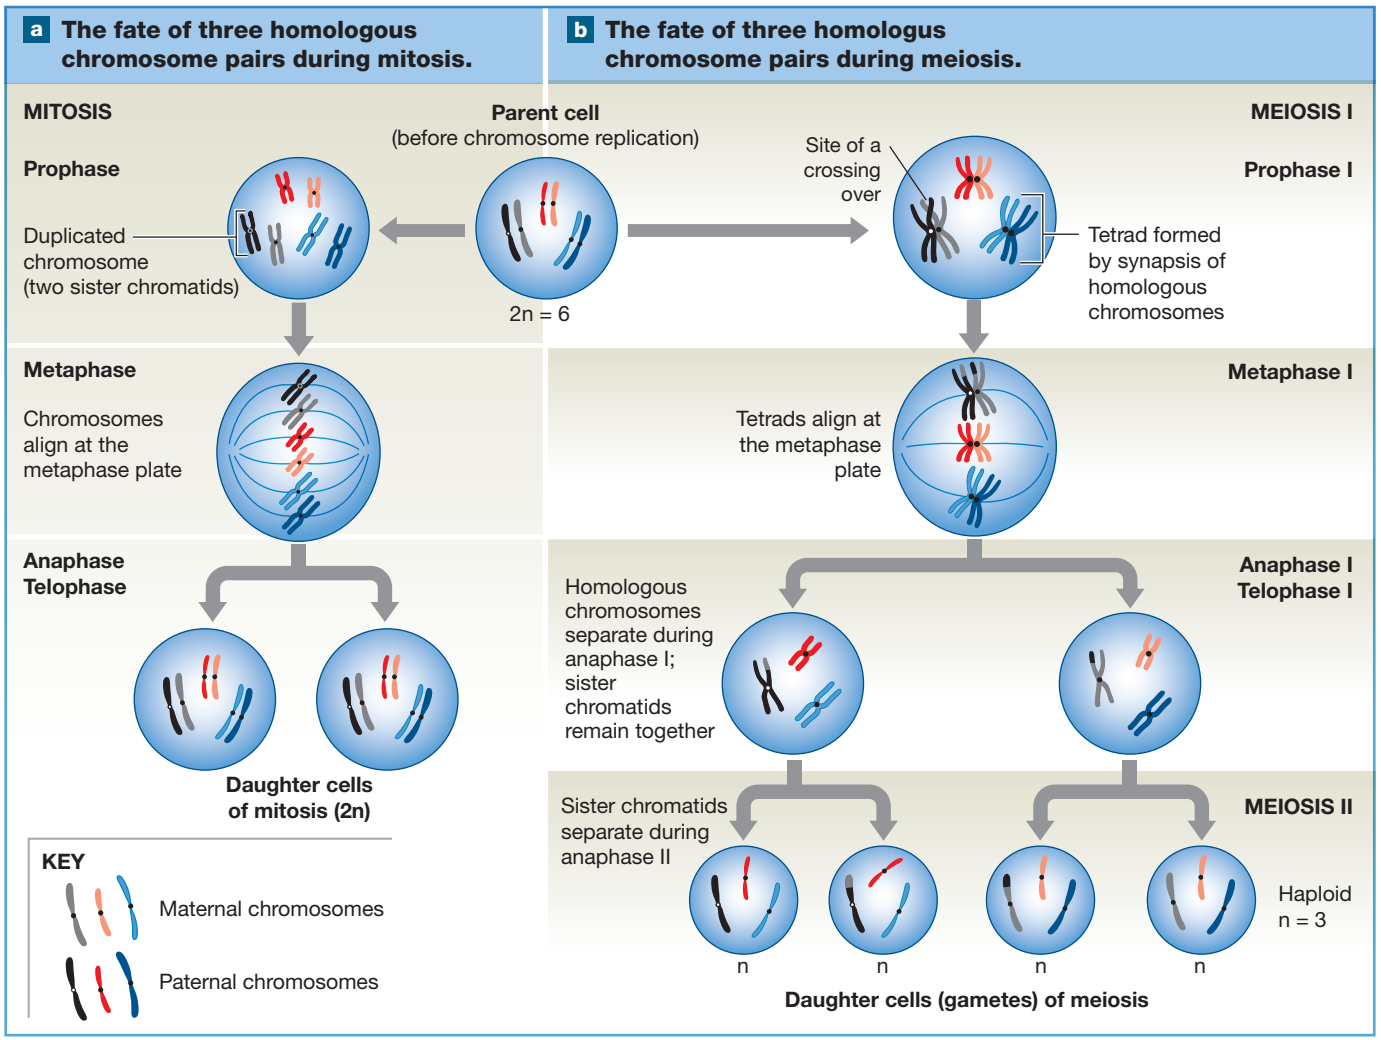
Learning Outcome Explain the differences between meiosis and mitosis, describe the process of spermatogenesis, and summarize the hormonal mechanisms that regulate male reproductive functions.

Overview of Mitosis and Meiosis

Mitosis, the production of genetically identical cells, and *meiosis*, the production of gametes, differ significantly in terms of the events that take place in the nucleus. Recall from Chapter 3 that human somatic cells contain 23 pairs of chromosomes, or 46 chromosomes altogether. Each pair consists of one chromosome provided by the father, and another provided by the mother, at the time of fertilization. The two members of each of the 22 pairs have similar sizes and genes and are known as **homologous** (huh-MOL-ō-gus) **chromosomes**.



Mitosis is part of the process of somatic cell division, producing two daughter cells each containing identical numbers and pairs of chromosomes. The pattern is illustrated in Figure 28–8a. Because daughter cells contain both members of each chromosome pair, they are called **diploid** (DIP-loyd; *diplo*, double) (2n = 46) cells. (You can review the description of mitosis and cell division in Chapter 3. ↩ pp. 150–151)

Meiosis is a specialized form of cell division that produces only gametes. In contrast to mitosis, meiosis follows the pattern in Figure 28–8b. It involves two cycles of cell division (*meiosis I* and *meiosis II*) and produces four cells, each containing 23 *individual* chromosomes. These cells are called **haploid** (HAP-loyd; *haplo*, single) (n = 23) cells and contain only one member of each homologous pair of chromosomes. Because gametes contain half the number of chromosomes found in somatic cells, the fusion of the nuclei of a male gamete and a female gamete produces a cell that has the normal number of chromosomes, rather than twice that number. The events in the nucleus shown in Figure 28–8b are the same for the formation of sperm in males or oocytes in females.

As a cell prepares to begin meiosis, DNA replication occurs within the nucleus just as it does in a cell preparing for mitosis. The duplicated chromosomes condense and become visible with a light microscope. As in mitosis, each chromosome now consists of two duplicate *chromatids* (KRŌ-mah-tidz).

At this point, the close similarities between meiosis and mitosis end. In meiosis, the corresponding maternal (inherited from the mother) and paternal (inherited from the father) chromosomes now come together in an event known as **synapsis** (sih-NAP-sis). Synapsis involves 23 pairs of chromosomes, and each member of each pair consists of two chromatids.

Figure 28–8 A Comparison of Chromosomes in Mitosis and Meiosis.

A matched set of four chromatids is called a **tetrad** (TET-rad; *tetras*, four) (Figure 28–8b). Some genetic material can be exchanged between the maternal and paternal chromatids of a chromosome pair at this stage of meiosis. Such an exchange, called *crossing over*, increases genetic variation among offspring. We discuss genetics in Chapter 29.

Meiosis includes two division cycles, referred to as **meiosis I** and **meiosis II**. We identify the stages within each cycle with I or II, for example as prophase I or metaphase II.

Meiosis I

Meiosis I begins with prophase I; the nuclear envelope disappears at the end of prophase I. As metaphase I begins, the tetrads line up along the metaphase plate. As anaphase I begins, the tetrads break up—the maternal and paternal chromosomes separate. This is a major difference between mitosis and meiosis: In mitosis, each daughter cell receives a copy of every chromosome, maternal and paternal, but in meiosis I, each daughter cell receives two copies of *either* the maternal chromosome *or* the paternal chromosome. (Compare the two parts of Figure 28–8.)

