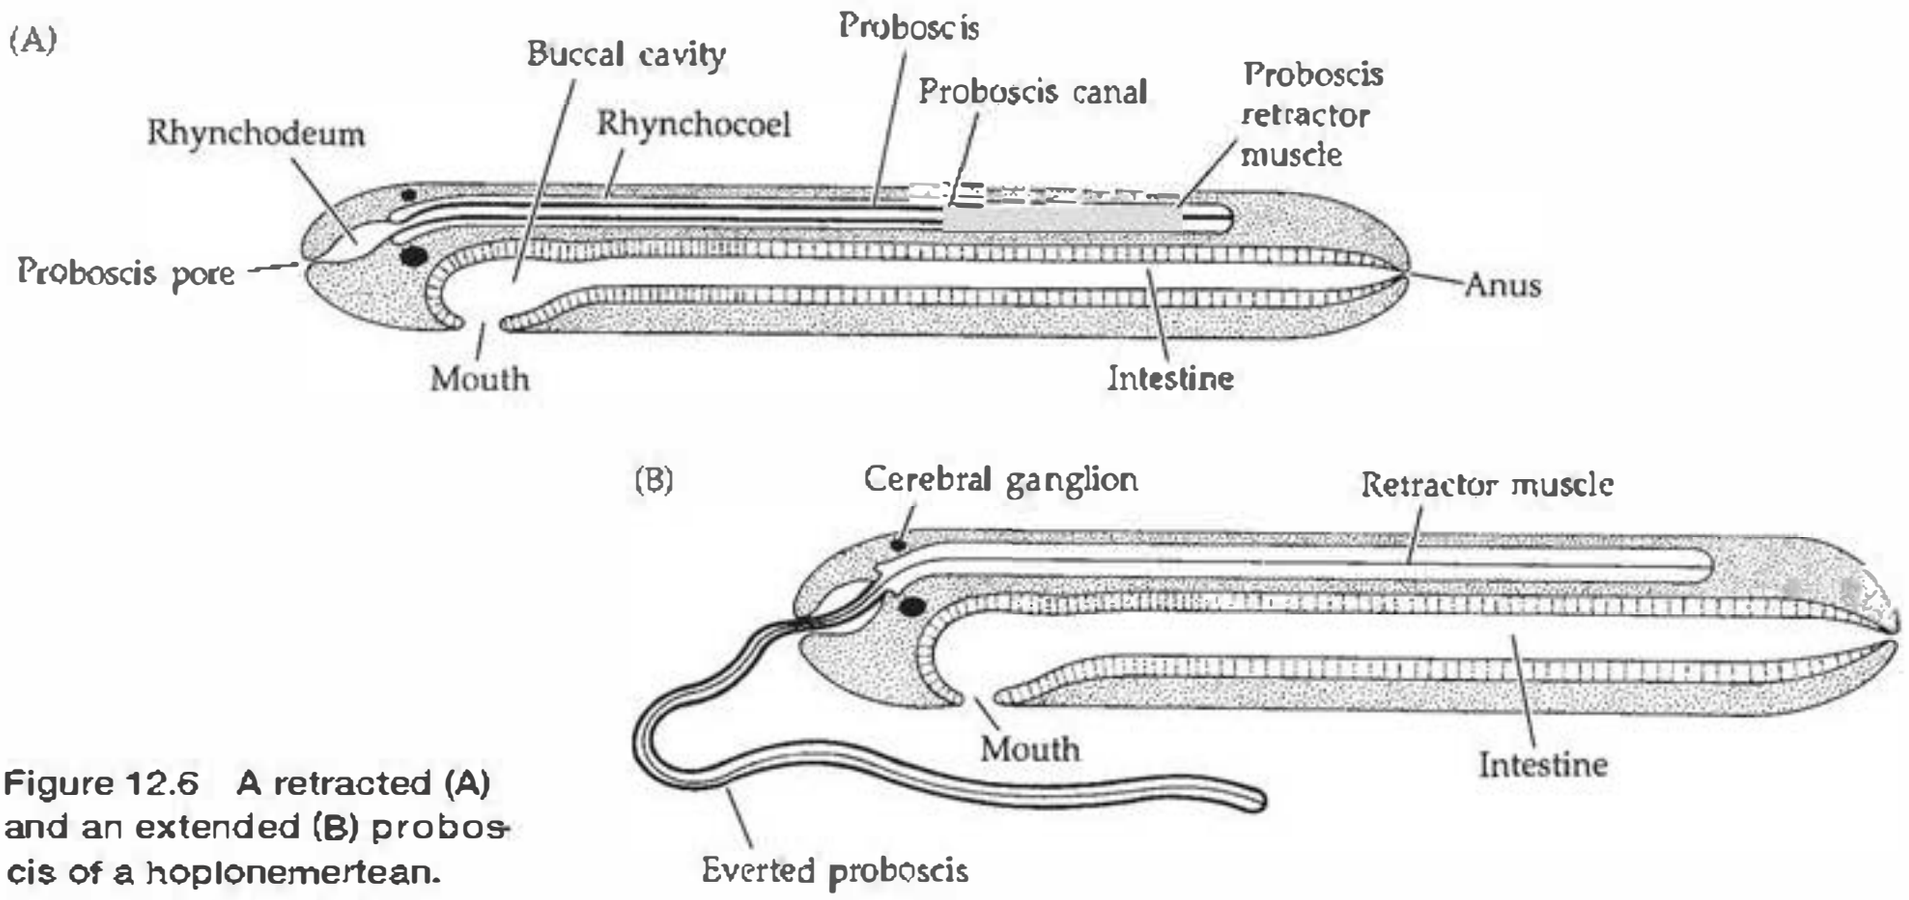
Eversion of the proboscis (Figure 12.6) is accomplished by contraction of the muscles around the rhynchocoel; this increases the hydrostatic pressure within the rhynchocoel itself, squeezing on the proboscis and causing its eversion. The everted proboscis moves with the muscles in its wall; the proboscis is retracted back inside the body by the coincidental relaxation of the muscles around the rhynchocoel and contraction of the proboscis retractor muscle. The retracted proboscis may extend nearly to the posterior end of the worm, and usually only a portion of it is extended during eversion.

Digestive system Nemerteans have a complete through gut with an anus (Figures 12.6 and 12.7). Associated with the one-way movement of food from mouth to anus we find various degrees of regional specialization (both structural and functional) in the guts of ribbon worms. The mouth leads inward to an ectodermally derived foregut (stomodeum) consisting of a bulbous buccal cavity, sometimes a short esophagus, and a stomach. The stomach leads to an elongate intestine or midgut, which is more or less straight but usually bears numerous lateral diverticula. In *Malacobdella,* the intestine is loosely coiled and lacks diverticula; diverticula are also lacking in the strange "segmented" *Annulonemertes*. At the posterior end of the intestine is a short ectodermally derived hindgut (proctodeum) or rectum, which terminates in the anus. Elaborations on this basic plan are common in certain taxa and may include various ceca arising from the stomach or from the intestine at its junction with the foregut.

The entire digestive tube is ciliated, the foregut more densely than the midgut. The gut epithelium is basically columnar, mixed with gland cells. The foregut contains a variety of mucus-producing cells, sometimes multicellular mucous glands, and occasionally enzymatic gland cells in the stomach region. The midgut is lined with vacuolated ciliated columnar cells; these are phagocytic and bear microvilli, greatly increasing their surface area. Enzymatic gland cells are abundantly mixed with the ciliated cells of the midgut. The hindgut typically lacks gland cells. Food is moved



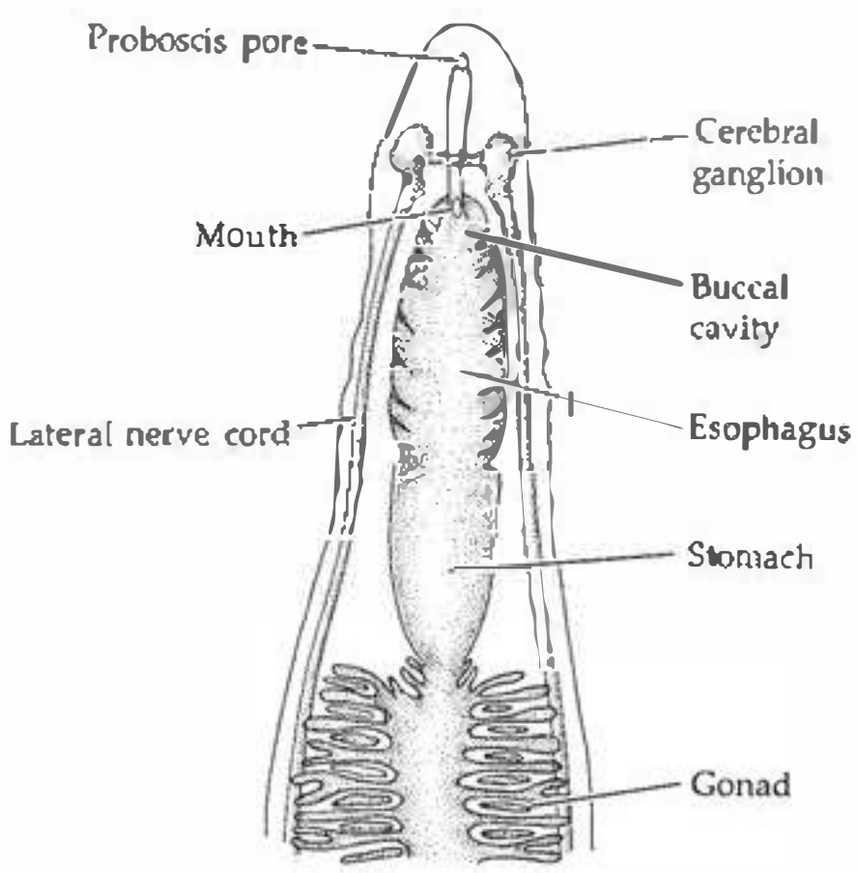


Figure 12.6 A retracted (A) and an extended (B) proboscis of a hoplonemertean.

through the digestive tract by cilia and by the action of the body wall muscles; there are usually no muscles in the gut wall itself, except in the foregut of some heteronemerteans.

The process of digestion in carnivorous nemerteans is a two-phase sequence of protein breakdown. The first step involves the action of endopeptidases released from gland cells into the gut lumen. This extracellular digestion is quite rapid and is followed by phagocytosis (and probably pinocytosis) of the partially digested material by the ciliated columnar cells of the midgut. Protein digestion is completed intracellularly by exopeptidases within the food vacuoles of the midgut epithelium. Lipases have been discovered in at least one species (*Lineus ruber*), and carbohydrases are known in the omnivorous commensal *Malacobdella*. Food is stored primarily in the form of fats, and to a much lesser extent as glycogen, in the wall of the midgut. Transportation of digested materials throughout the body is accomplished by the circulatory system, which absorbs these products from the cells lining the intestine. Indigestible materials are moved through the gut and out the anus.

Circulation and Gas Exchange

We have mentioned briefly the evolutionary and adaptive significance of the circulatory system in nemerteans and its general relationship to other systems and functions. This closed system consists of vessels and thin-walled spaces called lacunae (Figure 12.2B). There is a good deal of variation in the architecture of nemertean circulatory systems (Figure 12.8). The simplest arrangement occurs in certain palaeonemerteans in which a single pair of longitudinal vessels extends the length of the body, connecting anteriorly by a cephalic lacuna and posteriorly by an anal lacuna. Elaboration on this basic scheme may include transverse vessels

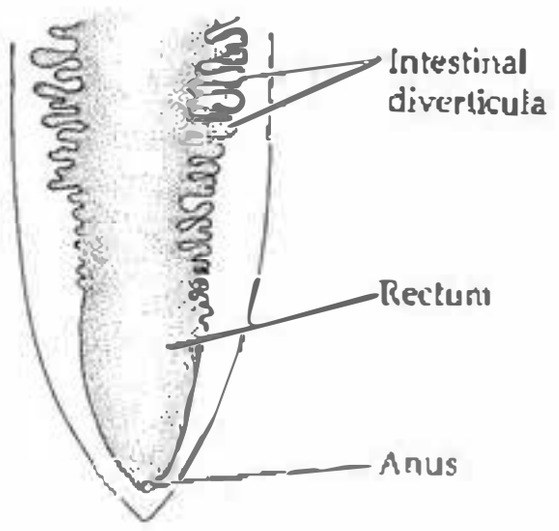

Figure 12.7 A nemertean digestive system. Anterior and posterior regions of the gut of *Carinoma* (ventral view).

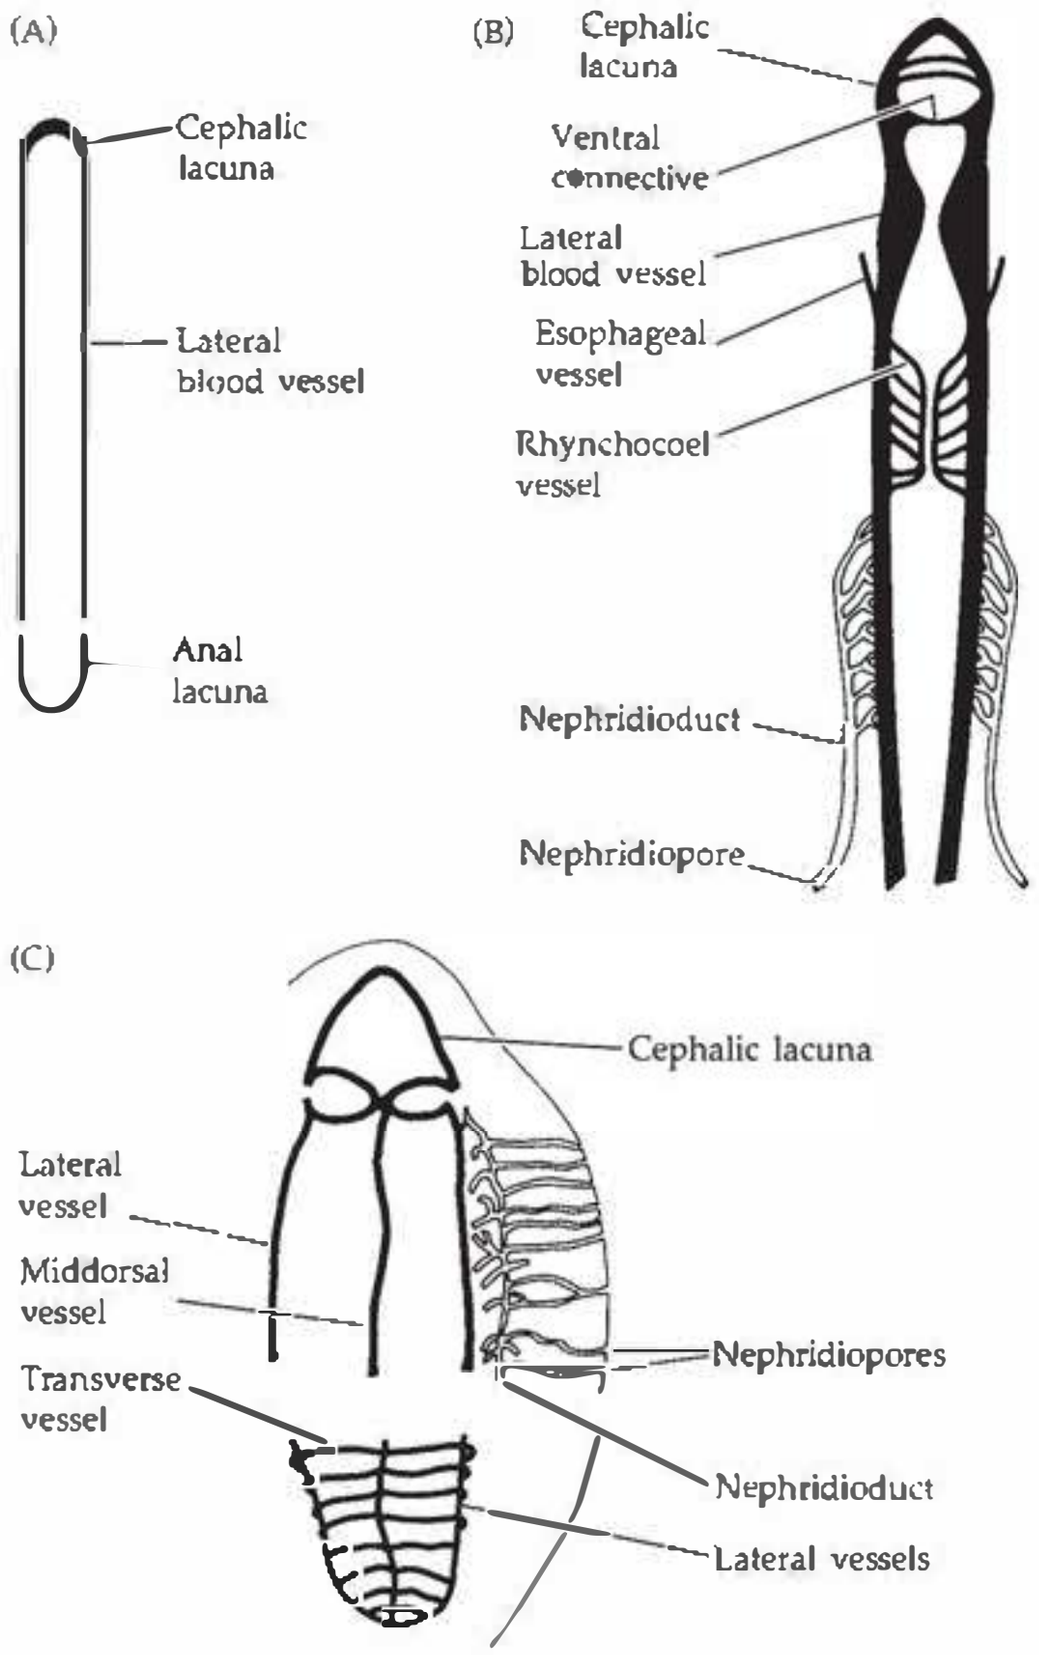

Figure 12.8 Nemertean circulatory systems. (A) The simple circulatory loop of *Cephalothrix* (Palaeonemertea) consists of a pair of lateral blood vessels connected by cephalic and anal lacunae. (B) The complex circulatory system of *Tubulanus* (Palaeonemertea). Note the intimate association of the nephridial system with the lateral blood vessels. (C) The circulatory system of *Amphiporus* (Hoplonemertea) includes a middorsal vessel and numerous transverse vessels.

between the longitudinal vessels, enlargement and compartmentalization of the lacunar spaces, and the addition of a middorsal vessel. The walls of the blood vessels are only slightly contractile, and general body movements generate most of the blood flow. There is no consistent pattern to the movement of blood through the system; it may flow either anteriorly or posteriorly in the longitudinal vessels, and currents often reverse directions.

The blood consists of a colorless fluid in which various cells are suspended. These cells can include pigmented corpuscles (yellow, orange, green, red), at least some of which contain hemoglobin, and a variety of so-called lymphocytes and leukocytes of uncertain function. The anatomical association of the circulatory system with other structures, as well as the composition of the blood, suggest several circulatory functions. Although conclusive evidence is lacking, the circulatory system appears to be involved with the transport of nutrients, gases, neurosecretions, and excretory products. Some intermediary metabolism probably occurs in the blood, as several appropriate enzymes have been identified in solution. The blood may also serve as an aid to body support through changes in hydrostatic pressure within the vessels and lacunar spaces. There is some evidence to support the idea that the blood may also function in osmoregulation.