As anaphase I proceeds, the maternal and paternal components are randomly and independently distributed. That is, as each tetrad splits, we cannot predict which daughter cell will receive copies of the maternal chromosome, and which will receive copies of the paternal chromosome. As a result, telophase I ends with the formation of two daughter cells containing unique combinations of maternal and paternal chromosomes. Both cells contain 23 chromosomes.

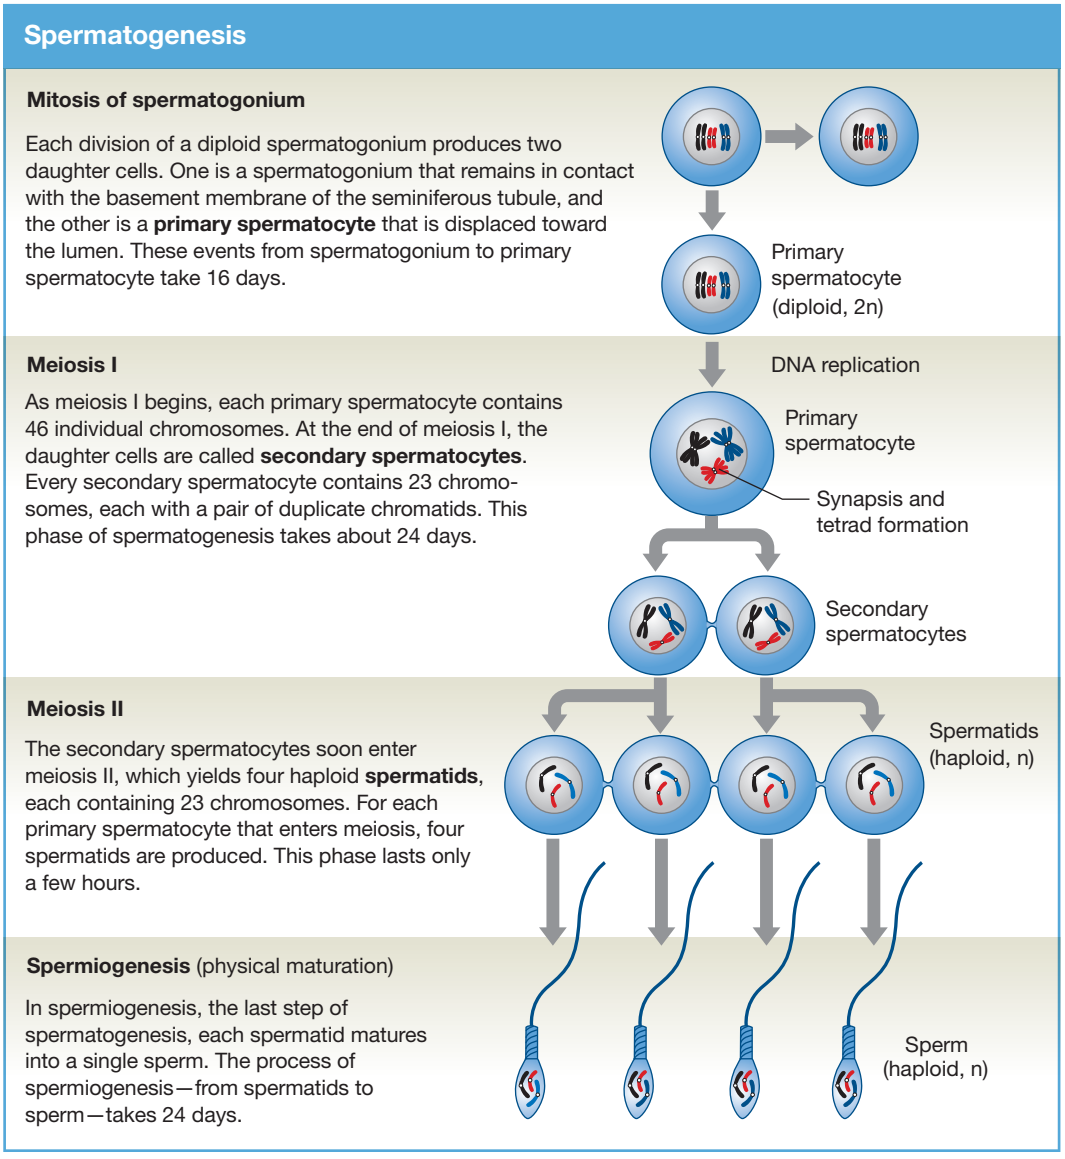
The first meiotic division is called a **reductional division** because it reduces the number of chromosomes from the diploid number ($2n = 46$) to the haploid number ($n = 23$). Each of these chromosomes still consists of two chromatids. The two chromatids will separate during meiosis II.

Meiosis II

The interphase between meiosis I and meiosis II is very brief. No DNA is replicated during that period. Each cell then proceeds

through prophase II, metaphase II, and anaphase II. During anaphase II, the chromatids separate. Telophase II yields four haploid cells, each containing 23 chromosomes. Because the number of chromosomes is unchanged, meiosis II is an **equational division**.

The chromosomes are evenly distributed among the four cells, but the cytoplasm may not be. In males, in the process of *spermatogenesis*, meiosis produces four immature gametes that are identical in size. Each will develop into a functional sperm. In females, meiosis produces one relatively huge oocyte and three tiny, nonfunctional polar bodies. (If fertilization takes place, the oocyte completes meiosis II, yielding an ovum.) We examine the details of spermatogenesis next. We will consider the production of female oocytes, *oogenesis*, in Section 28-5.



Spermatogenesis

As we have indicated, **spermatogenesis** (sper-ma-tō-JEN-eh-sis) is the process of sperm formation (Figure 28–9). Spermatogenesis begins at *puberty* (sexual maturation) and continues until relatively late in life (past age 70).

The complete process of spermatogenesis takes about 64 days. It involves three steps:

1. *Mitosis.* **Spermatogonia** (sper-ma-tō-GŌ-nē-uh) are stem cells in the seminiferous tubules that undergo cell divisions throughout adult life. Some of these cells differentiate into **primary spermatocytes** (sper-MA-tō-sīts), which prepare to begin meiosis.

Figure 28–9 The Process of Spermatogenesis. The fates of three representative chromosome pairs are shown; for clarity, maternal and paternal chromatids are not identified.

? What is the name of the cell at each stage of sperm development, from mitosis to spermiogenesis?

2. *Meiosis.* Primary spermatocytes then undergo meiotic divisions that produce **spermatids** (SPER-ma-tidz), undifferentiated male gametes.
3. *Spermiogenesis.* In *spermiogenesis*, spermatids differentiate into physically mature **sperm**.

Spermatogenesis is a continuous process, so all stages of meiosis are seen within the seminiferous tubules. Each seminiferous tubule contains spermatogonia, spermatocytes at various stages of meiosis, spermatids, and sperm. They also contain large *nurse cells*, which provide a microenvironment that supports spermatogenesis. The sperm eventually lose contact with the nurse cells of the seminiferous tubule and enter the fluid in the lumen.

Mitosis and Meiosis during Spermatogenesis

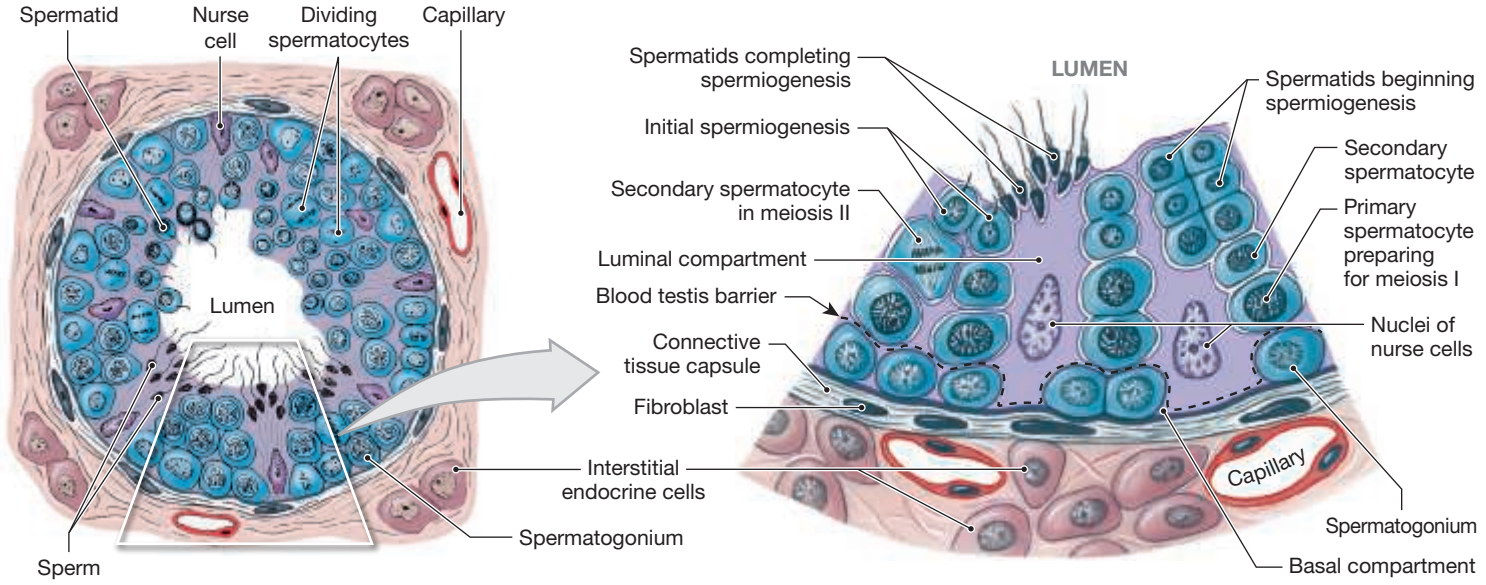
Spermatogenesis begins at the outermost layer of cells in the seminiferous tubules and proceeds toward the lumen (Figure 28–10a,b). At each step in this process, the daughter cells move closer to the lumen.

First, spermatogonia divide by mitosis to produce two daughter cells. One daughter cell from each division remains at that location as a spermatogonium, while the other is pushed toward the lumen (space) of the tubule. The displaced cell differentiates into a primary spermatocyte. Primary spermatocytes then begin meiosis, giving rise to *secondary spermatocytes* that divide and differentiate into immature spermatids.

Spermiogenesis

The four spermatids initially remain interconnected by bridges of cytoplasm because *cytokinesis* (cytoplasmic division) is not completed in meiosis I or meiosis II. These connections assist in transferring nutrients and hormones between the cells, helping ensure that the cells develop together. The bridges are not broken until the last stages of physical maturation.

In **spermiogenesis**, the last step of spermatogenesis, the spermatids gradually develop into mature sperm (Figures 28–9, 28–11). At *spermiation*, a sperm loses its attachment to the nurse cell and enters the lumen of the seminiferous tubule.



The Role of Nurse Cells

Developing spermatocytes undergoing meiosis, and spermatids undergoing spermiogenesis, are not free in the seminiferous tubules. Instead, they are surrounded by the cytoplasm of adjacent *nurse cells*. **Nurse cells**, which are also known as *Sertoli cells*, play a critical supportive role in spermatogenesis.

These cells have six important functions that directly or indirectly affect mitosis, meiosis, and spermiogenesis within the seminiferous tubules:

- *Maintenance of the Blood Testis Barrier.* A **blood testis barrier** isolates the seminiferous tubules from the general circulation. This barrier is comparable in function to the blood brain barrier. p. 519 Nurse cells are joined by tight junctions between basal cytoplasmic processes. They form a layer that divides the seminiferous tubule into an outer basal compartment and an inner luminal compartment. The *basal compartment* contains the spermatogonia. Meiosis and spermiogenesis occur in the *luminal compartment* (see Figure 28–10a,b). Transport across the nurse cells is tightly

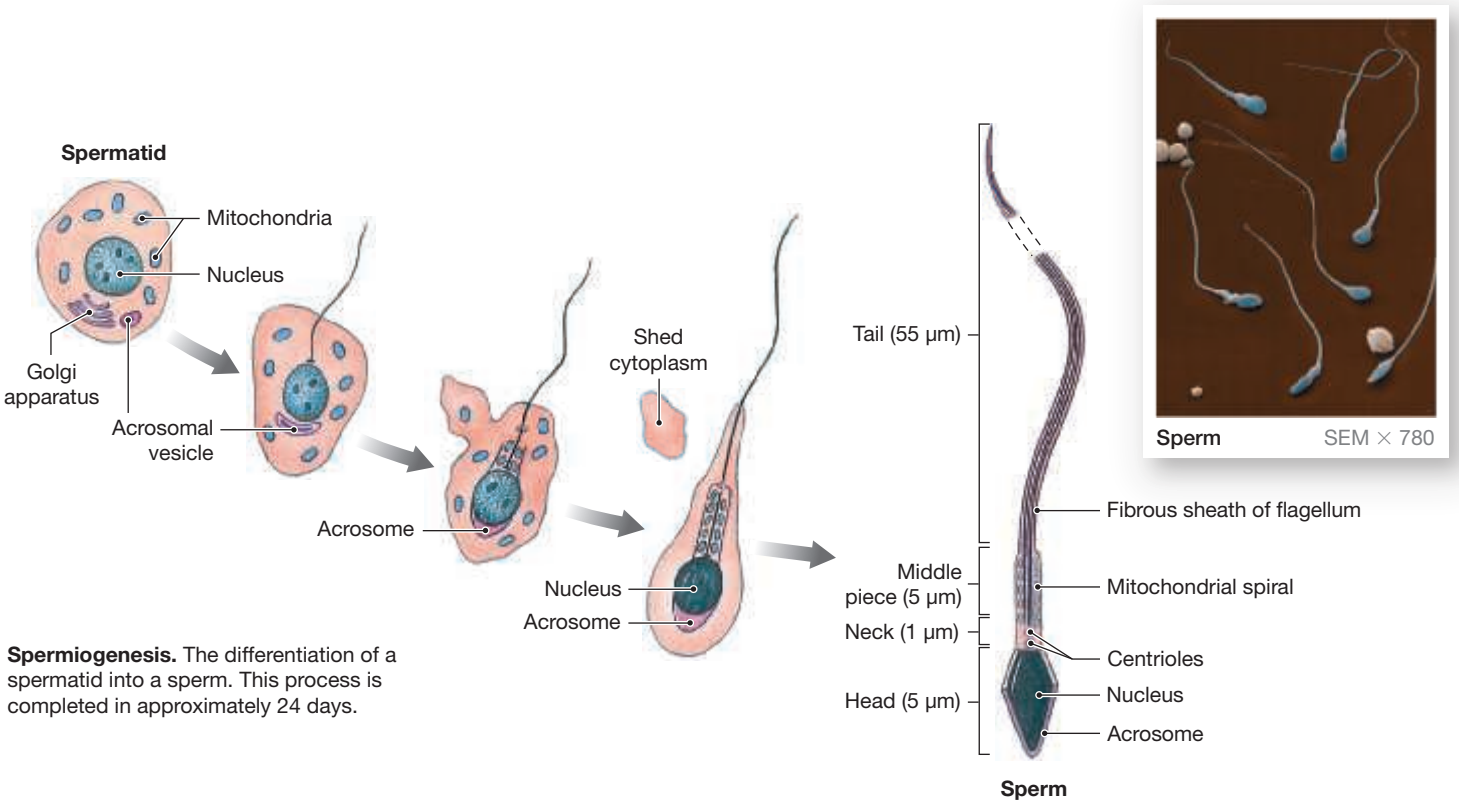


Figure 28–10 Spermatogenesis in a Seminiferous Tubule.

a Nurse cells surround the stem cells of the tubule and support the developing spermatocytes and spermatids.

b Stages in spermatogenesis in the wall of a seminiferous tubule.