Gas exchange in nemerteans is epidermal and does not involve any special structures. Oxygen and carbon dioxide diffuse readily across the moist body surface, which is usually covered with mucous secretions. Some robust forms (e.g., *Cerebratulus*) augment this passive exchange of gases across the skin with regular irrigation of the foregut, where there is an extensive system of blood vessels. In those species in which hemoglobin occurs, this pigment probably aids in oxygen transport or storage within the blood.

Excretion and Osmoregulation

The excretory system of most nemerteans consists of two to thousands of flame bulb protonephridia (Figures 12.8 and 12.9) similar to those found in free-living flatworms. However, apparently the deep-sea pelagic hoplonemerteans lack protonephridia altogether. The flame bulbs are usually intimately associated with the lateral blood vessels or less commonly with other parts of the circulatory system. The nephridial units are often pressed into the blood vessel walls, and in some instances the walls are actually broken down so that the nephridia are bathed directly in blood. In the simplest case, a single pair of flame bulbs leads to two nephridioducts, each with its own laterally placed nephridiopore. More complex conditions include rows of single flame bulbs or clusters of flame bulbs with multiple ducts. In some species the walls of the nephridioducts are syncytial and lead to hundreds or even thousands of pores on the epidermis. The most elaborate conditions occur in certain terrestrial nemerteans where approximately 70,000 clusters of flame bulbs (six to eight in each cluster) lead to as many surface pores. In some heteronemerteans (e.g., *Baseodiscus*), the excretory system discharges into the foregut.

The functioning of nemertean protonephridia in the excretion of metabolic wastes has not been well studied. The close association of the flame bulbs with the circulatory system suggests that nitrogenous wastes (probably ammonia), excess salts, and other metabolic products are removed from the blood as well as from the surrounding mesenchyme by the nephridia. If such is the case, it explains again the significance of the circulatory system in overcoming surface-to-volume

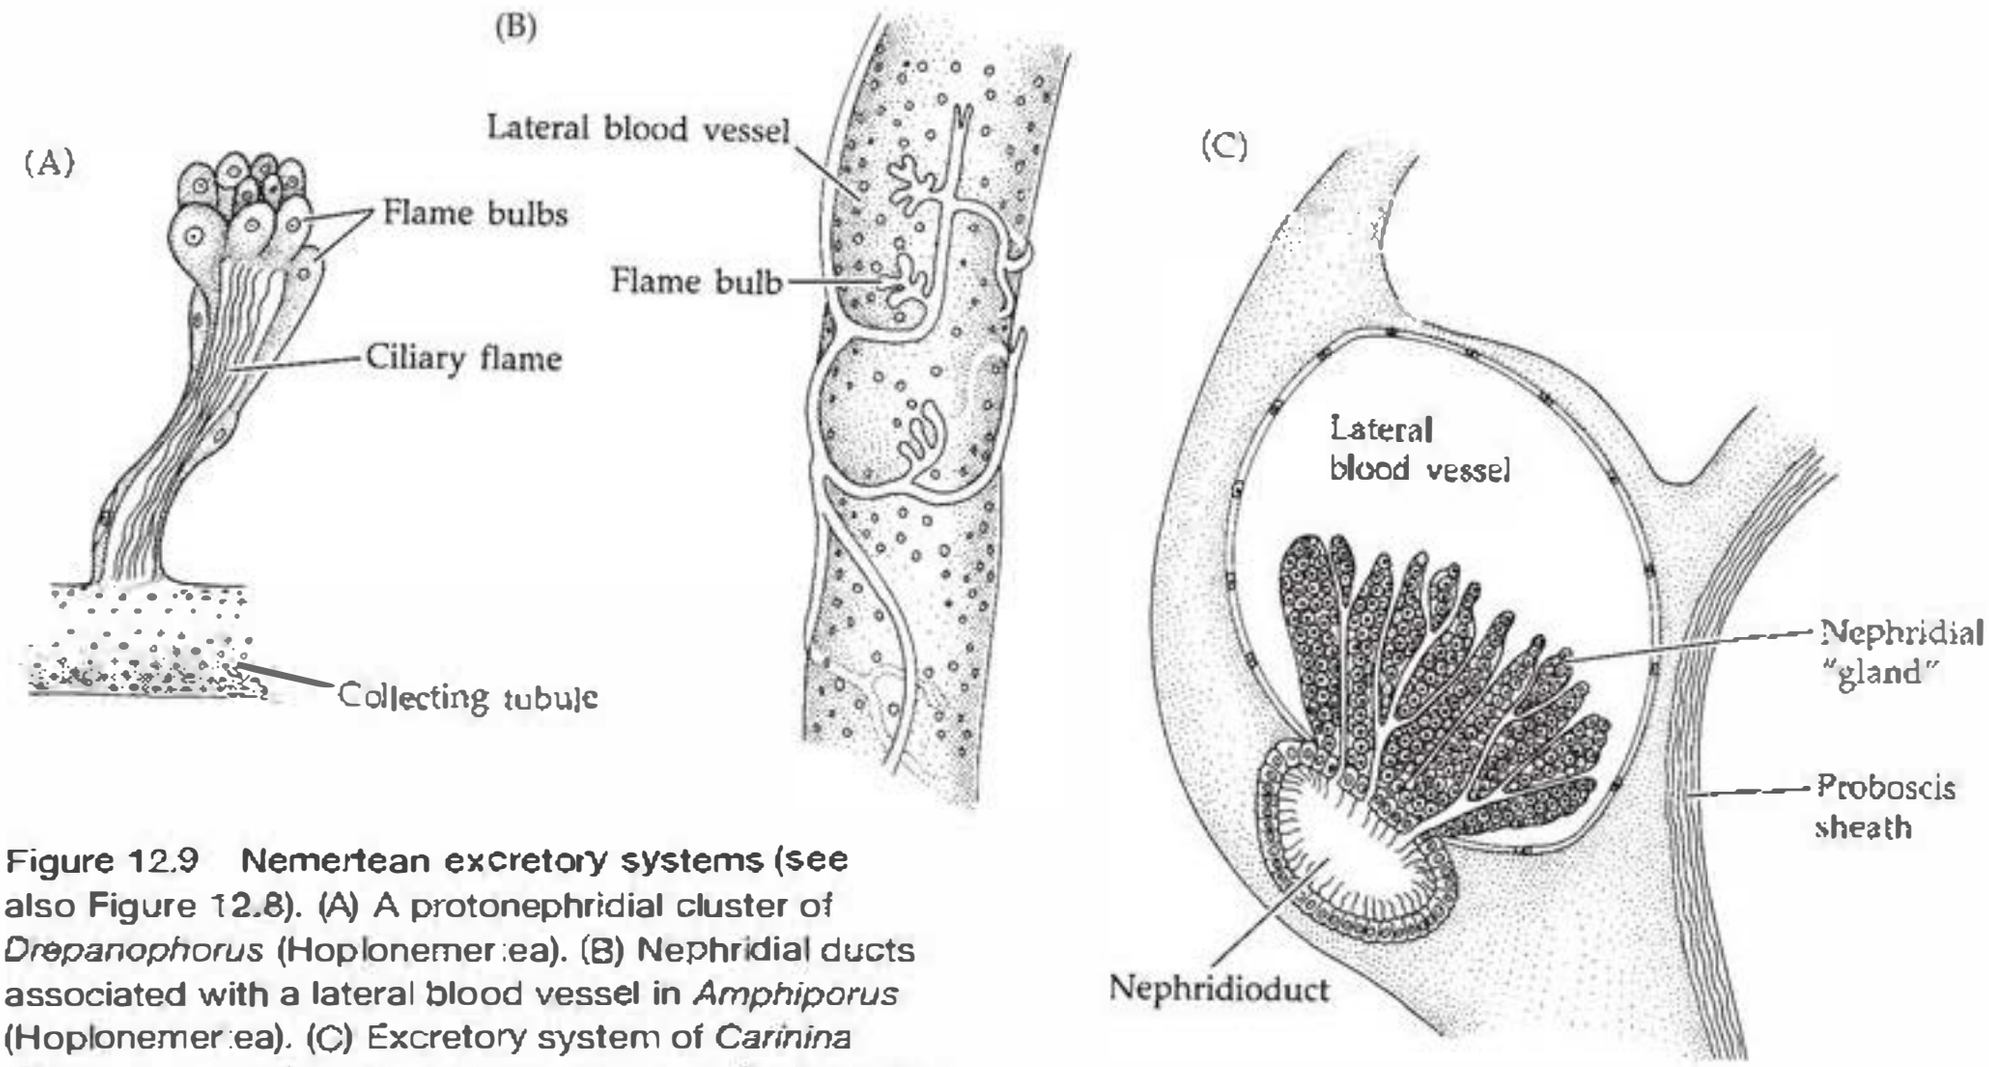

Figure 12.9 Nemertean excretory systems (see also Figure 12.8). (A) A protonephridial cluster of *Drepanophorus* (Hoplonemertea). (B) Nephridial ducts associated with a lateral blood vessel in *Amphiporus* (Hoplonemertea). (C) Excretory system of *Carinina* (Palaeonemertea) in which the secretory units (so-called nephridial gland) project into the lumen of the lateral blood vessel.

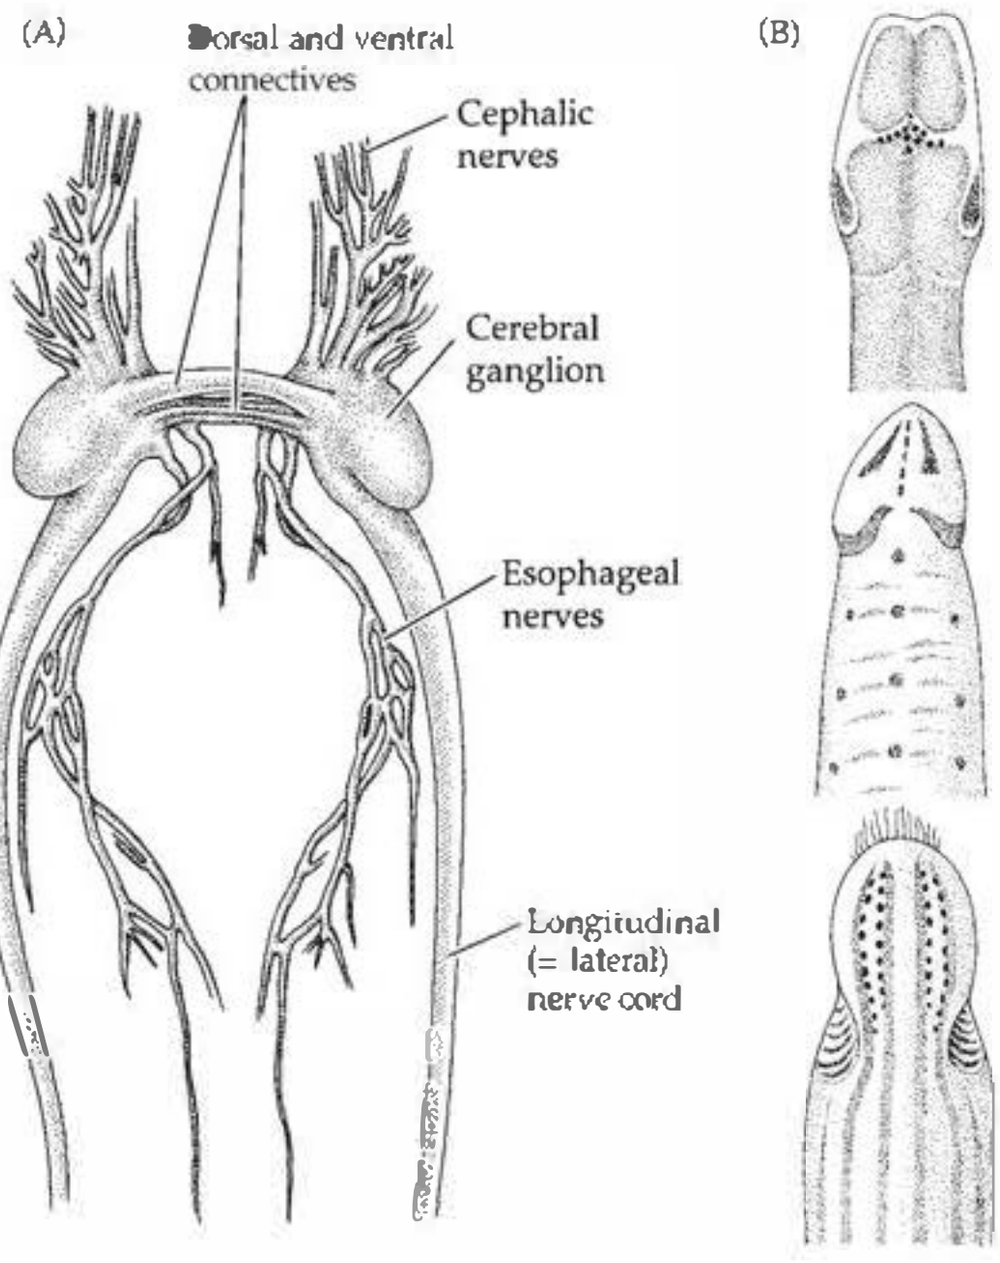
problems and the constraints of simple diffusion on body size. Relatively active animals produce large amounts of metabolic wastes. Dependence on diffusion alone would seriously limit any increase in body bulk, but the transport of these wastes from the tissues to the protonephridial system by circulatory vessels greatly eases this limitation. One of the most remarkable evolutionary achievements of the nemerteans has been their ability to grow to great size, particularly in length, without segmentation or the development of a large body cavity.

There is some morphological and experimental evidence that the protonephridia also play an important role in osmoregulation, especially in freshwater and terrestrial ribbon worms. It is in some of these forms, which are subjected to extreme osmotic stress, that the most elaborate excretory systems are found and these systems are probably associated with water balance. Furthermore, it appears that there may be a very complex interaction between the nervous system (neurosecretions), the circulatory system, and the nephridia to facilitate osmoregulatory mechanisms, but the details remain to be studied. Some members of Heteronemertea and Hoplonemertea have invaded fresh water and must combat water influx from their strongly hypotonic surroundings. Members of some genera (e.g., *Geonemertes*) are terrestrial, although restricted to moist shady habitats where they avoid serious problems of desiccation. In addition, they tend to cover their bodies with a mucous coat that reduces water loss. Those forms that inhabit marine subtidal or deep-water environments, or are endosymbiotic (one genus of Heteronemertea and several genera of Hoplonemertea), face little or no osmotic stress. But the many species found intertidally do face periods of exposure to air and to lowered (or elevated) salinities. Their soft bodies are largely unprotected, and they are relatively intolerant of fluctuations in environmental conditions. Intertidal nemerteans rely strongly on behavioral attributes to survive periods of potential osmotic stress and remain in moist areas during low tide periods. Burrowing in soft, water-soaked substrata, or living among algae or mussel beds, in cracks and crevices, or other areas that retain seawater at low tide are lifestyles illustrating how habitat preference and behavior prevent exposure to stress. In addition, most intertidal nemerteans are somewhat negatively phototactic, and many restrict their activities to night hours or to foggy or overcast mornings and evenings. A marine meiofaunal species from North Carolina lives in sediments at about 1 m depth above high tide level, probably relying on the water that fills the interstices of sand by capillarity.

Nervous System and Sense Organs

The basic organization of the nemertean nervous system reflects a relatively active lifestyle. Nemerteans are cephalized, especially in the anterior placement of the mouth and feeding structures, and we find related concentrations of sensory and other nervous elements in the head. The central nervous system of ribbon worms consists of a complex cerebral ganglion from which arises a pair of ganglionated, longitudinal (lateral) nerve cords (Figure 12.10A). The cerebral ganglion is formed of four attached lobes that encircle the proboscis apparatus (not the gut, as in many other



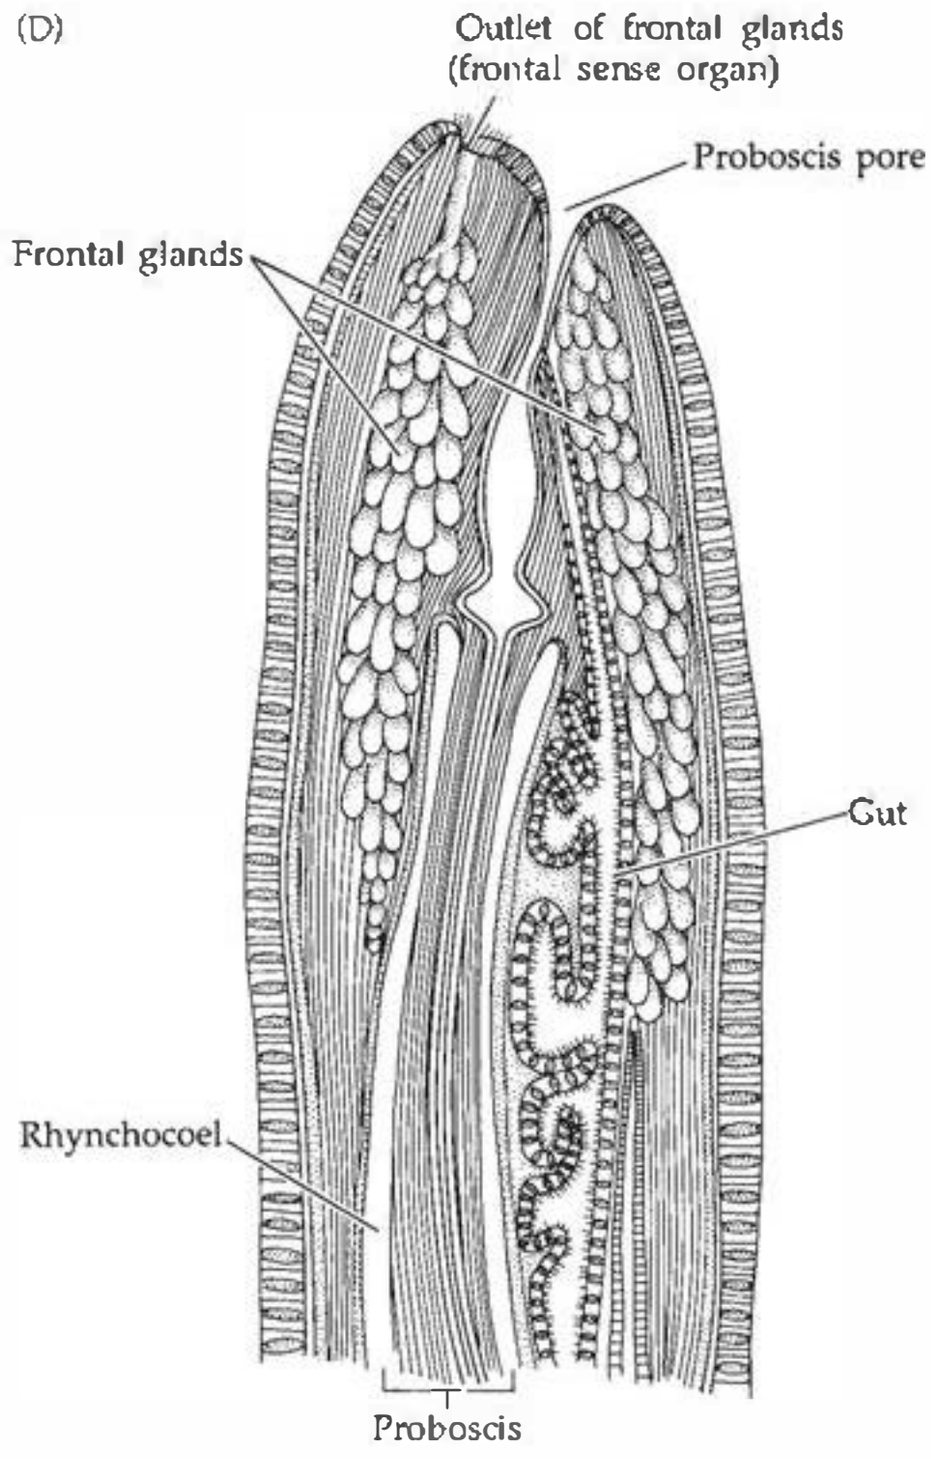


Figure 12.10 Nervous system and sense organs of nemerteans. (A) Anterior portion of the nervous system of *Tubulanus* (Palaeonemertea); see text for explanation of variations. (B) The cephalic slits and grooves and eye spots are visible on the heads of three nemerteans. (C) The cerebral organ of *Tubulanus* (cross section). Note the association of the organ with the cerebral canal, the nervous system, and the blood system. (D) Clusters of frontal glands occur in the anterior end of a hoplonemertean (longitudinal section).

invertebrates). Each side of the cerebral ganglion includes a dorsal and a ventral lobe; the two sides are attached to one another by dorsal and ventral connectives. Several pairs of sensory nerves provide input directly to the cerebral ganglion from various cephalic sense organs. The main longitudinal nerve cords arise from the ventral lobes of the cerebral ganglion and pass posteriorly; they attach to each other at various points by branched transverse connectives and terminally by an anal commissure. The longitudinal nerves also give rise to peripheral sensory and motor nerves along the length of the body. Elaboration on this basic plan includes additional longitudinal nerve cords, frequently a middorsal one arising from the dorsal commissure of the cerebral ganglion, and a variety of connectives, nerve tracts, and plexus.

As noted in the classification scheme, the positions of the major longitudinal nerve cords vary among the nemertean orders (Figure 12.3). These changes in the position of the nerve cords from epidermal to mesenchymal correspond to general increases in body complexity and tendencies toward specialization. Most workers agree that these differences reflect a plesiomorphic (epidermal) to apomorphic (subepidermal) trend among these taxa.

Ribbon worms possess a variety of sensory receptors, many of which are concentrated at the anterior

end and associated with an active, typically hunting lifestyle and with other aspects of their natural history. Nemerteans are very sensitive to touch. This tactile sensitivity plays a role in food handling, avoidance responses, locomotion over irregular surfaces, and mating behavior. Several types of modified ciliated epidermal cells are scattered over the body surface (especially abundant at the anterior and posterior ends) and are presumed to have a tactile function. The cells occur either singly or in clusters; some of the latter types are located in small depressions and can be thrust out from the body surface.

The eyes of ribbon worms are located anteriorly and number from two to several hundred; they can be arranged in various patterns (Figure 12.10B). Most of these ocelli are of the inverted pigment cup type, similar to those seen in flatworms, although a few species possess lensed eyes. As discussed in Chapter 4, these types of eyes typically are sensitive to light intensity and light direction. They help the nemerteans avoid bright light and potential exposure to predators or environmental stresses.

Much of the sensory input important to nemerteans is chemosensory. These worms are very sensitive to dissolved chemicals in their environment and employ this sensitivity in food location, probably mate location, substratum testing, and general water analysis. Probably all nemerteans respond to contact with chemical stimuli, and many are capable of distance chemoreception of materials in solution. At least three different nemertean structures have been implicated (some through speculation) in the initiation of chemotactic responses: cephalic slits or grooves, cerebral organs, and frontal glands (= cephalic glands) (Figures 12.10B–D). Cephalic slits are furrows of variable depth that occur laterally on the heads of many ribbon worms (see also Figure 12.1E,F). These furrows are lined with a ciliated sensory epithelium supplied with nerves from the cerebral ganglion. Water is circulated through the cephalic slits and over this presumably chemosensory epithelial lining

Most nemerteans possess a pair of the remarkably complex cerebral organs (Figure 12.10C). The core of each cerebral organ is a ciliated epidermal invagination (the cerebral canal), which is expanded at its inner end. These canals lead laterally to pores within the cephalic slits (when present) or else directly to the outside via separate pores on the head. The inner ends of the canals are surrounded by nervous tissue of the cerebral ganglion, and by glandular tissue, and they are often intimately associated with lacunar blood spaces. Cilia in the cerebral canal circulate water through the open portion of the organ; this activity intensifies in the presence of food. Nemerteans presumably use this mechanism when hunting and tracking prey or in other chemotactic responses. The association of the cerebral canals with glandular, nervous, and circulatory structures has led some workers to suggest an endocrine and/or neurosecretory function for the cerebral organs. Other suggestions have included auditory, gas exchange, excretory, and tactile activities Cerebral organs are absent in several genera, including the symbiotic *Carcinonemertes* and *Malacobdella*, and the pelagic hoplonemerteans.

In the region anterior to the cerebral ganglion, large frontal glands open to the outside through a pitlike frontal sense organ (Figure 12.10D). These structures receive nerves from the cerebral ganglion and appear to be chemosensory, but solid evidence for this suggestion is lacking Finally, statocysts have also been found in some nemerteans, including pelagic forms where geotaxis is an obvious advantage.

Reproduction and Development

Asexual processes Many nemerteans show remarkable powers of regeneration, and nearly all species can regenerate at least posterior portions of the body Those with the greatest regenerative abilities are certain species of *Lineus*, which engage in a remarkable form of asexual reproduction on a regular basis by undergoing multiple transverse fission into numerous fragments. The fragments are often extremely small and the process is sometimes referred to simply as fragmentation. The small pieces often form mucous cysts within which the new worm regenerates; larger pieces grow into new animals without the protection of a cyst. In some nemerteans only anterior fragments can regenerate into new worms.

Sexual reproduction Nemerteans show remarkable variation in reproductive and developmental strategies. Most ribbon worms are gonochoristic, although protandric and even simultaneous hermaphrodites are known. The reproductive system of nemerteans has gonads that are simply specialized patches of mesenchymal tissue arranged serially along each side of the intestine and alternate with the midgut diverticula (Figure 12.11). In *Malacobdella* and a few others, the gonads are more or less packed within the mesenchyme (Figure 12.1H). In most nemerteans the development of gonads occurs along nearly the entire length of the body, but in a few species they are restricted to certain regions, usually toward the anterior end. The gonads begin to enlarge and hollow just prior to the onset of breeding activities. Specialized cells in the walls of the rudimentary ovaries and testes proliferate eggs and sperm into the lumina of the enlarging gonadal sacs. In females additional special cells are responsible for yolk production. There is evidence that maturation is under neurosecretory hormonal control, at least in some species. The secretions are probably from the cerebral organ complex.

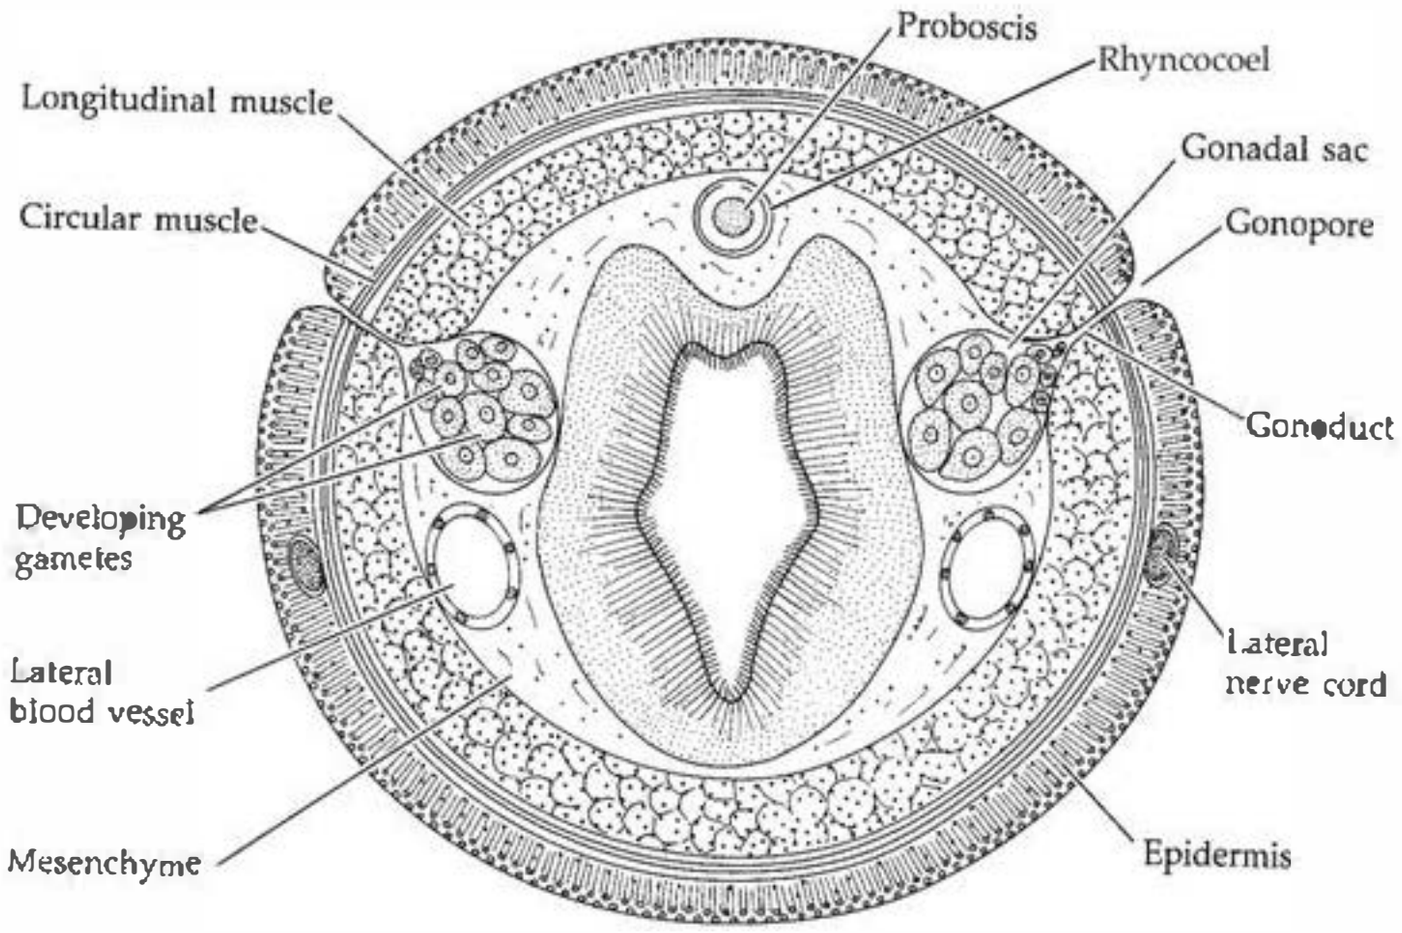

Figure 12.11 Arrangement of gonads in the palaeonemertean *Carinina* (cross section). Note the position of a pair of gonads in the mesenchyme. See also Figure 12.7.

With the proliferation of gametes, the gonadal sacs expand to almost fill the area between the gut and the body wall. When the animals are nearly ready to spawn, mating behavior is initiated and the worms become increasingly active. As mentioned earlier, mate location probably depends on chemotactic responses. The same is apparently true of spawning itself, at least for some species, because the presence of a ripe conspecific stimulates the release of gametes from other mature individuals. Experimental evidence indicates that physical contact is not necessary for such a spawning response; thus, some sort of pheromone is probably involved. In nature, however, spawning usually occurs in concert with actual physical contact; tactile responses evidently follow chemotactic mate location. During such mating activities, veritable knots of scores of worms may writhe in a mucus-covered mating mass. The coordinated release of ripe gametes under such conditions ensures successful fertilization. The gametes are extruded through temporary pores or through ruptures in the body wall. Rupture occurs by contraction of the body wall muscles or of special mesenchymal muscles surrounding the gonads.

Fertilization is often external, either free in the seawater or in a gelatinous mass of mucus produced by the mating worms. In the latter situation, actual egg cases are frequently formed, and part or all of the embryonic development occurs within them (Figure 12.12). Internal fertilization occurs in certain nemerteans. In some cases the sperm are released into the mucus surrounding the mating worms and then move into the ovaries of the female; once fertilized, the eggs are usually deposited in egg capsules, where they develop, although some Antarctic species brood with cocoons. Some terrestrial species are ovoviviparous; the embryos are retained within the body of the female and development is fully direct—an obvious advantage for surviving on land. Ovoviviparity is also known in a few other nemerteans, including deep-sea pelagic forms. Since the population densities of these pelagic worms are extremely low, they must presumably capitalize on the relatively infrequent encounters of males and females and ensure successful fertilization. In a few cases the males are equipped with suckers, which are used to clasp the female, or, rarely, with a protrusible penis, which is used to transfer sperm.

Regardless of the method of fertilization, development through the gastrula is similar among most of the nemerteans studied to date. Cleavage is holoblastic and spiral, producing either three (*Tubulanus*) or, more typically, four quartets of micromeres. A coeloblastula forms, and this often shows the rudiments of an apical ciliary tuft associated with a slight thickening of the blastula wall at or near the animal pole. Gastrulation is usually by invagination of the macromeres and the fourth micromere quartet to produce a coelogastrula. In at least one genus (*Prostoma*, a hermaphroditic freshwater form), gastrulation is by unipolar ingression of

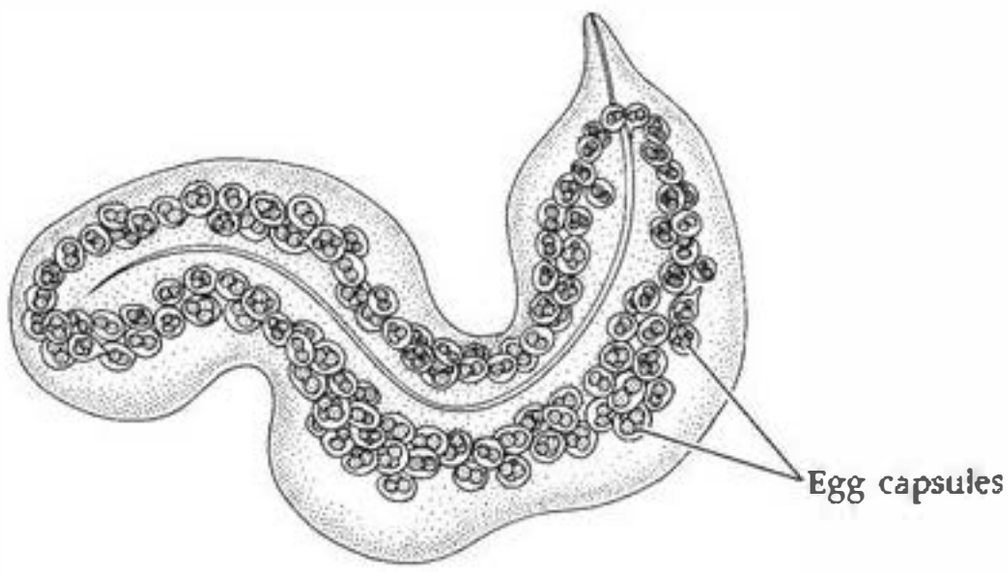

Figure 12.12 Egg capsules in the heteronemertean *Lineus ruber*.

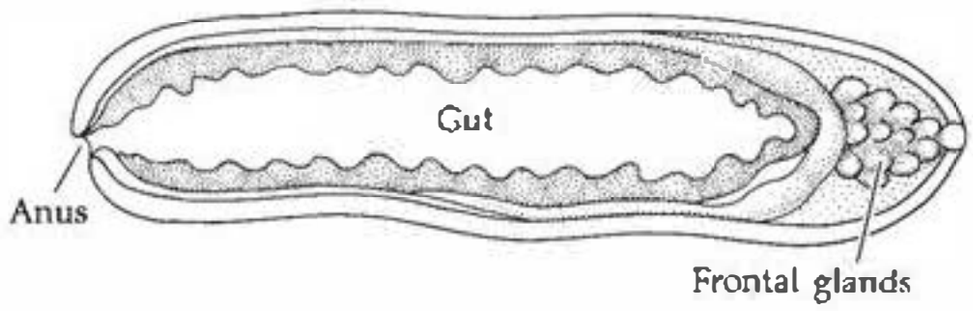

Figure 12.13 Hatching form produced by direct development in *Prosorhochmus*, a hoplonemertean.

the vegetal macromeres; this movement produces a stereogastrula, which later hollows. Mesoderm may originate in several ways, and in some cases the processes are poorly understood. In *Cerebratulus*, one of the best-studied nemerteans developmentally, ectomesoderm is derived from two blastomeres (3a and 3b), which give rise to the extensive array of the larval muscle cells. *Cerebratulus lacteus* also possesses a true mesentoblast (4d) which gives rise to a pair of small mesodermal bands, and scattered mesenchymal cells. This dual origin of the mesoderm, as both ectomesoderm and endomesoderm, appears to be a condition present in all spiralians. The gut is formed by all the fourth quartet micromeres as well as the vegetal macromeres (4A, 4B, 4C, 4D). Unraveling the embryogeny of nemerteans has led to the recent discovery that the rhynchocoel is formed by schizocoely, and it therefore represents a true coelomic cavity.

Developmental strategies are also varied among nemerteans. Members of Palaeonemertea and Hoplonemertea undergo direct development within egg cases. The embryos in these groups develop gradually to juvenile worms without any abrupt metamorphosis (Figure 12.13), but may have multiple invaginations and shedding of a transitory larval epidermis. These embryos are nourished by yolk until they hatch, whereupon they commence feeding. This is especially true of the palaeonemerteans, in which the proboscis apparatus is not fully formed at hatching (the proboscis of heteronemerteans and *Malacobdella* is functional at the time of hatching).

A recent study of embryogenesis of the palaeonemertean *Carinoma tremaphoros* has shown large squamous cells covering the entire larval surface except for the apical and posterior regions. Although apical and posterior cells continue to divide, in the large surface cells cleavage arrest and form a contorted preoral belt. Based on its position, cell lineage, and fate, it has been suggested that this belt corresponds to the prototroch of other trochozoans.