Figure 28–11 The Process of Spermiogenesis and Anatomy of a Sperm. ATLAS: Plate 60a

Spermiogenesis. The differentiation of a spermatid into a sperm. This process is completed in approximately 24 days.

? In which of the four parts of a sperm are the centrioles found?

regulated, so conditions in the luminal compartment remain very stable.

- The nurse cells produce the fluid in the lumen of a seminiferous tubule. They also regulate the fluid's composition. This luminal fluid is very different from the surrounding interstitial fluid. It is high in androgens, estrogens, potassium ions, and amino acids. The blood testis barrier is essential to preserving the differences between the luminal fluid and the interstitial fluid.
- In addition, this barrier prevents immune system cells from detecting and attacking the developing sperm. The plasma membranes of sperm contain sperm-specific antigens not found in somatic cell membranes, so they might be identified as "foreign."

- *Support of Mitosis and Meiosis.* Circulating follicle-stimulating hormone (FSH) and testosterone stimulate nurse cells. These stimulated nurse cells then promote the division of spermatogonia and the meiotic divisions of spermatocytes.
- *Support of Spermiogenesis.* Spermiogenesis requires nurse cells. These cells surround and enfold the spermatids, providing nutrients and chemical stimuli that promote their development. Nurse cells also phagocytize cytoplasm that is shed by spermatids as they develop into sperm.
- *Secretion of Inhibin.* Nurse cells secrete the peptide hormone *inhibin* (in-HIB-in) in response to factors released by developing sperm. Inhibin depresses the pituitary production of FSH, and perhaps the hypothalamic secretion of gonadotropin-releasing hormone (GnRH). The faster the rate of sperm production, the more inhibin is secreted. By regulating FSH and GnRH secretion, nurse cells provide negative feedback control of spermatogenesis.
- *Secretion of Androgen-Binding Protein. Androgen-binding protein* (ABP) binds androgens (primarily testosterone) in the luminal fluid of the seminiferous tubules. This protein is likely important for increasing androgen concentration and stimulating spermiogenesis. FSH stimulates the production of ABP.

Maturation of Sperm

The sperm that lie within the lumen of the seminiferous tubule have most of the physical characteristics of mature sperm, but are functionally immature and incapable of coordinated movement or fertilization. It takes up to 2 weeks for a sperm to pass through the epididymis and complete its functional maturation. During this time, sperm exist in a sheltered environment that is precisely regulated by the surrounding epithelial cells.

Sperm leaving the epididymis are mature but immobile. To become *motile* (actively swimming) and fully functional, they must undergo a process called **capacitation**. When mixed with the secretions of the seminal glands, sperm undergo the first step in capacitation and begin beating their flagella,. Capacitation normally takes place in two steps: (1) Sperm become motile when they are mixed with secretions of the seminal glands, and (2) they become capable of successful fertilization when exposed to conditions in the female reproductive tract. The epididymis secretes a substance (as yet unidentified) that prevents premature capacitation.

The Anatomy of a Sperm

Sperm are among the most highly specialized cells in the body. Each sperm has four distinct regions: head, neck, middle piece, and tail (Figure 28–11). The **head** is a flattened ellipse containing a nucleus with densely packed chromosomes. At the tip of the head is the **acrosome** (AK-rō-sōm), a membranous compartment containing enzymes essential to fertilization. During spermiogenesis, saccules of the spermatid's Golgi apparatus fuse and flatten into an *acrosomal vesicle*, which ultimately forms the acrosome.

A short **neck** attaches the head to the **middle piece.** The neck contains both centrioles of the original spermatid. The microtubules of the distal centriole are continuous with those of the middle piece and tail. Mitochondria in the middle piece are arranged in a spiral around the microtubules. Mitochondria provide the ATP required to move the tail.

The **tail** is the only flagellum in the human body. A *flagellum* is a whiplike organelle that moves a cell from one place to another. Cilia beat in a predictable, wavelike fashion, but the tail of a sperm has a whip-like, corkscrew motion.

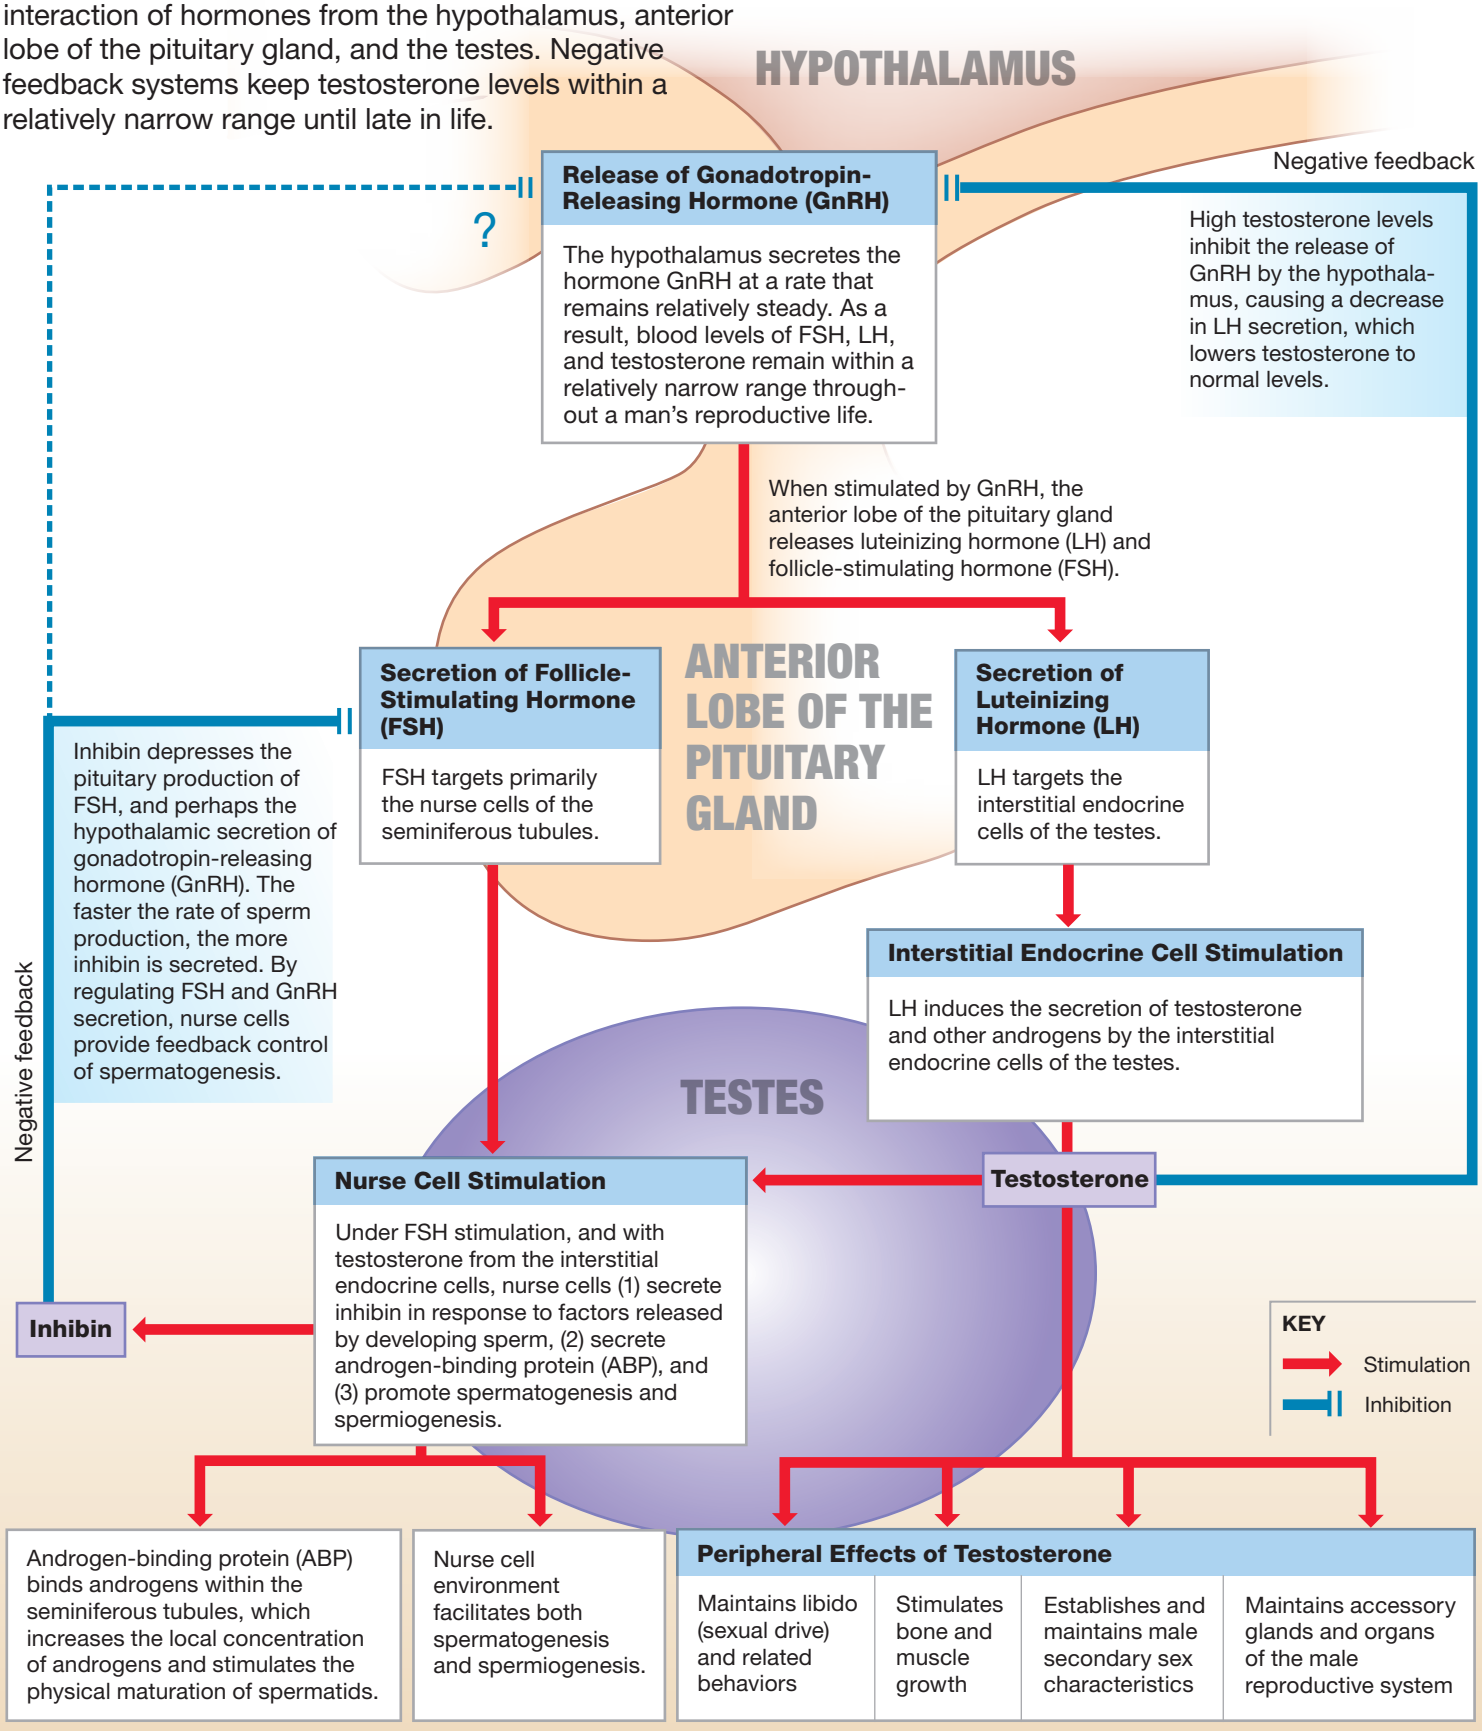
Unlike other, less specialized cells, a mature sperm lacks an endoplasmic reticulum, a Golgi apparatus, lysosomes, peroxisomes, inclusions, and many other organelles. The loss of these organelles reduces the cell's size and mass. A sperm is essentially a mobile carrier for chromosomes, and extra weight would slow it down. Because a sperm lacks glycogen or other energy reserves, it must absorb nutrients (primarily fructose) from the surrounding fluid.

Hormonal Regulation of Male Reproductive Function

The hormonal interactions that regulate male reproductive function are diagrammed in Spotlight Figure 28–12. We introduced major reproductive hormones in Chapter 18. p. 690 The anterior lobe of the pituitary gland releases *follicle-stimulating hormone* (FSH) and *luteinizing hormone* (LH). The pituitary releases these hormones in response to *gonadotropin-releasing hormone* (GnRH). This peptide is synthesized in the hypothalamus and carried to the anterior lobe by the hypophyseal portal system.

The hormone GnRH is secreted in pulses rather than continuously. In adult males, small pulses occur at 60- to 90-minute intervals. As levels of GnRH change, so do the rates of secretion of FSH and LH (and testosterone, which is released in response to LH). The GnRH pulse frequency in adult males remains relatively steady from hour to hour, day to day, and year to year, unlike the situation in women, as we will see later in the chapter. As a result, plasma levels of FSH, LH, and testosterone remain within a relatively narrow range until relatively late in a man's life.

Testosterone plays a major role in maintaining male sexual function (see Spotlight Figure 28–12). Testosterone functions like other steroid hormones, circulating in the bloodstream while bound to one of two types of transport proteins. These proteins are (1) *gonadal steroid-binding globulin* (GBG), which carries about two-thirds of the circulating testosterone, and (2) the albumins, which bind the remaining one-third. Testosterone diffuses across the plasma membrane of target cells and binds to an intracellular receptor. The hormone–receptor complex then binds to the DNA in the nucleus.



+ Clinical Note Dehydroepiandrosterone (DHEA)

Dehydroepiandrosterone, or **DHEA**, is the primary androgen secreted by the zona reticularis of the adrenal cortex. p. 682 As noted in Chapter 18, these androgens, which are secreted in small amounts, are converted to testosterone (or estrogens) by other tissues. The significance of this small adrenal androgen secretion in both sexes remains unclear, but DHEA is being promoted as a wonder drug for increasing vitality, strength, and muscle mass. The effects of long-term high doses of DHEA remain largely unknown. However, high levels of DHEA in women have been linked to an increased risk of ovarian cancer as well as to masculinization, due to the conversion of DHEA to testosterone. The International Olympic Committee, NCAA, MLB, and NFL have banned the use of DHEA.

SPOTLIGHT

Figure 28–12
Hormonal Regulation of Male Reproduction

Male reproductive function is regulated by the complex interaction of hormones from the hypothalamus, anterior lobe of the pituitary gland, and the testes. Negative feedback systems keep testosterone levels within a relatively narrow range until late in life.