The Pilidiophora undergo a bizarre and fascinating pattern of indirect development. Most species in this subclass produce a free-swimming, planktotrophic larva called the pilidium (Figure 12.14). At this stage the gut is incomplete, consisting of a mouth located between a pair of flaplike ciliated lobes, a stomodeal foregut, and a blind intestine; the anus forms later as a proctodeal invagination. Interestingly, the intestinal diverticula of nemerteans do not form as evaginations of the gut wall but are produced by medial encroachments of mesenchyme, which press in the gut wall, thus creating the diverticula. As the pilidium swims and feeds, a series of invaginations in the larval ectoderm (Figure 12.14B) eventually pinch off internally to produce the presumptive adult ectoderm. Perhaps the most striking characteristic of the pilidium is the way the juvenile worm develops inside the larva from a series of isolated rudiments, called the imaginal discs. The paired cephalic discs, cerebral organ discs, and trunk discs originate as invaginations of larval epidermis and subsequently grow and fuse around the larval gut to form the juvenile (Figure 12.14C). The fully formed juvenile ruptures the larval body and, more often than not, devours the larva during catastrophic metamorphosis. In this way, the animal prepares for benthic life before it faces the rigors of

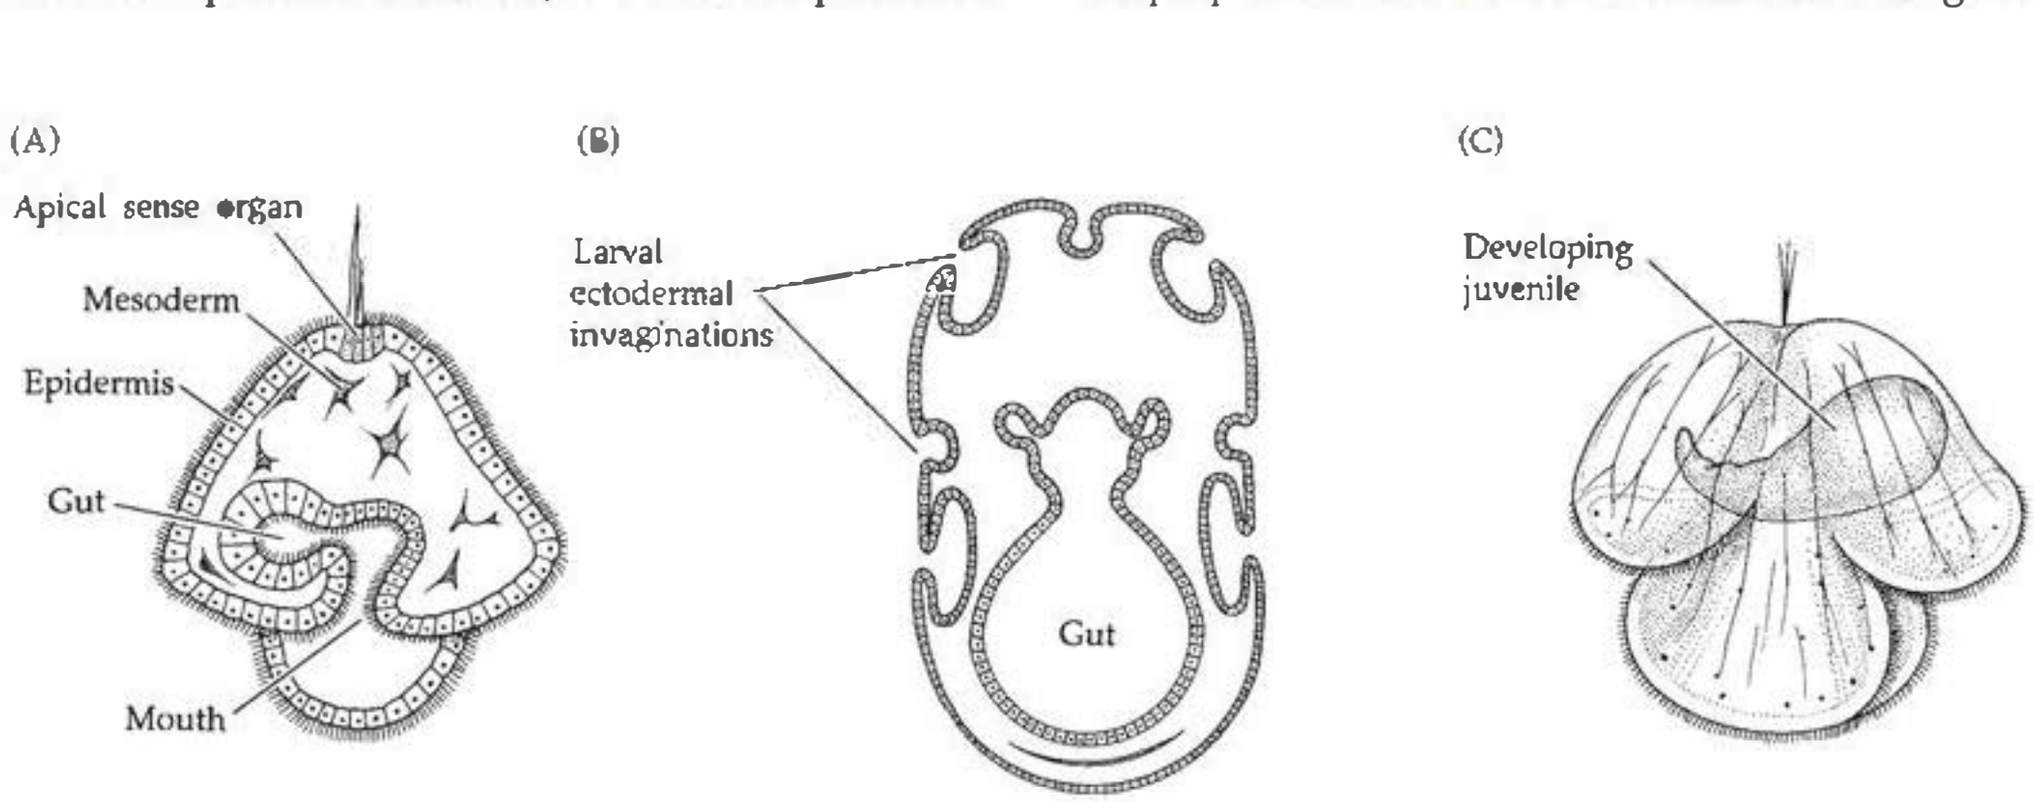

Figure 12.14 Development of a pilidium larva. (A) Pilidium larva (sagittal section). (B) A pilidium larva (transverse section) during invagination of larval ectoderm to form adult skin. (C) Late pilidium larva with juvenile formed within.

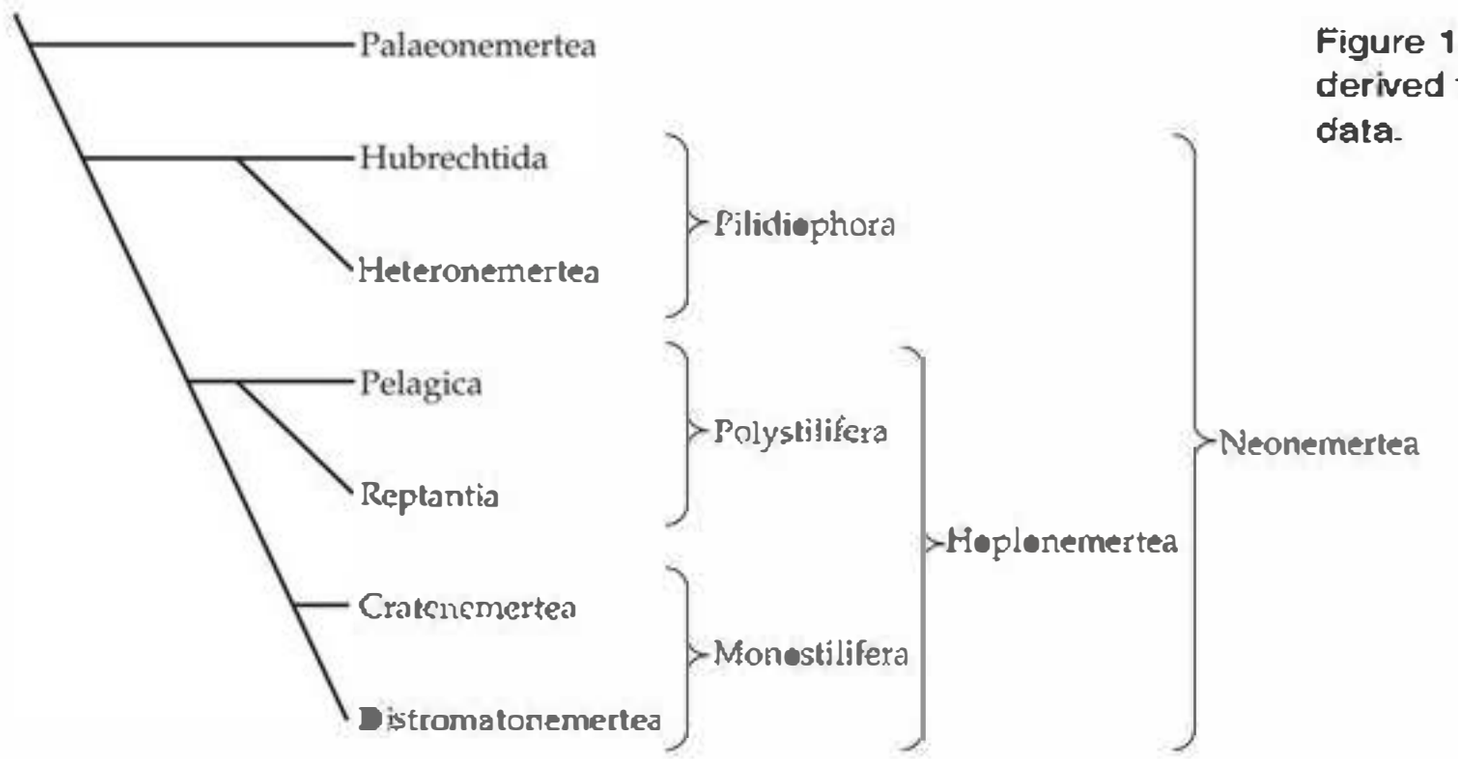

Figure 12.15 Phylogeny of Nemertea derived from recent analyses of molecular data.

settlement. When development is completed, the larval skin is shed and the juvenile assumes its life on the sea floor. Pilidia from different species vary in shape, size, and color. Modifications of pilidial development include Desor's larva in *Lineus viridis*, Schmidt's larva in *Lineus ruber*, and Iwata's larva in several *Micrura* species. Development of Desor's and Schmidt's larva is encapsulated, while the others have planktonic lecithotrophic development. In all of these cases, the pilidial lobes are lacking, the blastocoel is reduced, the larva does not feed but, similar to the canonical pilidium, the juvenile develops via imaginal discs.

Nemertean Phylogeny

The fossil record is, unfortunately, of little use in establishing the origin of nemerteans in geological time, but the group obviously diverged sometime after the origin of the spiralian bilateral condition. Although now viewed to be part of the spiralian clade, related to other spiralians with trochophore larvae, nemerteans had long been considered to be related to flatworms (Chapter 10). However, this idea is refuted by the discovery of the coelomic nature of the nemertean rhynchocoel and blood vessels, which place them closer to other phyla of coelomate spiralians. An older view is that nemerteans arose from an early archoöphoran "turbellarian" stock, perhaps sharing common ancestry with the macrostomid flatworms. The nemerteans and free-living platyhelminths display a number of similarities including protonephridia, types of ocelli, certain histological characteristics (especially of the epidermis), and the general organization of the nervous system. Furthermore, various ciliated slits and depressions among free-living flatworms resemble the cephalic slits and similar structures of the nemerteans. Some flatworms possess frontal (cephalic) glands long thought to be homologous to those of ribbon worms, but these could be symplesiomorphic for Spiralia or they could be convergences. Their mode or early egg cleavage places them as clear members of the clade Spiralia, and interpretations of the arrested cells of some embryos suggest a relationship to phyla with trochophore larvae—a relationship otherwise unsupported by any other anatomical characters. This is why their phylogenetic placement has been in flux for quite some time. However, molecular data strongly suggest a relationship to Mollusca, Annelida, and the lophophorate phyla (and probably also the Entoprocta).

The phylogenetic relationships among the various taxa of Nemertea have been examined in detail in the past few years and now include a phylogenomic analysis using hundreds of genes (Figure 12.15). These new studies are largely congruent with some of the traditional classifications, but they have found paraphyly of the former class Anopla, and include some important rearrangements, like the placement of Hubrechtida as sister group to Heteronemertea and not as a member of Palaeonemertea, or the placement of the former monogeneric order Bdellonemertea within Monostilifera. The former result is not really that surprising, as species of Hubrechtida have a mosaic of palaeonemertean and heteronemertean characters and some authors have considered them as a "transitional stage" between palaeonemerteans and basal heteronemerteans. Furthermore, the new evolutionary tree therefore implies that certain characters found in Anopla are actual symplesiomorphies for Nemertea, including the unarmed proboscis or the separation of the opening of mouth and proboscis. Within Hoplonemertea, Monostilifera appear divided into two clades, Cratenemertea and Distromatonemertea, whereas Polystilifera splits into the clades Pelagica and Reptantia.

One of the principal structural trends among the nemerteans is the internalization of the major longitudinal nerve cords. We assume that the earliest ribbon

worms possessed epidermal nerve cords, as do some modern palaeonemerteans. Palaeonemerteans and pilidiophorans retain the plesiomorphic feature of the placement of the mouth posterior to the cerebral ganglion. The relatively simple and unarmed proboscis and the placement of the nerve cords external to the mesenchyme suggest further that these clades retain the plesiomophic character states among the ribbon worms. Pilidiophorans acquired indirect development, the unique formation of the double larval and adult ectoderm during metamorphosis, and the evolution of their unique arrangement of body wall muscles. The encapsulation, and thus functionally direct development, of those heteronemerteans with a Desor larva is almost certainly a secondary abandonment of free pilidial larval life.

The hoplonemerteans show some distinct changes from the members mentioned above. Most notable are the regional specialization and armature of the proboscis, the movement of the nerve cords to a mesenchymal position, and the movement of the mouth more anteriorly. The bdellonemerteans are a specialized offshoot of Monostilifera that displays significant modification for an endosymbiotic lifestyle, including simplification of the proboscis, coiling and increased relative length of the gut (probably associated with their herbivorous habits), a posterior body sucker, and decreased body length.

CHAPTER 13

Phylum Mollusca

Molluscs include some of the best-known invertebrates; almost everyone is familiar with snails, clams, slugs, squids, and octopuses. Molluscan shells have been popular since ancient times, and some cultures still use them as tools, containers, musical devices, money, fetishes, religious symbols, ornaments, and decorations and art objects. Evidence of historical use and knowledge of molluscs is seen in ancient texts and hieroglyphics, on coins, in tribal customs, and in archaeological sites and aboriginal kitchen middens or shell mounds. Royal or Tyrian purple of ancient Greece and Rome, and even Biblical blue (Num. 15:38), were molluscan pigments extracted from certain marine snails.[1] Many aboriginal groups have for millenia relied on molluscs for a substantial portion of their diet and for use as tools. Today, coastal nations annually harvest millions of tons of molluscs commercially for food.

There are approximately 80,000 described, living mollusc species and about the same number of described fossil species. However, many species still await names and descriptions, especially those from poorly studied regions and time periods, and it has been estimated that only about half of the living molluscs have so far been described. In addition to three familiar molluscan classes comprising the clams (Bivalvia), snails and slugs (Gastropoda), and squids and octopuses (Cephalopoda), five other extant classes exist: chitons (Polyplacophora), tusk shells (Scaphopoda), *Neopilina* and its kin (Monoplacophora), and the vermiform sclerite-bearing aplacophoran classes—Caudofoveata (or Chaetodermomorpha) and Solenogastres (or Neomeniomorpha). Although members of these eight classes differ enormously in superficial appearance, there is a suite of characters that diagnose their fundamental body plan (Box 13A).

Taxonomic History and Classification

Molluscs carry the burden of a very long and convoluted taxonomic history, in which hundreds of names for various taxa have come and gone. Aristotle recognized molluscs, dividing them into Malachia (the cephalopods) and Ostrachodermata (the shelled forms), the latter being divided into univalves and bivalves. Joannes Jonston (or Jonstonus) created the name Mollusca[2] in 1650 for the cephalopods and barnacles, but this name was not accepted until it was resurrected and redefined by Linnaeus nearly a hundred years later. Linnaeus's Mollusca included cephalopods, slugs, and pteropods, as well as tunicates, anemones, medusae, echinoderms, and polychaetes but included chitons, bivalves, univalves, nautiloids, barnacles, and the serpulid polychaetes (which secrete calcareous tubes) in another group, Testacea. In 1795 Georges Cuvier published a revised classification of the Mollusca that was the first to approximate modern views. Henri de Blainville (1825) altered the name Mollusca to Malacozoa, which won little favor but survives in the terms malacology, malacologist, etc.

Much of the nineteenth century passed before the phylum was purged of all extraneous groups. In the 1830s, J. Thompson and C. Brumeister identified the larval stages of barnacles and revealed them to be crustaceans, and in 1866 Alexander Kowalevsky removed the tunicates from Mollusca. Separation of the brachiopods from the molluscs was long and controversial and not resolved until near the end of the nineteenth century.

The first sclerite-covered wormlike aplacophorans, members of what today we recognize as the class Caudofoveata, were discovered in 1841 by the Swedish naturalist Sven Lovén. He classified them with holothuroid echinoderms because of their vermiform bodies and the presence of calcareous sclerites in the body walls of both groups. In 1886, another Swede, Tycho Tullberg, described the first representative of the other aplacophoran group the Solenogastres. Ludwig von Graff (1875) recognized both groups as molluscs and they were united in the Aplacophora in 1876 by Hermann von Ihering. The Aculifera hypothesis of Amélie Scheltema unites molluscs that possess calcareous sclerites by placing Polyplacophora as the sister taxon of the aplacophorans (Caudofoveata + Solengastres). Aculifera was sometimes also called Amphineura, although this latter term has also been used by some workers to refer only to chitons. Sclerites are spicules, scales, and so on that cover or are embedded in the epidermis of molluscs and are often calcified.

The history of classification of species in the class Gastropoda has been volatile, undergoing constant change since Cuvier's time. Most modern malacologists adhere more or less to the basic schemes of Henri Milne-Edwards (1848) and J. W. Spengel (1881). The former, basing his classification on the respiratory organs, recognized the groups Pulmonata, Opisthobranchia, and Prosobranchia. Spengel based his scheme on the nervous system and divided the gastropods into the Streptoneura and Euthyneura. In subsequent classifications, Streptoneura was equivalent to Prosobranchia; Euthyneura included Opisthobranchia and Pulmonata. The bivalves have been called Bivalvia, Pelecypoda, and Lamellibranchiata. More recently, anatomical, ultrastructural, and molecular studies have brought about considerable changes to molluscan classification, as outlined below. Many taxa have multiple names and the more commonly encountered ones are noted below.

Molluscan classification at the generic and species levels is also troublesome. Many species of gastropods

BOX 13A Characteristics of the Phylum Mollusca

1. Bilaterally symmetrical (or secondarily asymmetrical), unsegmented, coelomate protostomes
2. Coelom limited to small spaces in nephridia, heart, and gonads
3. Principal body cavity is a hemocoel (open circulatory system)
4. Viscera concentrated dorsally as a "visceral mass"
5. Body covered by a cuticle-covered epidermal sheet of skin, the mantle
6. Mantle with shell glands that secrete calcareous epidermal sclerites, shell plates, or shells
7. Mantle overhangs and forms a cavity (the mantle cavity) in which are housed the ctenidia, osphradia, nephridiopores, gonopores, and anus
8. Heart situated in a pericardial chamber and composed of a single ventricle and one or more separate atria
9. Typically with large, well-defined muscular foot, often with a flattened creeping sole
10. Buccal region provided with a radula and muscular odontophore
11. Complete (through) gut, with marked regional specialization, including large digestive glands
12. With large, complex metanephridial "kidneys"
13. Cleavage spiral and embryogeny protostomous
14. With trochophore larva, and a veliger larva in two major groups

---

[2]The name of the phylum derives from the Latin *molluscus*, meaning "soft," in allusion to the similarity of clams and snails to the mollusca, a kind of Old World soft nut with a thin but hard shell. The vernacular for Mollusca is often spelled mollusks in the United States, whereas in most of the rest of the world it is typically spelled molluscs. In biology, a vernacular or diminutive name is generally derived from the proper Latin name; thus the custom of altering the spelling of Mollusca by changing the c to k seems to be an aberration (although it may have its historic roots in the German language, which does not have the free standing c; e.g., Molluskenkunde). We prefer the more widely used spelling "molluscs," which seems to be the proper vernacularization and is in line with other accepted terms, such as molluscan, molluscoid, molluscivore, etc.

and bivalves are also burdened with numerous names (synonyms) that have been proposed for the same species. This tangle is partly the result of a long history of amateur shell collecting beginning with the natural history cabinets of seventeenth century Europe, which required documentation and promoted multiple taxonomies and names based only on shell characters. Today, species are recognized based on a combination of shell, anatomical, and, most recently molecular characters. However, because of the tremendous diversity of gastropods and bivalves many species still remain known only from their shells.