In many target tissues, some of the arriving testosterone is converted to **dihydrotestosterone (DHT)**. A small amount of DHT diffuses back out of the cell and into the bloodstream, and DHT levels are usually about 10 percent of circulating testosterone levels. Dihydrotestosterone can also enter peripheral cells and bind to the same hormone receptors targeted by testosterone. In addition, some tissues (notably those of the external genitalia) respond to DHT rather than to testosterone. Other tissues (including the prostate) are more sensitive to DHT than to testosterone.

In adult males, negative feedback controls the level of testosterone production. Above-normal testosterone levels inhibit the release of GnRH by the hypothalamus, causing a reduction in LH secretion and lowering testosterone levels (see Spotlight Figure 28–12).

The plasma of adult males also contains relatively small amounts of the estrogenic hormone *estradiol* (2 ng/dL versus 525 ng/dL of testosterone). Seventy percent of the estradiol is formed from circulating testosterone. Interstitial endocrine cells and nurse cells of the testes secrete the rest. An enzyme called aromatase converts testosterone to estradiol. For unknown reasons, estradiol production increases in older men.

Checkpoint

7. **What effect would a low FSH level have on sperm production?**

See the blue Answers tab at the back of the book.

Clinical Note Enlarged Prostate

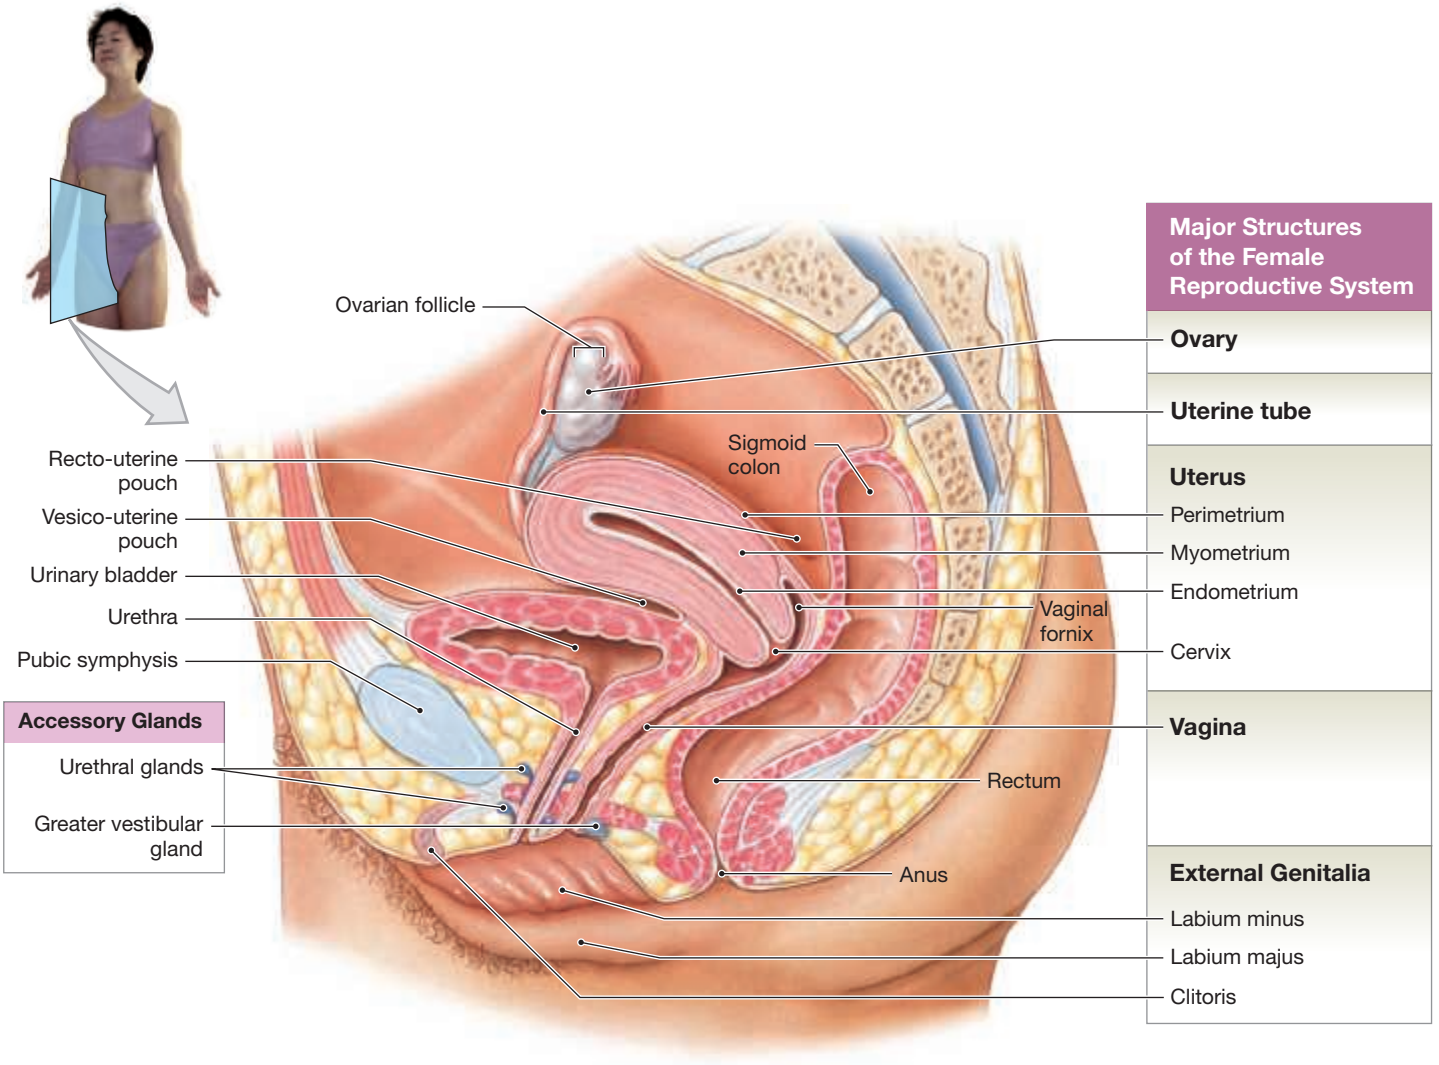
Enlargement of the prostate, or **benign prostatic hyperplasia**, is so common in men over the age of 50 that it is considered an aspect of aging. The increase in size happens as testosterone production by the interstitial endocrine cells decreases. For unknown reasons, small masses called *prostatic concretions* may form within the glands. At the same time, the interstitial endocrine cells begin releasing small quantities of estrogens into the bloodstream. The combination of a lower testosterone level and the presence of estrogens probably stimulates prostatic growth. In severe cases, prostatic swelling constricts and blocks the urethra and constricts the rectum. If not corrected, the urinary obstruction can cause permanent kidney damage. Partial surgical removal is the most effective treatment. In the procedure known as a **TURP** (*transurethral prostatectomy*), an instrument pushed along the urethra cuts away the swollen prostatic tissue. Most of the prostate remains in place, and normal function returns.

Clinical Note Prostate Cancer

Prostate cancer is the second most common cancer and the second most lethal cancer in males. For reasons that are poorly understood, prostate cancer rates for Asian American males are relatively low compared with those of either Caucasian Americans or Black Americans. For all ages and ethnic groups, the rate of prostate cancer is rising sharply. The reason for the increase is not known. Aggressive diagnosis and treatment of localized prostate cancer in elderly patients is controversial because many of these men have nonmetastatic tumors (tumors that have not spread). In addition, even if their cancer is left untreated, these men are more likely to die of some other disease.

Clinical Note Prostate-Specific Antigen (PSA) Testing

Blood tests are used to screen for prostate cancer and to monitor the success of treatment. The most sensitive is a blood test called **prostate-specific antigen (PSA)**. An elevated level of this antigen, which is normally present in a low concentration, may indicate the presence of prostate cancer. Screening with periodic PSA tests is now being recommended for some men over age 50. If prostate cancer is detected, treatment decisions vary depending on how rapidly the PSA level is rising.