Only taxa with extant members are included in the following classification and not all families are listed in the taxonomic synopses. The classification is mostly ranked, but in a few cases unranked group names are used.[3] Examples of the major molluscan taxa appear in Figure 13.1.

ABBREVIATED CLASSIFICATION OF THE PHYLUM MOLLUSCA

CLASS CAUDOFOVEATA Caudofoveatan aplacophorans (spicule "worms")

CLASS SOLENOGASTRES Solenogaster aplacophorans (spicule "worms")

CLASS MONOPLACOPHORA Monoplacophorans. Deep sea, limpet-like

CLASS POLYPLACOPHORA Chitons, with eight shell valves

CLASS GASTROPODA Snails, slugs and limpets

SUBCLASS PATELLOGASTROPODA The true limpets

SUBCLASS VETIGASTROPODA "Primitive" marine top shell snails, abalones and "limpets"

SUBCLASS NERITIMORPHA Marine, land and freshwater neritic snails and "limpets"

SUBCLASS CAENOGASTROPODA Marine, freshwater and land snails (creepers, periwinkles, conchs, whelks, cowries etc.) and some "limpets"

"ARCHITAENIOGLOSSA" Nonmarine basal caenogastropods (paraphyletic)

INFRACLASS SORBEOCONCHA All remaining caenogastropods

SUPERORDER CERITHIOMORPHA Creepers, turret shells, etc.

COHORT HYPSOGASTROPODA Higher caenogastropods

SUPERORDER LITTORINIMORPHA Periwinkles, cowries, triton shells, etc.

SUPERORDER NEOGASTROPODA Whelks, volutes, rock shells etc.

SUBCLASS HETEROBRANCHIA Marine, freshwater and land snails, most sea slugs, all and slugs, and some "false limpets"

"LOWER HETEROBRANCHIA" A few primitive heterobranch groups including sundial shells, valvatids, etc.

INFRACLASS EUTHYNEURA "Opisthobranchs" and "pulmonates"

COHORT NUDIPLEURA Side gilled sea slugs and nudibranchs

COHORT EUOPISTHOBRANCHIA Bubble shells, sea hares, pteropods, etc.

COHORT PANPULMONATA "Pulmonates," pyramidellids, sacoglossan sea slugs, most land snails, all land slugs

CLASS BIVALVIA Clams and their kin (bivalves)

SUBCLASS PROTOBRANCHIA "Primitive" deposit-feeding bivalves

SUBCLASS AUTOBRANCHIA "Lamellibranch" suspension feeding bivalves

COHORT PTERIOMORPHIA Mussels, oysters, scallops, and their kin

COHORT HETEROCONCHA Marine and freshwater clams

MEGAORDER PALAEOHETERODONTA Freshwater clams (mussels), broch shells

MEGAORDER HETERODONTA Most marine clams

SUPERORDER ARCHIHETERODONTA A few families of primitive marine clams

SUPERORDER EUHETERODONTA The majority of marine and some freshwater clams

CLASS SCAPHOPODA Tusk shells

CLASS CEPHALOPODA Nautilus, squids, octopuses

SUBCLASS PALCEPHALOPODA

COHORT NAUTILIDA Chambered nautilus

SUBCLASS NEOCEPHALOPODA

COHORT COLEOIDEA Octopuses, squids, cuttlefish

SUPERORDER OCTOPODIFORMES Octopuses, vampire squid

SUPERORDER DECAPODIFORMES Cuttlefish, squid

---

[3] Multitudes of extinct molluscs have been described. Perhaps the most well known are some of the groups of cephalopods that had hard external shells, similar to those of living *Nautilus*. One of these groups was the ammonites. They differed from nautiloids in having shell septa that were highly fluted on the periphery, forming complex mazelike septal sutures. Ammonites also had the siphuncle lying against the outer wall of the shell, as opposed to the condition seen in many nautiloids where the siphuncle runs through the center of the shell.

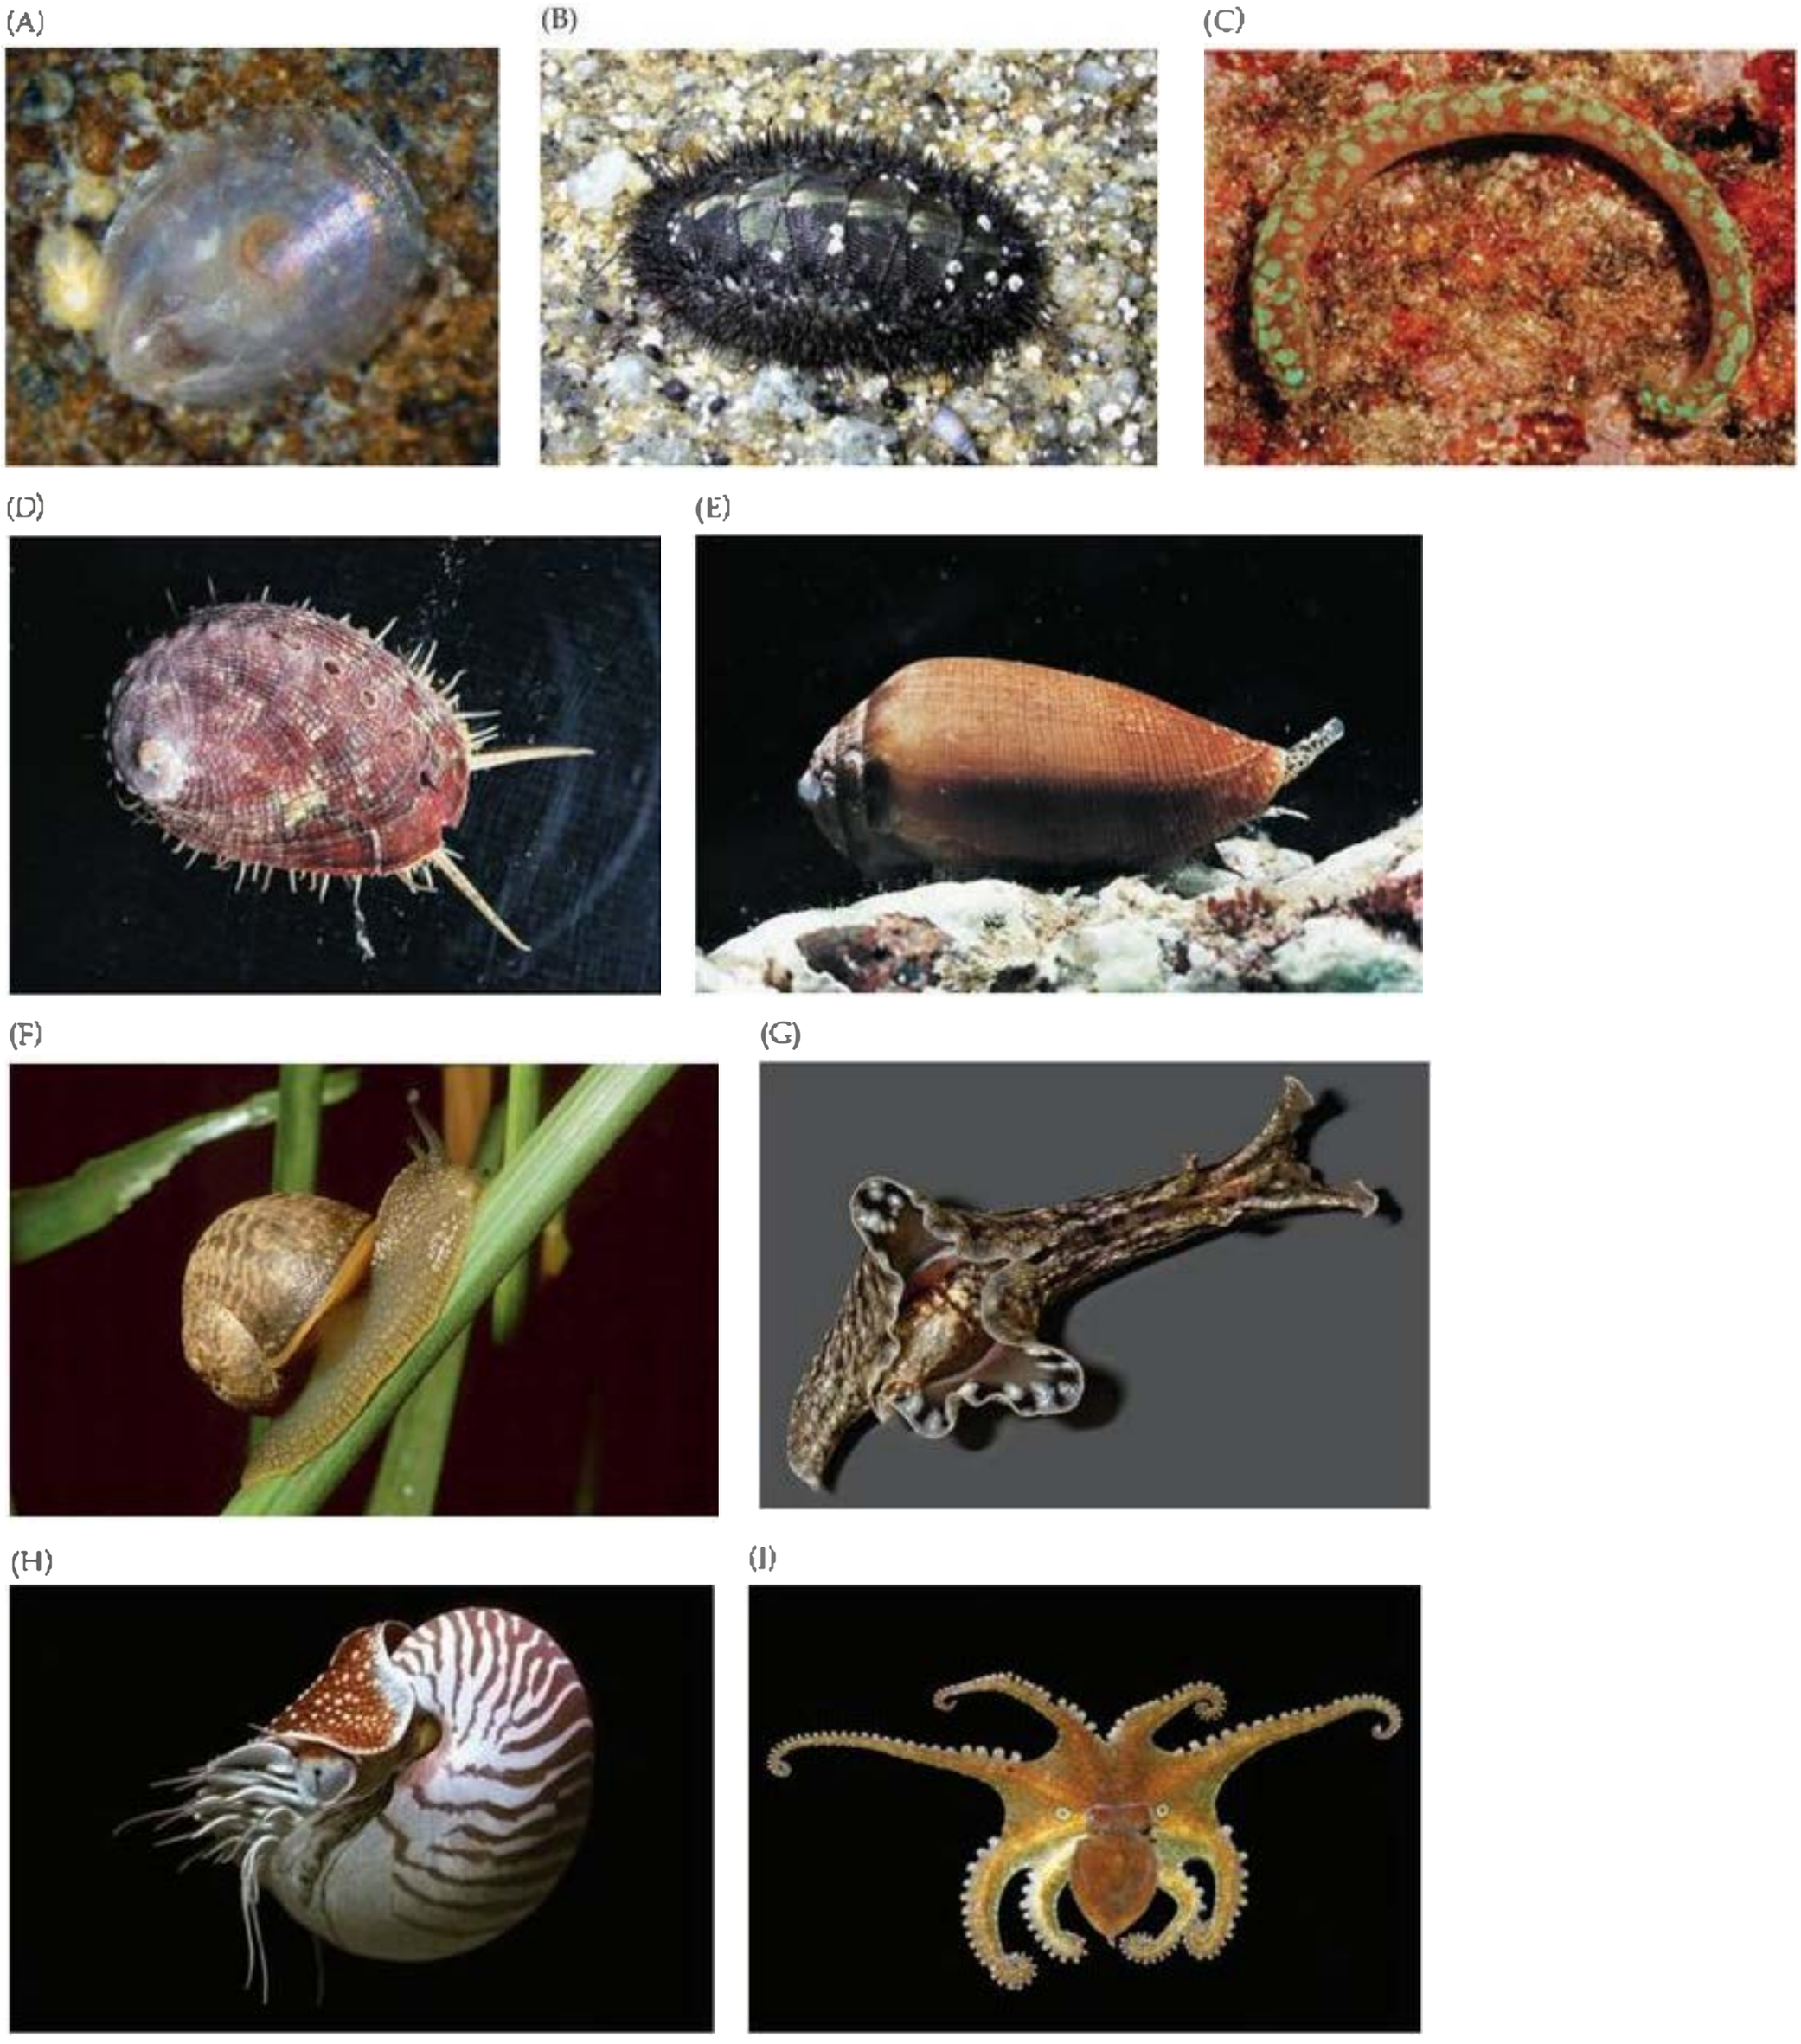

Figure 13.1 Morphological diversity among the molluscs. (A) *Laevipilina hyalina* (Monoplacophora). (B) *Mopalia muscosa*, the mossy chiton (Polyplacophora). (C) *Epimenia australis* (Solenogastres). (D) *Haliotis rufescens*, the red abalone, (Gastropoda); note the exhalant holes in the shell. (E) *Conus*, a predatory neogastropod; note anterior siphon extending beyond shell. (F) The common garden snail, *Cornu aspersum* (Gastropoda). (G) *Aplysia*, the sea hare (Gastropoda: Euopisthobranchia). (H) The chambered *Nautilus* (Cephalopoda). ( ) *Octopus bimaculoides* (Cephalopoda). (J) *Sepioteuthis lessoniana*, the bigfin reef squid (Cephalopoda). (K) *Histioteuthis*, a pelagic squid (Cephalopoda). (L) *Fustiaria* a tusk shell (Scaphopoda). (M) Scallops (Bivalvia: Pteriomorphia: Pectinidae), with a hermit crab in the foreground. (N) The giant clam *Tridacna maxima* (note zooxanthellate mantle), from the Marshall Islands, Northwest Pacific (Bivalvia: Heterodonta: Cardiida). (O) The European cockle *Acanthocardia tuberculata* (Bivalvia: Heterodonta: Cardiida). Note the partly extended foot (P) *Lima*, a tropical clam that swims by clapping the valves together (Bivalvia). (Q) The highly modified bivalve *Brechites*. (Heterodonta: Poromyata). *Brechites* are known as watering pot shells. They begin their life as a typical small bivalve, but then secrete a large calcareous tube around themselves through which water is pumped for suspension feeding.

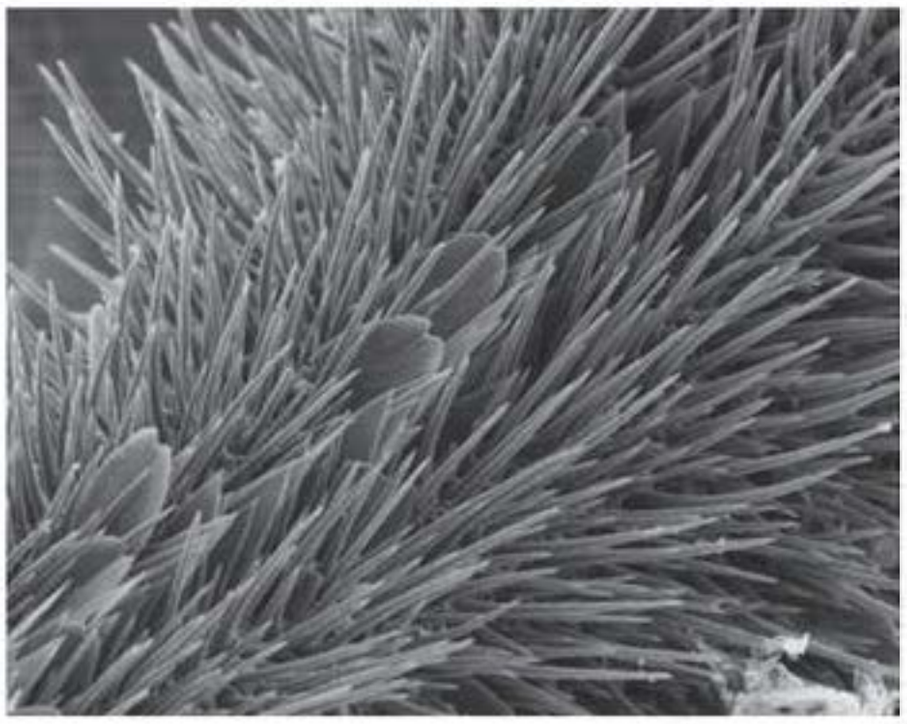
SYNOPSES OF MOLLUSCAN GROUPS



CLASS CAUDOFOVEATA (= CHAETODERMOMORPHA) (Figure 13.2A–C). Spicule "worms." Marine, benthic, burrowing; body vermiform, cylindrical, lacking any trace of a shell; body wall with a chitinous cuticle and imbricating scale-like aragonitic calcareous sclerites; mouth shield anterior to or surrounding the mouth; small posterior mantle cavity with a pair of bipectinate ctenidia; radula present; gonochoristic. Without foot, eyes, tentacles, statocysts, crystalline style, osphradia, or nephridia. About 120 species; burrow in muddy sediments and consume microorganisms such as foraminiferans. (e.g., *Chaetoderma, Chevroderma, Falcidens, Limifosser, Prochaetoderma, Psilodens, Scutopus*)

CLASS SOLENOGASTRES (= NEOMENIOMORPHA) (Figure 13.2D–K). Spicule "worms." Marine, benthic; body vermiform and nearly cylindrical; vestibulum (= atrium) with sensory papillae anterior to the mouth; small posterior mantle cavity lacking ctenidia but often with respiratory folds; body wall with a chitinous cuticle and imbued with calcareous sclerites (as spines or scales); with or without radula; hermaphroditic; pedal glands opening into a pre-pedal ciliary pit, foot weakly muscular, narrow, and can be retracted into a ventral furrow or "pedal groove." Without eyes, tentacles, statocysts, crystalline style, osphradia or nephridia. About 260 described species, but many undescribed species are thought to exist; epibenthic carnivores, often found on (and consuming) cnidarians and a few other types of

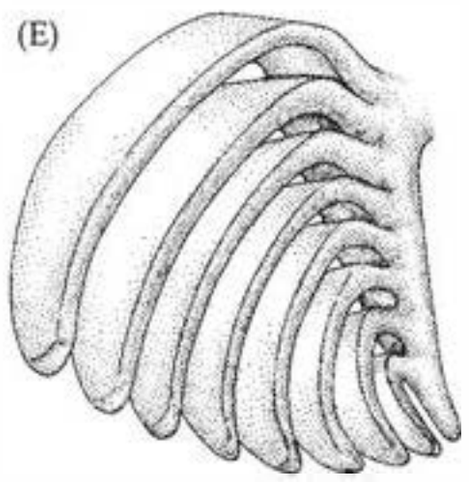
(G) *Epimenia verrucosa*. The body is covered with warts. (H) *Neomenia carinata*, ventral view. (I) *Entonomenia tricarinata*, ventral view (X-ray micro-CT). (J) *Macellomenia morseae*. SEM of ventral surface showing two types of scalelike sclerites surrounding the foot and spiny sclerites covering the rest of the surface of the body. (K) *Macellomenia schanderi*. SEM of ventral surface of anterior end showing densely ciliated pedal pit and mouth. (L) Anterior region of *Spengelomenia bathybia* (highly stylized sagittal section drawing).



invertebrates. Solenogastres and Caudofoveata are probably sister groups and are sometimes regarded as subclasses within the class Aplacophora. (e.g., *Alexandromenia*, *Dondersia*, *Epimenia*, *Kruppomenia*, *Neomenia*, *Proneomenia*, *Pruvotina*, *Rhopalomenia*, *Spengelomenia*, *Wirenia*)

CLASS MONOPLACOPHORA Monoplacophorans. With a single, cap-like shell; foot forms weakly muscular ventral disc, with 5 pairs of retractor muscles; shallow mantle cavity around foot encloses 3–6 pairs ctenidia; 2 pairs gonads; 3–7 pairs nephridia; 2 pairs heart atria; a pair of statocysts; with radula and distinct but small head region; without eyes; short oral tentacles present around mouth; with posterior anus; without a crystalline style; gonochoristic or, rarely, hermaphroditic (Figures 13.1A and 13.3). Until the first living species (*Neopilina galatheae*) was discovered by the Danish Galathea Expedition in 1952, monoplacophorans were

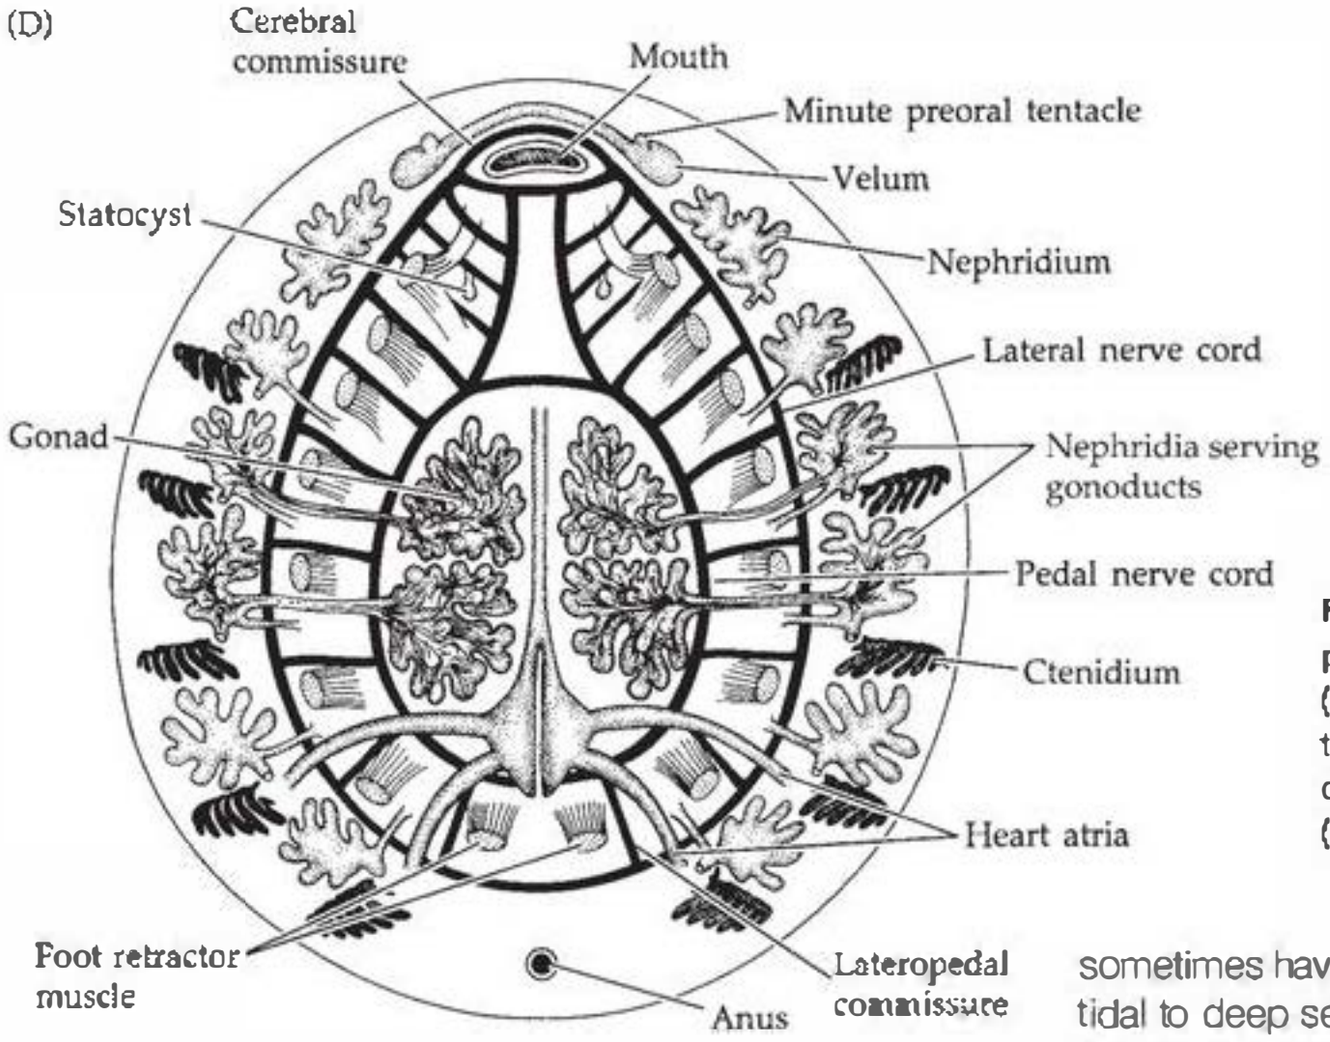


Figure 13.3 General anatomy of a monoplacophoran (*Neopilina*). (A) Dorsal view (shell). (B) Ventral view. (C) Photograph of the ventral surface of a preserved specimen of *Neopilina*. (D) Ventral view, foot removed. (E) One of the gills.

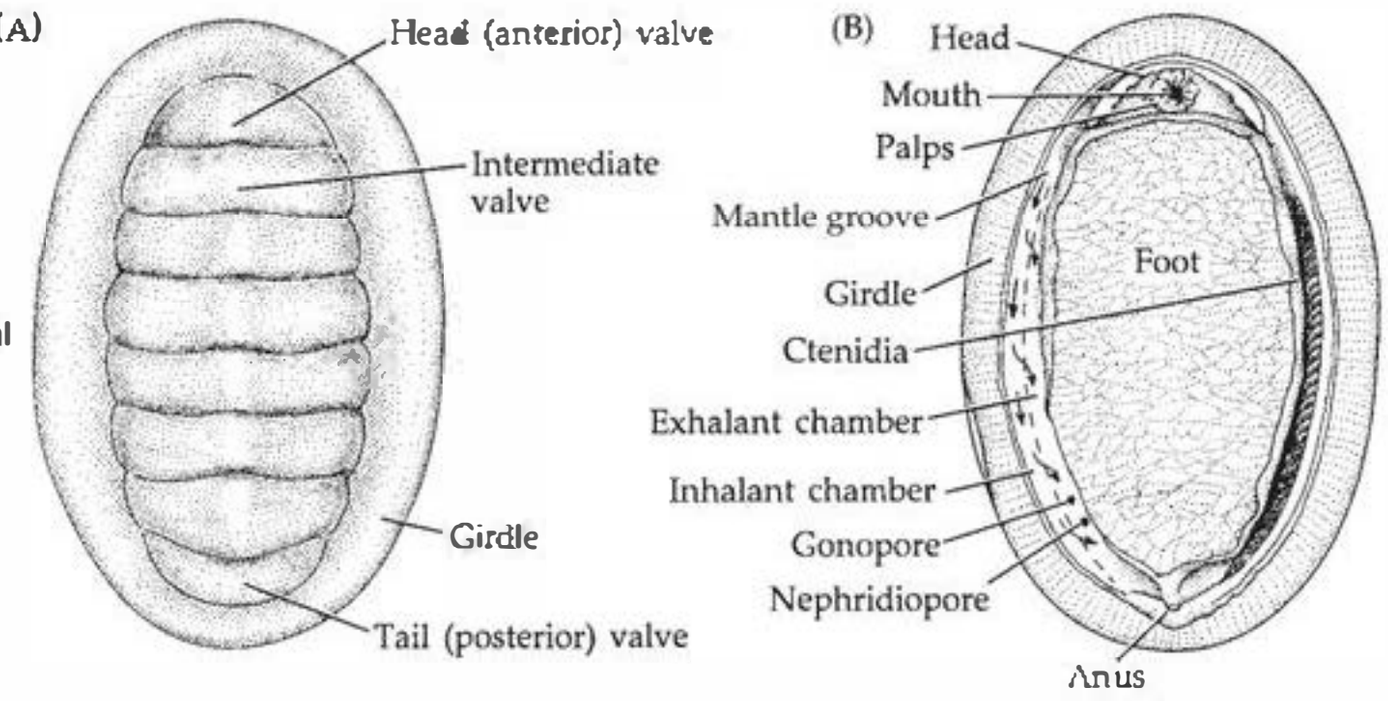
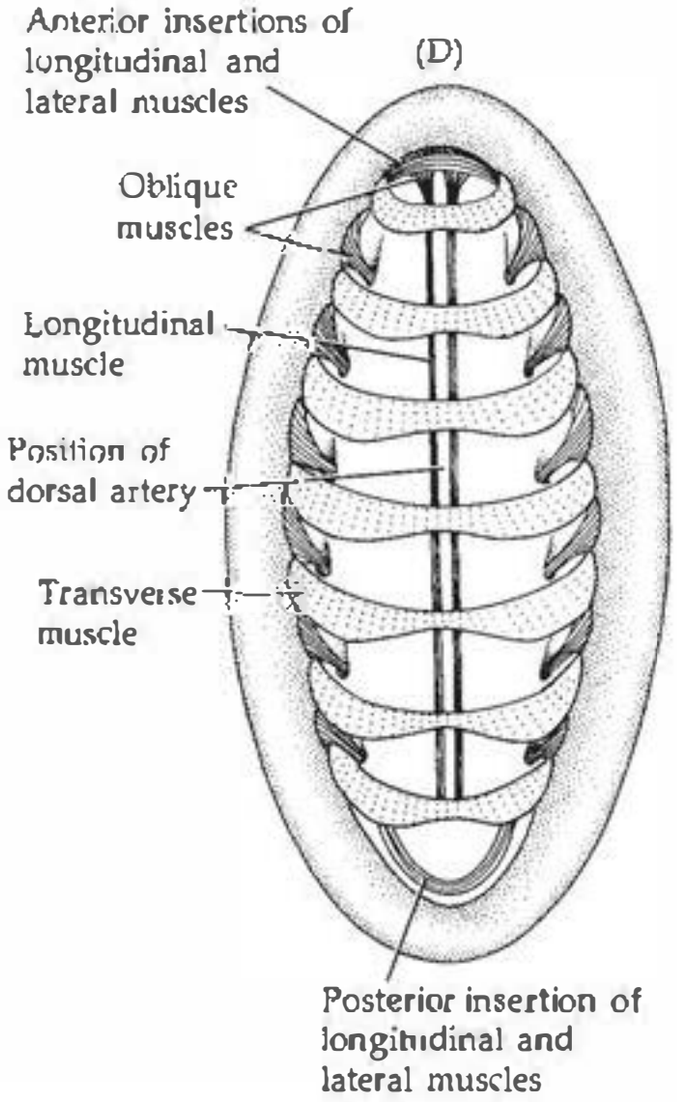
known only from lower Paleozoic fossils. Since then their unusual anatomy has been a source of much evolutionary speculation. Monoplacophorans are limpet-like in appearance, living species are less than 3 cm in length, and most live at considerable depths. About 30 described species, in 8 genera (*Adenopilina*, *Laevipilina*, *Monoplacophorus*, *Neopilina*, *Rokopella*, *Veleropilina*, *Vema*, *Micropilina*).

CLASS POLYPLACOPHORA Chitons (Figures 13.1B and 13.4). Flattened, elongated molluscs with a broad ventral foot and 8 dorsal shell plates (composed of aragonite); mantle forms thick girdle that borders and may partly or entirely cover shell plates; epidermis of girdle usually with calcareous spines, scales, or bristles; mantle cavity encircles foot and bears from 6 to more than 80 pairs of bipectinate ctenidia; 1 pair nephridia; head without eyes or tentacles; crystalline style, statocysts and osphradia absent; nervous system lacking discrete ganglia, except in buccal region; well-developed radula present. Shell canals (aesthetes) sometimes have shell eyes (Figure 13.43C,D). Marine, intertidal to deep sea. Chitons are unique in their possession of 8 separate shell plates, called valves, and a thick marginal girdle; about 850 described species in one living order.[4]

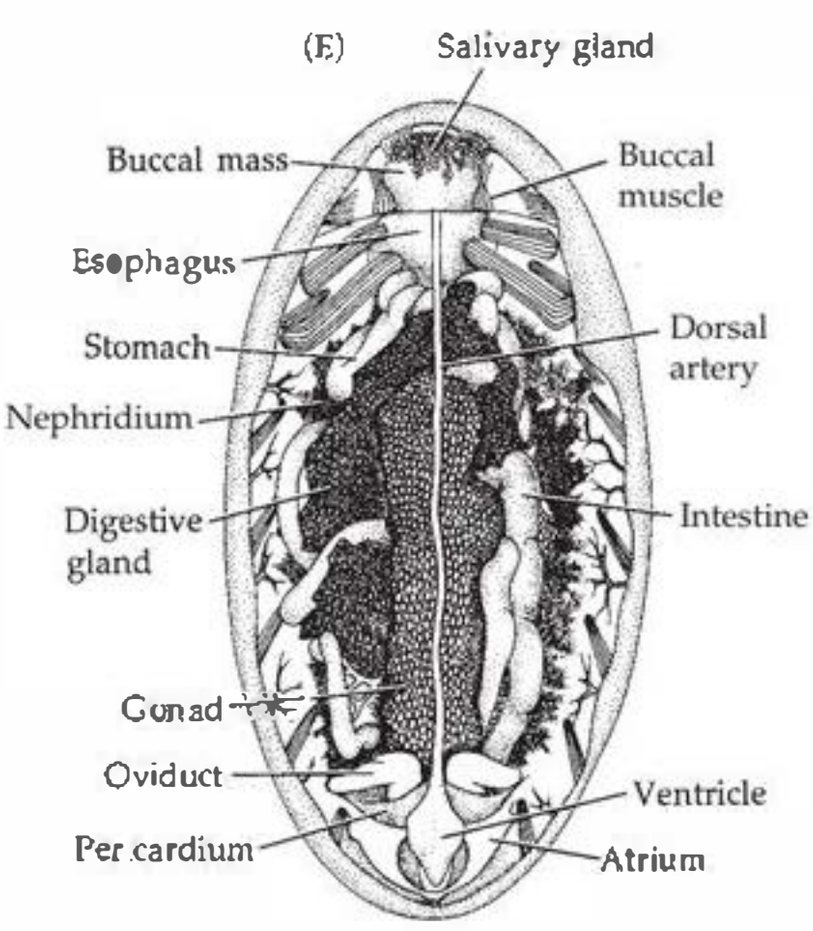


ORDER NEOLORICATA Shells with unique articulamentum layer, which forms insertion plates that interlock the valves.

SUBORDER LEPIDOPLEURIDA Chitons with outer edge of shell plates lacking attachment teeth; girdle not extending over plates; ctenidia limited to a few posterior pairs. (e.g., *Choriplax*, *Lepidochiton*, *Lepidopleurus*, *Oldroydia*)



SUBORDER CHITONIDA Outer edges of shell plates with attachment teeth; girdle not extending over plates, or extending partly over plates; ctenidia occupying most of mantle groove, except near anus. (e.g., *Callistochiton*, *Chaetopleura*, *Ischnochiton*,



[4]Uncommon, aberrant individuals have been found with only 7 valves.