28-4 The structures of the female reproductive system consist of the ovaries, uterine tubes, uterus, vagina, and external genitalia

Learning Outcome Describe the anatomy and functions of the ovaries, the uterine tubes, the uterus, the vagina, and the structures of the female external genitalia.

A woman's reproductive system produces sex hormones and functional gametes. It must also be able to protect and support a developing embryo and nourish a newborn infant. The main organs of the female reproductive system are the *ovaries*, the *uterine tubes*, the *uterus*, the *vagina*, and the components of the external genitalia—the *clitoris* and the *labia majora* and *labia minora* (Figure 28–13). As in males, a variety of accessory glands—the *urethral glands* and the *greater vestibular glands*—release secretions into the female reproductive tract.

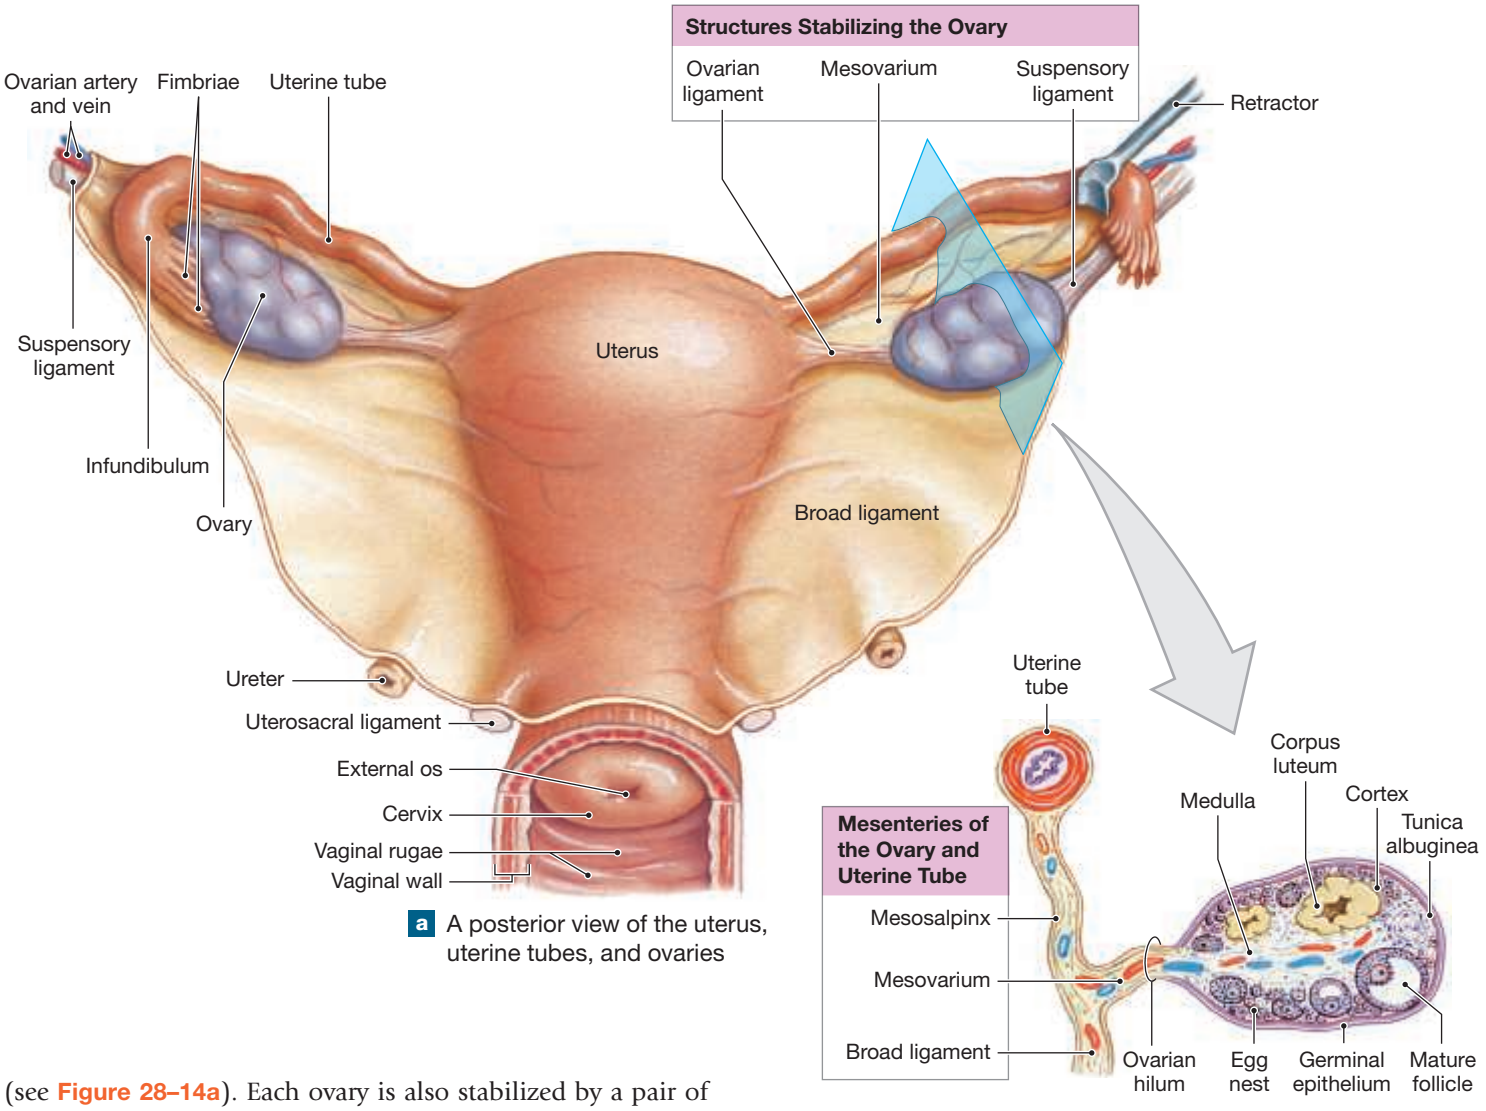
The ovaries, uterine tubes, and uterus are enclosed within an extensive mesentery known as the **broad ligament**

Figure 28–13 Sagittal Section of the Female Reproductive System. ATLAS: Plate 65

(Figure 28–14a). The uterine tubes run along the superior border of the broad ligament and open into the pelvic cavity lateral to the ovaries. The broad ligament attaches to the sides and floor of the pelvic cavity, where it becomes continuous with the parietal peritoneum. The broad ligament subdivides this part of the peritoneal cavity.

The pocket formed between the posterior wall of the uterus and the anterior surface of the colon is the **recto-uterine** (rek-tō-YŪ-ter-in) **pouch**. The pocket formed between the uterus and the posterior wall of the bladder is the **vesico-uterine** (ves-ih-kō-YŪ-ter-in) **pouch**. These subdivisions are easily seen in sagittal section (see Figure 28–13).

Several other ligaments assist the broad ligament in supporting and stabilizing the uterus and associated reproductive organs. These ligaments lie within the mesentery sheet of the broad ligament and are connected to the ovaries or uterus. The broad ligament limits side-to-side movement and rotation, and the other ligaments (described in our discussion of the ovaries and uterus) prevent superior–inferior movement.



Let's look further at the structures and basic functions of the female reproductive system.

The Ovaries

The paired ovaries are small, lumpy, almond-shaped organs near the lateral walls of the pelvic cavity (Figure 28–14b). The ovaries perform three main functions. They (1) produce immature female gametes, or oocytes; (2) secrete female sex hormones, including *estrogens* and *progesterone*; and (3) secrete inhibin, involved in the feedback control of pituitary FSH production.