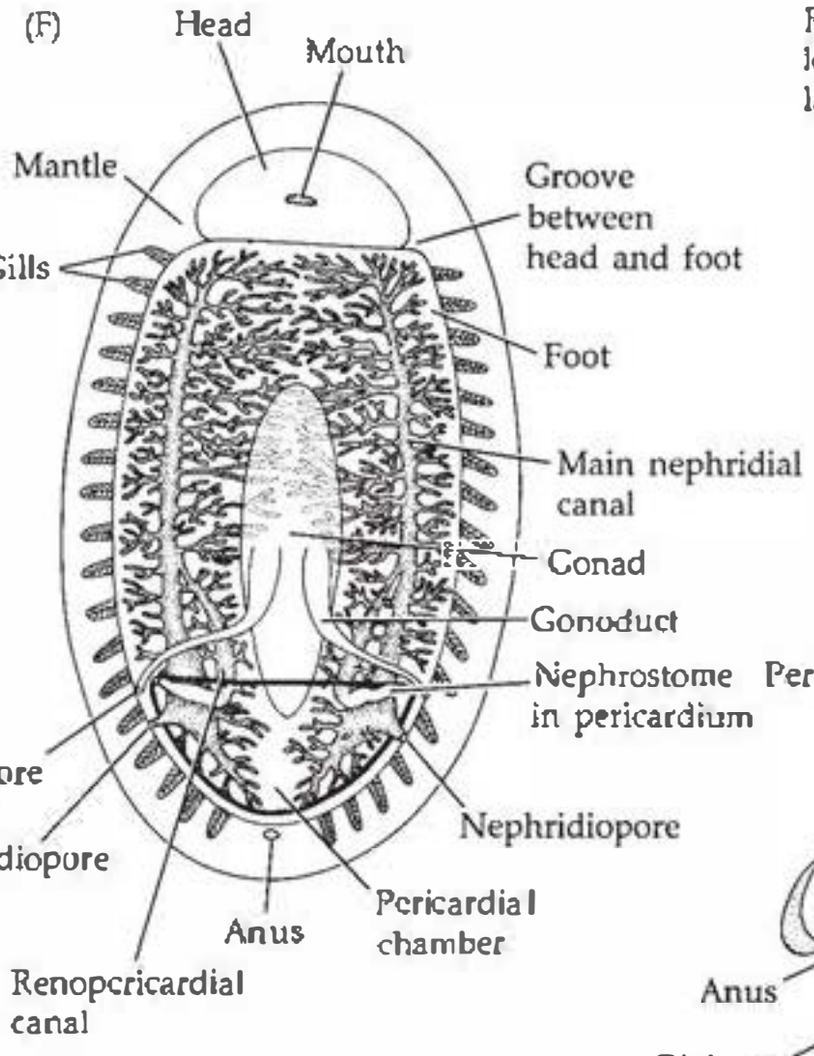


Figure 13.4 Generalized anatomy of chitons (Polyplacophora). (A,B) A typical chiton (dorsal and ventral views). (C) The Pacific lined chiton, *Tonicella lineata*. (D) Dorsal view of a chiton, shell plates (valves) removed. (E) Dorsal view of a chiton, dorsal musculature removed to reveal internal organs. (F) Dorsal view of a chiton, showing extensive nephridia. (G) The arrangement of internal organs in a chiton (lateral view).

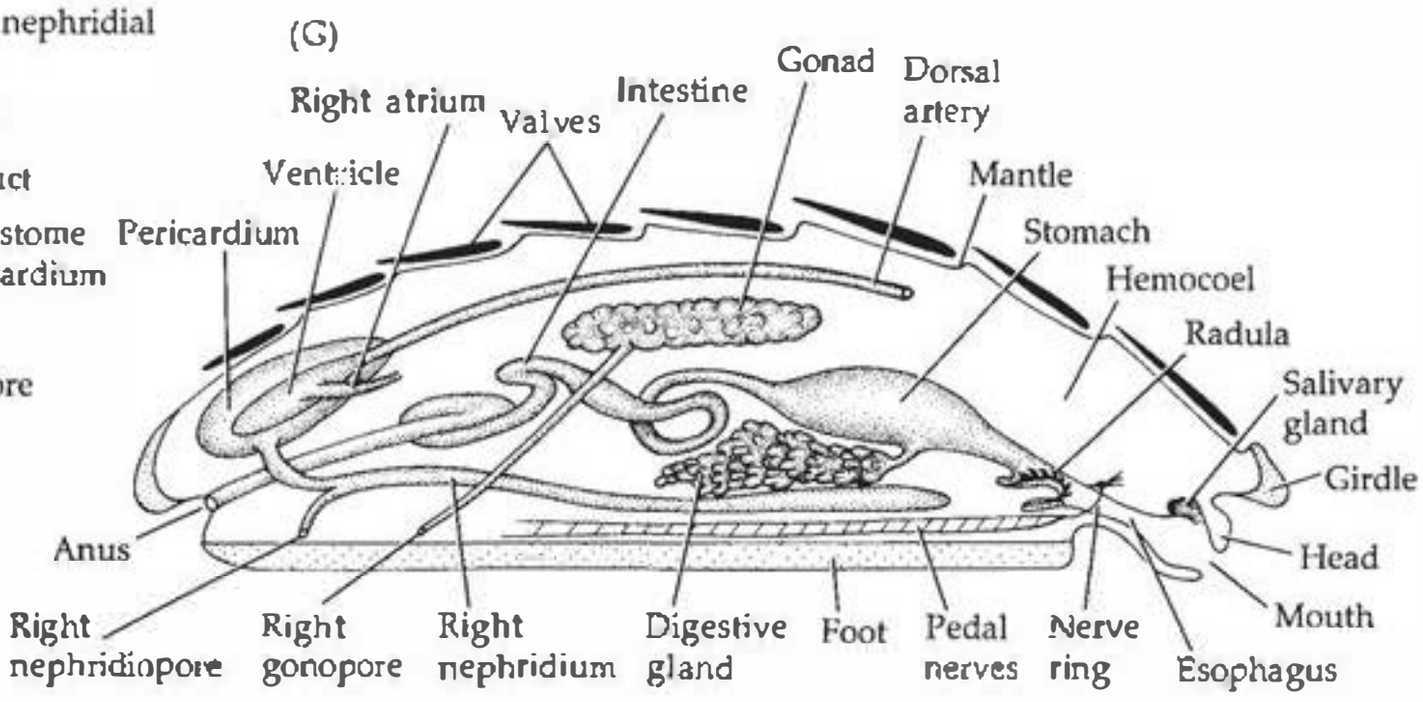

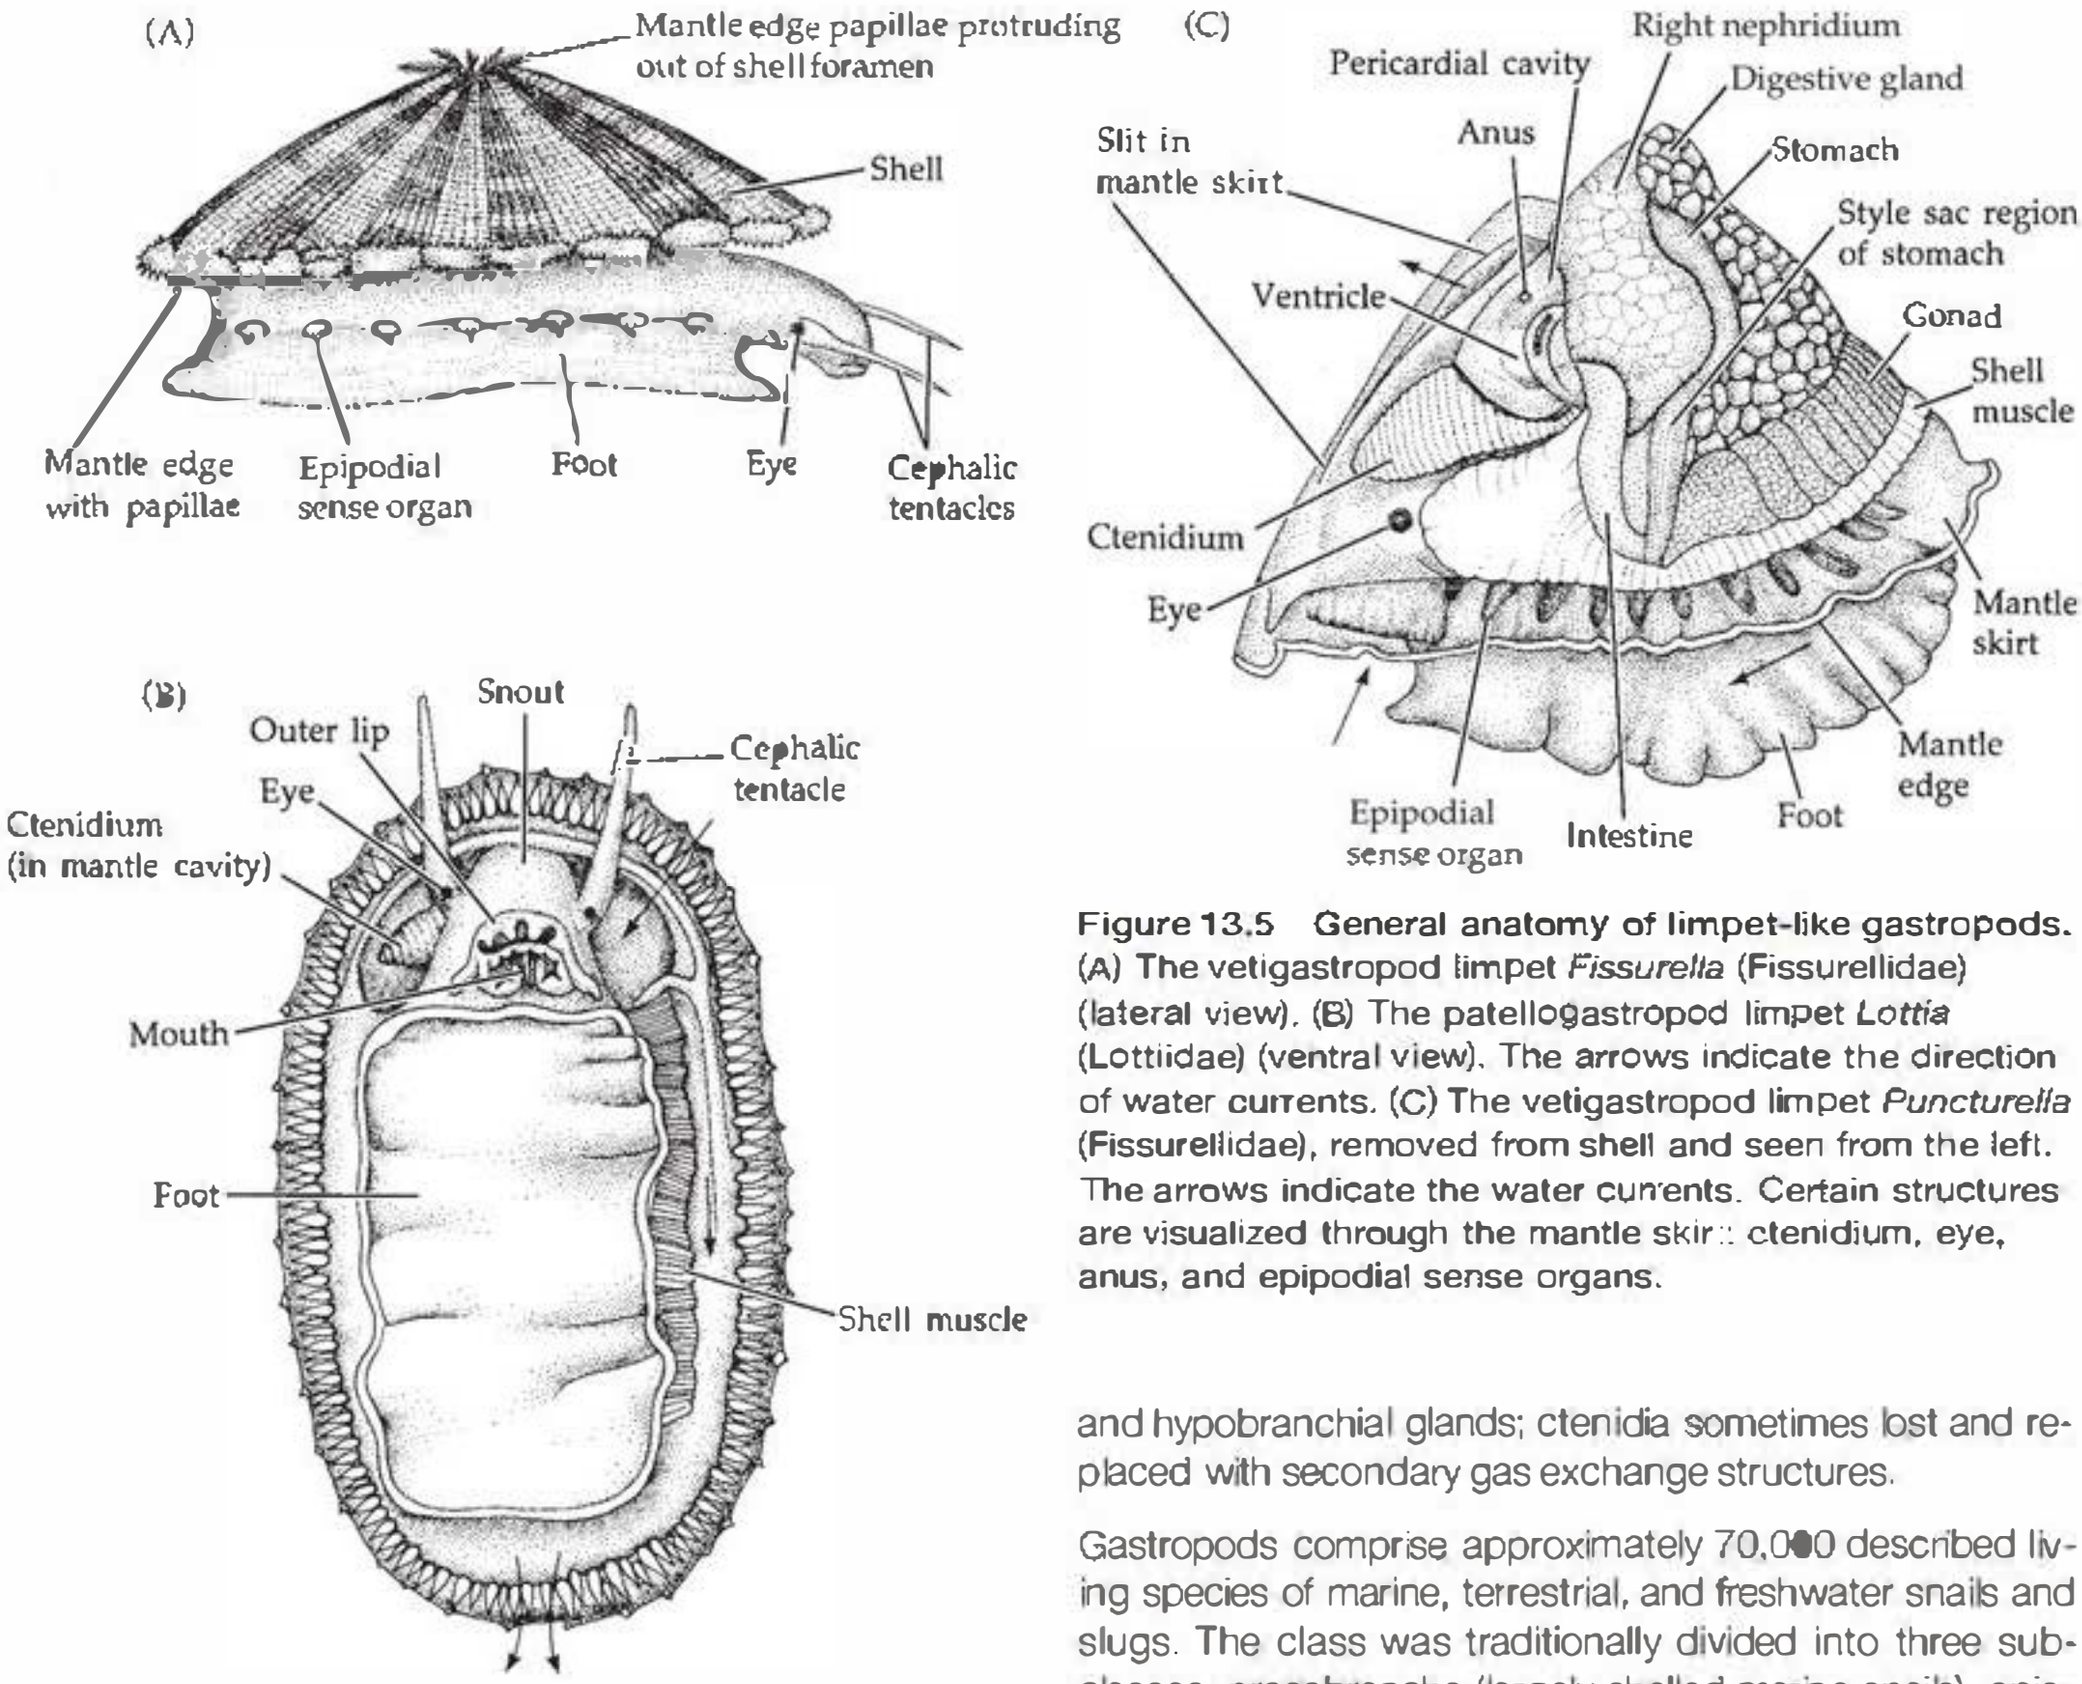

Figure 13.5 General anatomy of limpet-like gastropods. (A) The vetigastropod limpet *Fissurella* (Fissurellidae) (lateral view). (B) The patellogastropod limpet *Lottia* (Lottiidae) (ventral view). The arrows indicate the direction of water currents. (C) The vetigastropod limpet *Puncturella* (Fissurellidae), removed from shell and seen from the left. The arrows indicate the water currents. Certain structures are visualized through the mantle skirt: ctenidium, eye, anus, and epipodial sense organs.

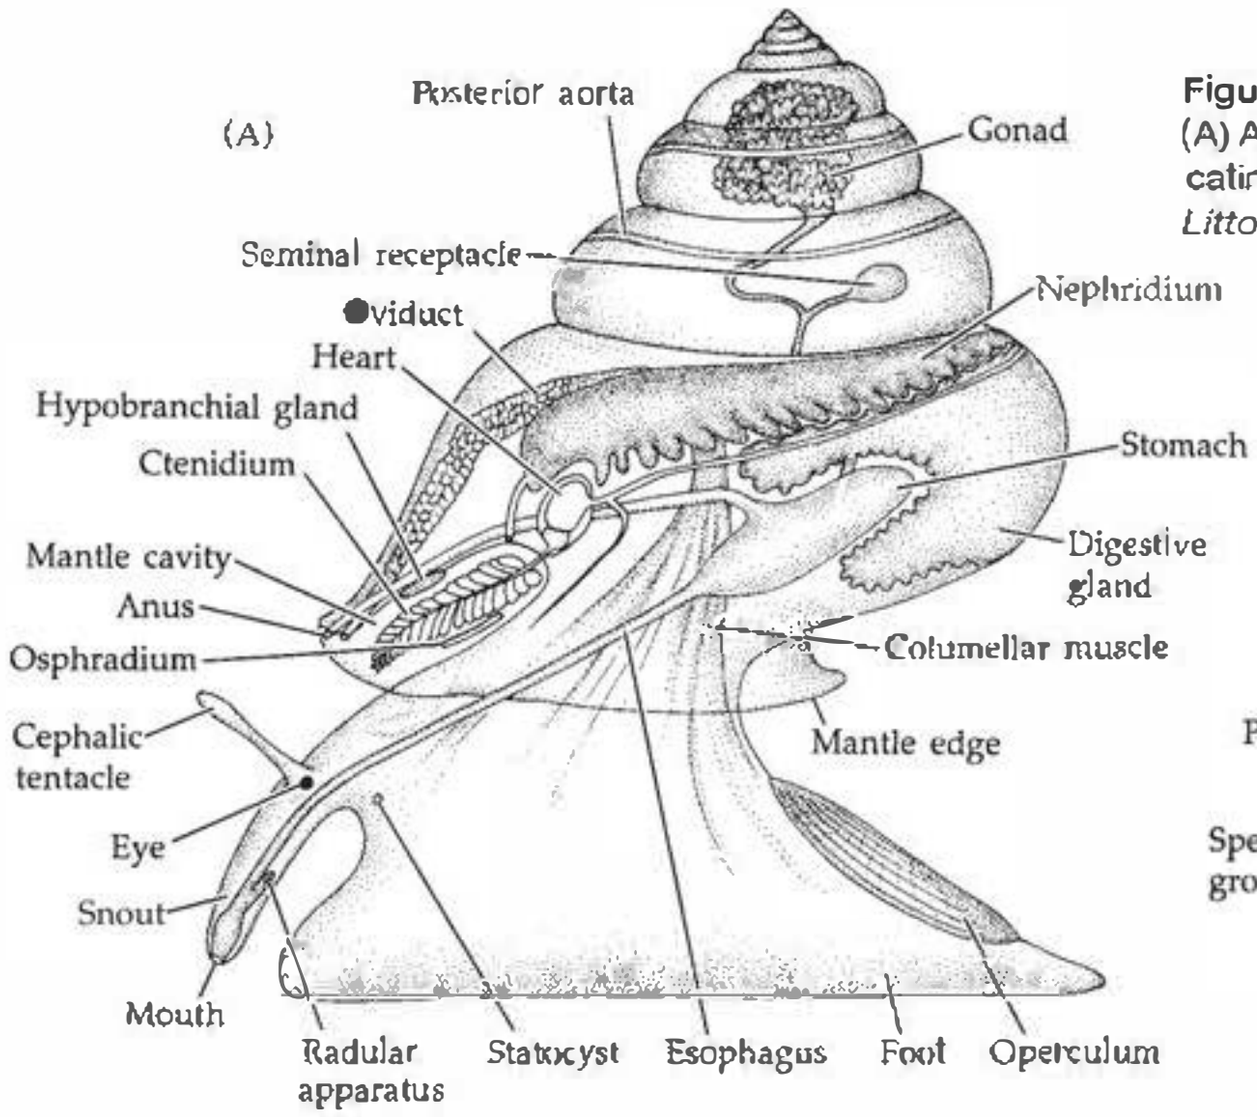

Katharina, Lepidozona, Mopalia, Nuttallina, Placiphorella, Schizoplax, Tonicella)

SUBORDER ACANTHOCHITONIDA Outer edge of shell plates with well-developed attachment teeth; shell valves partially or completely covered by girdle; ctenidia do not extend full length of foot. (e.g., *Acanthochitona, Cryptochiton, Cryptoplax*)

CLASS GASTROPODA Snails, limpets and slugs (Figures 13.1D–G, 13.5, 13.6, and 13.7). Asymmetrical molluscs with single, usually spirally coiled shell into which body can be withdrawn; shell lost or reduced in many groups; during development, visceral mass and mantle rotate 90–180° on foot (a process known as torsion), so mantle cavity lies anteriorly or on right side (rather than posteriorly as in other molluscs), and gut and nervous system are twisted; some taxa have partly or totally reversed the rotation (detorsion); with muscular creeping foot (modified in swimming and burrowing taxa); foot with operculum in larva and often in adult; head with eyes (often reduced or lost), and 1–2 pairs of tentacles, and a snout; most with radula and some with crystalline style, the latter being absent in most primitive and in many advanced groups; 1–2 nephridia; mantle (= pallium) usually forms anterior cavity housing ctenidia, osphradia, and hypobranchial glands; ctenidia sometimes lost and replaced with secondary gas exchange structures.

Gastropods comprise approximately 70,000 described living species of marine, terrestrial, and freshwater snails and slugs. The class was traditionally divided into three subclasses: prosobranchs (largely shelled marine snails), opisthobranchs (marine slugs), and pulmonates (terrestrial snails and slugs). However, recent anatomical and molecular studies have shown that classification to be incorrect, as reflected in the classification below.

SUBCLASS PATELLOGASTROPODA Cap-shaped (limpets) with porcelaneous, nonnacreous shell; operculum absent in adult; cephalic tentacles with eyes at outer bases; radula docoglossate, with iron impregnated teeth, rest of gut with large esophageal glands and simple stomach lacking a crystalline styte; intestine long and looped; gill configuration variable, single bipectinate ctenidium sometimes present (Figure 13.5B), and/or with mantle groove secondary gills, or gills lacking; shell muscle divided into discrete bundles; mantle cavity without siphon or hypobranchial glands; 2 rudimentary osphradia; single atria; 2 nephridia; usually gonochoristic; nervous system weakly concentrated, pleural ganglia near pedal ganglia, pedal and lateral cords present. Primarily marine with a few estuarine species; herbivorous. The patellogastropods include 6 families: Patellidae (e.g., *Patella, Scutellastra*), Nacellidae (e.g., *Cellana*), Lottiidae (e.g., *Lottia*), Acmaeidae (e.g., *Acmaea*), Lepetidae (e.g., *Lepeta*), and Neolepetopsidae (e.g., *Neolepetopsis*). These are often regarded as the "true" limpets.

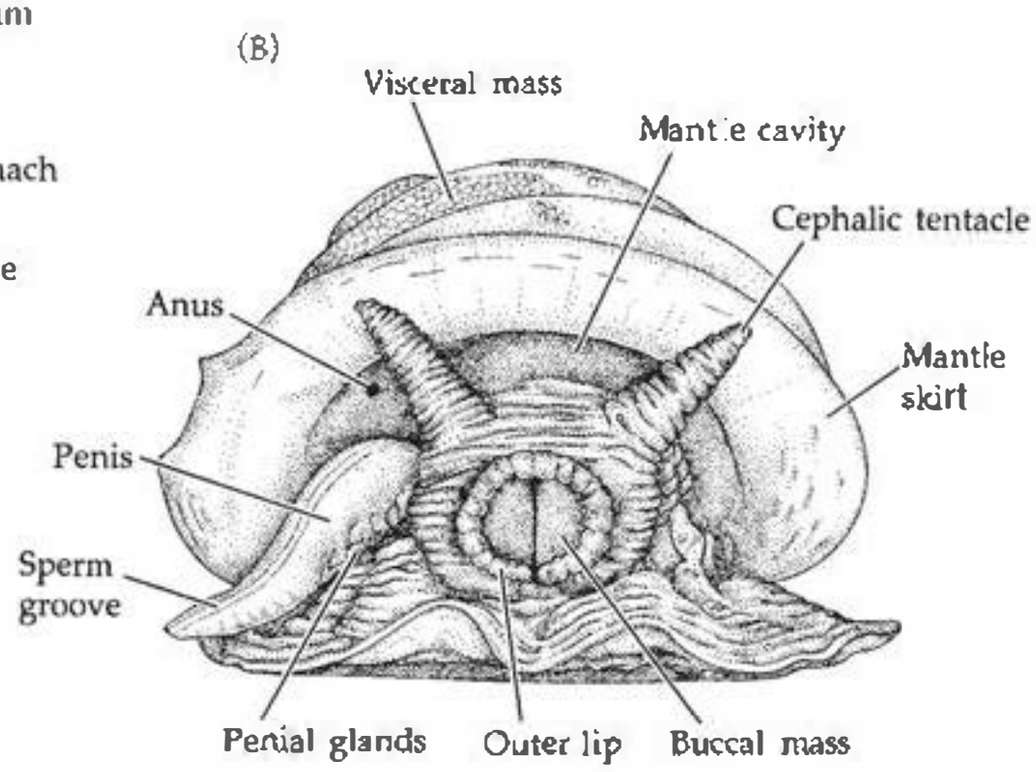

Figure 13.6 General anatomy of coiled gastropods. (A) A generalized coiled-shell gastropod (female), indicating positions of internal organs. (B) The periwinkle, *Littorina*, removed from its shell (anterior view).

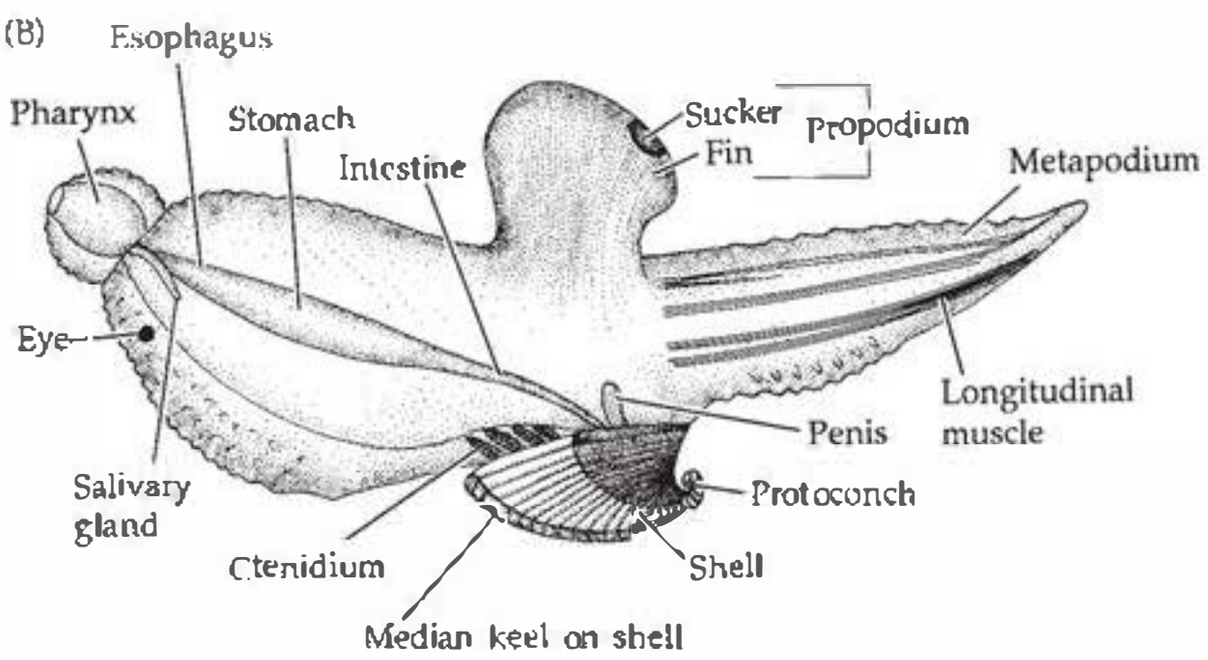
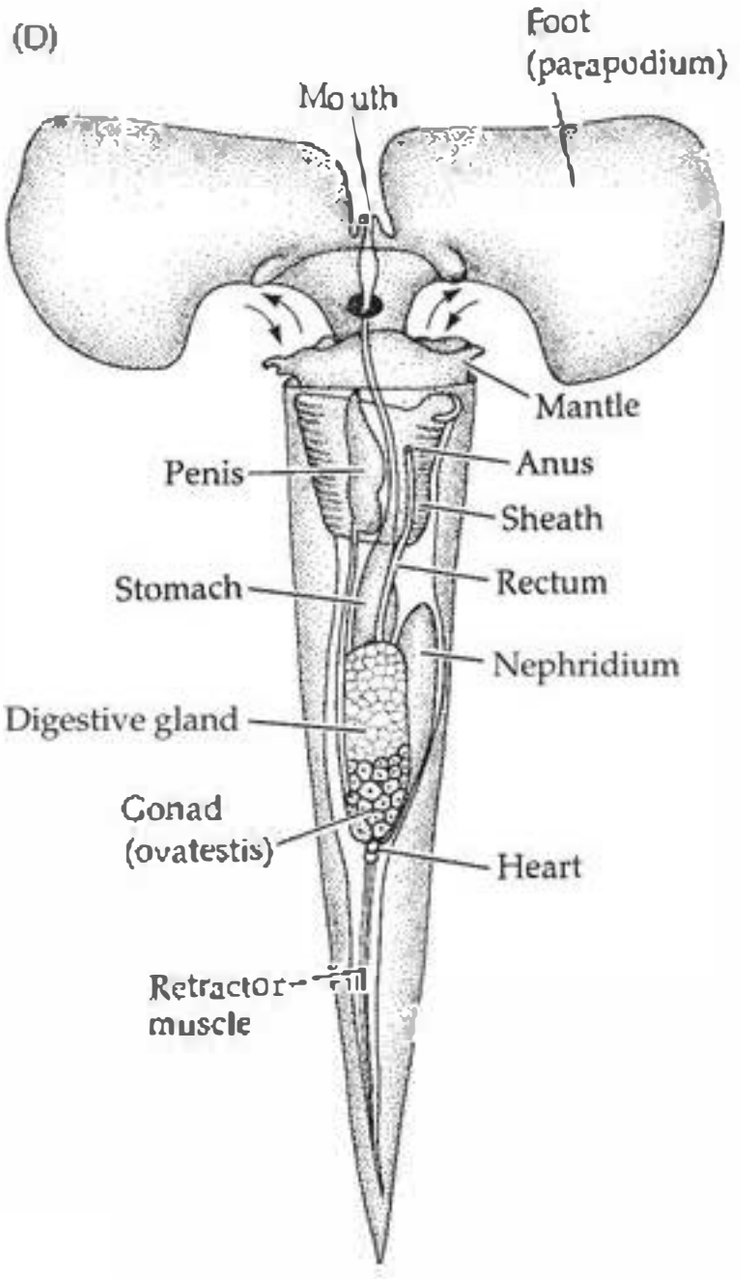
SUBCLASS VETIGASTROPODA Shells both porcelaneous and nacreous; cephalic tentacles usually with eyes on short processes on outer bases; operculum usually circular, with a central nucleus and often many spirals, horny or calcareous; radula usually rhipidoglossate (with numerous transverse rows of teeth), rest of gut with esophagus having large glands, complex stomach with style sac but no crystalline style, looped intestine; 1–2 bipectinate ctenidia; shell muscles paired or single; mantle cavity with 2 hypobranchial glands, 2 atria, and 2 nephridia; usually gonochoristic; male generally without penis; nervous system weakly concentrated, ganglia poorly formed, pedal cords present; 1–2 osphradia, small, inconspicuous. All marine and benthic. Many species are microdetritivores or feed on films of bacteria or other organisms, or are microherbivores; some are macroherbivores, some grazing carnivores, and a few suspension feeders. Most gastropods found at hydrothermal vents, cold seeps, and on deep sea hard substrates are vetigastropods. Vetigastropods comprise about 30 families and while the internal classification remains unsettled, three main groups are often recognized, which we treat here as orders.

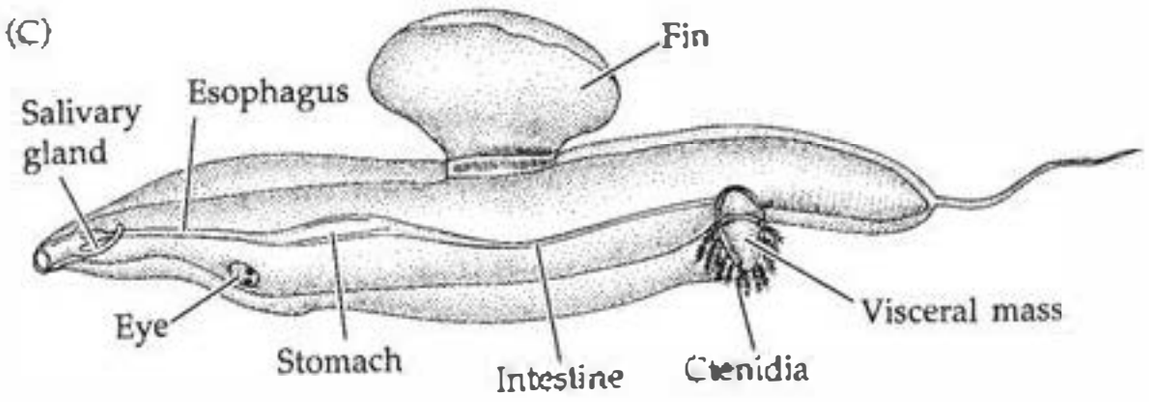
ORDER TROCHIDA Most of the vetigastropods, including the slit-shelled snails Pleurotomaridae (e.g., *Perotrochus*, *Pleurotomaria*), Scissurellidae (e.g., *Scissurella*) and Anatomidae (e.g., *Anatoma*), the abalones Haliotidae (e.g., *Haliotis*), the keyhole and slit limpets Fissurellidae (e.g., *Diodora*, *Fissurella*, *Lucapinella*, *Puncturella*), deep sea limpets comprising the Lepetellidae and related families (e.g., *Lepetella*, *Pseudococculina*), trochids Trochidae (e.g., *Trochus*, *Monodonta*) and related families such as Calliostomatidae (e.g., *Calliostoma*), Margaritidae (e.g., *Margarites*), Tegulidae (e.g., *Tegula*), and turbans Turbinidae (e.g., *Turbo*, *Astrea*).



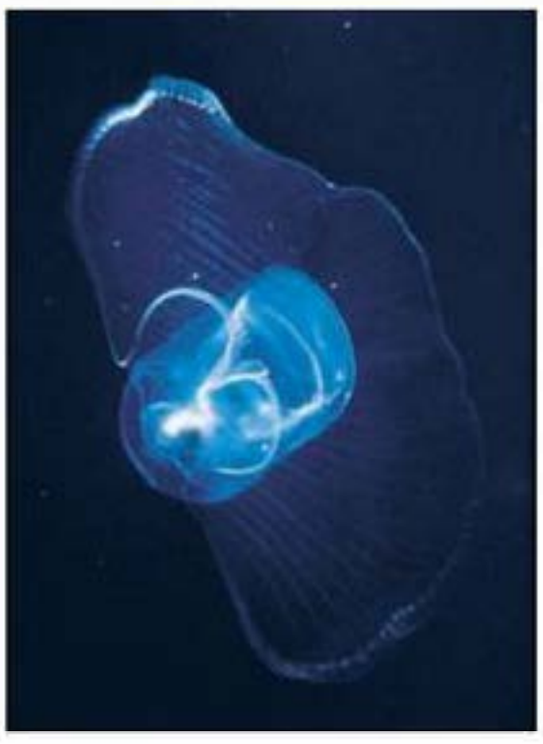
ORDER NEOMPHALIDA Comprises many of the hot vent snails and limpets Neomphalidae (e.g., *Neomphalus*), Peltospiridae (e.g., *Peltaspira*), Lepetodrilidae (e.g., *Lepetodrilus*).



ORDER COCCULINIDA (= COCCULINIFORMES IN PART) The small, deep-sea wood and bone limpets Cocculinidae (e.g., *Cocculina*).



SUBCLASS NERITIMORPHA Shell coiled, limpet-like, or lost (Titiscaniidae). Shell porcelaneous, with interior whorls reabsorbed in many coiled groups; operculum typically present, of few spirals and with non-central nucleus, horny or calcified, usually with internal peg; shell muscle divided into discrete bundles; only left ctenidium present; hypobranchial glands often lost on left side; stomach highly modified; right nephridium incorporated into complex reproductive system with multiple openings into mantle cavity; radula rhipidoglossate; most species gonochoristic, with copulatory structures; nervous system with ganglia concentrated, pleural ganglia near pedal ganglia, pedal cords present. Globally distributed in marine, estuarine, freshwater, and terrestrial habitats. There are 9 families of neritimorphans, four of which, Helicinidae (e.g., *Alcadia*, *Helicina*), Hydrocenidae (*Hydrocena*, *Georissa*), Proserpinellidae (e.g., *Proserpinella*), and Proserpinidae (*Proserpina*) are exclusively terrestrial; also Neritopsidae (neritopsids, *Neritopsis*), Titiscaniidae (titiscaniid, *Titiscania*), Neritidae (nerites, e.g., *Nerita*, *Theodoxus*), Neritiliidae (cave nerites, e.g., *Pisulina*, *Neritilia*) and Phenacolepadidae (*Phenacolepas*).



SUBCLASS CAENOGASTROPODA Shell mainly porcelaneous; operculum usually present and corneous, rarely calcified, with few spirals and usually with a non-central nucleus, mostly non-nacreous, rarely with internal peg(s); head with pair of cephalic tentacles, with eyes at outer bases; mantle cavity asymmetrical, with incurrent