The **mesovarium** (mez-ō-VĀ-rē-um), a thickened fold of mesentery, supports and stabilizes the position of each ovary

Figure 28–14 Relationships between the Ovaries, Uterine Tubes, and Uterus. ATLAS: Plate 67

(see Figure 28–14a). Each ovary is also stabilized by a pair of supporting ligaments: the ovarian ligament and the suspensory (*infundibulopelvic*) ligament. The **ovarian ligament** extends from the uterus, near the attachment of the uterine tube, to the medial surface of the ovary. The **suspensory ligament** extends from the lateral surface of the ovary past the open end of the uterine tube to the pelvic wall. The suspensory ligament contains the major blood vessels of the ovary: the **ovarian artery** and **ovarian vein**. These vessels are connected to the ovary at the **ovarian hilum**, where the ovary attaches to the mesovarium (see Figure 28–14b).

A typical ovary is about 5 cm long, 2.5 cm wide, and 8 mm thick (2 in. × 1 in. × 0.33 in.). It weighs 6–8 g (about 0.25 oz). An ovary is pink or yellowish and has a nodular consistency. The visceral peritoneum, or *germinal epithelium*, covers the surface of each ovary and consists of a layer of columnar epithelial cells that overlies a dense connective tissue layer called the **tunica albuginea** (al-bū-JIN-ē-ah) (see Figure 28–14b). We divide the interior tissues, or **stroma**, of the ovary into a superficial *cortex* and a deeper *medulla*. Gametes are produced in the cortex.

The Uterine Tubes

Each **uterine tube** (*fallopian tube* or *oviduct*) is a hollow, muscular cylinder measuring roughly 13 cm (5.2 in.) in length (see Figure 28–14a).

Regions of the Uterine Tubes

We divide each uterine tube into three regions, from lateral to medial (Figure 28–15a):

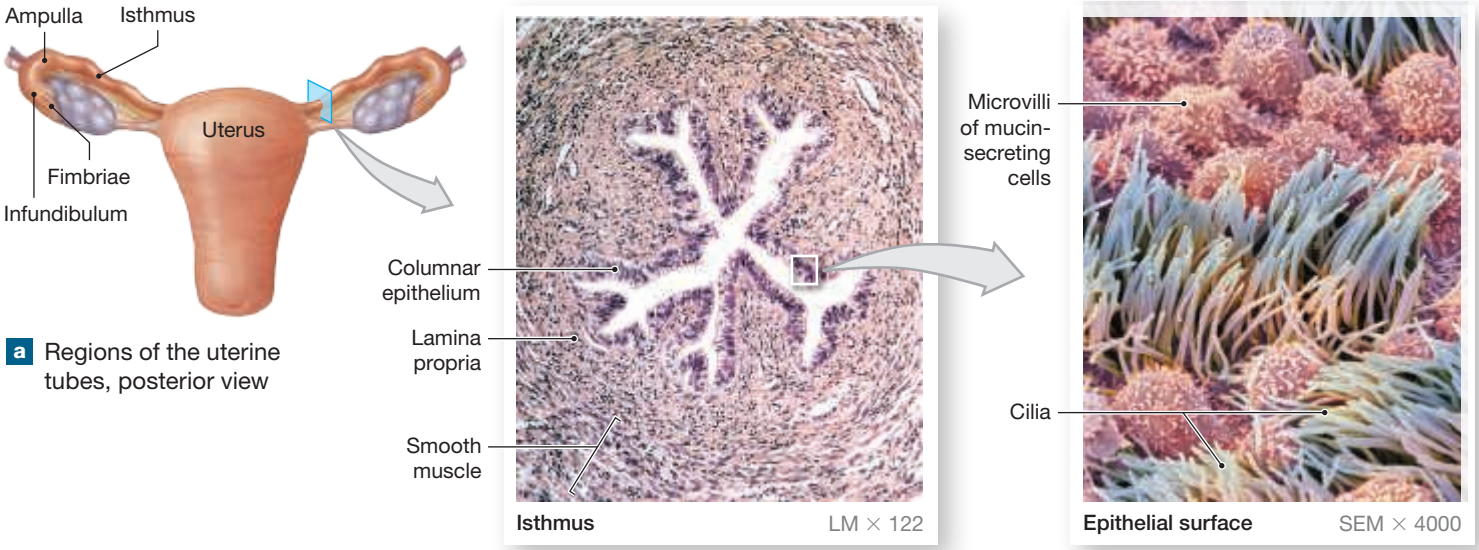
1. *The Infundibulum.* The end closest to the ovary forms an expanded funnel, or **infundibulum**, with numerous finger-like projections that extend into the pelvic cavity. The projections are called **fimbriae** (FIM-brē-ē) (Figure 28–16a). Fimbriae drape over the surface of the ovary, but there is no physical connection between the two structures. The inner surfaces of the infundibulum are lined with cilia that beat toward the middle region of the uterine tube.
2. *The Ampulla.* The middle region is the called the **ampulla**. The thickness of its smooth muscle layers gradually increases as the tube approaches the uterus.
3. *The Isthmus.* The ampulla leads to the **isthmus** (IS-mus), a short region connected to the uterine wall.

+ Clinical Note Ovarian Cancer

Ovarian cancer is not the most common female reproductive cancer—it is the third most common—but it is the most dangerous, because it is so difficult to diagnose in its early stages. A woman in the United States has a 1-in-70 chance of developing ovarian cancer in her lifetime. The prognosis is relatively good for cancers that originate in the general ovarian tissues or from abnormal oocytes. These cancers generally respond well to some combination of chemotherapy, radiation, and surgery. However, 85 percent of ovarian cancers develop from epithelial cells, and sustained remission occurs in only about one-third of these cases.

Functional Anatomy of the Uterine Tube

The epithelium lining the uterine tube is composed of ciliated columnar epithelial cells with scattered mucin-secreting cells. Concentric layers of smooth muscle surround the mucosa (Figure 28–15b). A combination of ciliary movement and peristaltic contractions in the walls of the uterine tube transports oocytes toward the uterus (Figure 28–15c). In addition, the uterine tube provides a nutrient-rich environment that contains lipids and glycogen for both oocytes and sperm. If fertilization occurs, it typically takes place near the boundary between the ampulla and isthmus of the uterine tube.



In addition to ciliated cells, the epithelium lining the uterine tubes contains *peg cells*. The peg cells project into the lumen of the uterine tube. They secrete a fluid that both completes the capacitation of sperm and supplies nutrients to sperm and the pre-embryo.

The Uterus

The **uterus** protects, nourishes, and removes wastes for the developing *embryo* (weeks 1–8) and *fetus* (week 9 through delivery). In addition, contractions of the muscular uterus are important in expelling the fetus at birth.

The uterus is a small, pear-shaped organ (Figure 28–16). It is about 7.5 cm (3 in.) long with a maximum diameter of 5 cm (2 in.). It weighs 50–100 g (1.75–3.5 oz). In its normal position, the uterus bends anteriorly near its base, a condition known as *anteflexion* (an-tē-FLEK-shun) (look back at Figure 28–13). In this position, the uterus covers the superior and posterior surfaces of the urinary bladder. If the uterus bends

Figure 28–15 Anatomy of the Uterine Tubes.

b A superior view of the ligaments that stabilize the position of the uterus in the pelvic cavity.

c Superior view of the female pelvic cavity showing supporting ligaments of uterus and ovaries. In the photo, the urinary bladder cannot be seen because it is covered by peritoneum.

backward toward the sacrum, the condition is termed *retroflexion* (re-trō-FLEK-shun). Retroflexion occurs in about 20 percent of adult women and has no clinical significance. (A retroflexed uterus generally becomes anteflexed spontaneously during the third month of pregnancy.)

Suspensory Ligaments of the Uterus

In addition to the broad ligament, three pairs of suspensory ligaments stabilize the uterus and limit its range of movement (Figure 28–16b). The **uterosacral** (yū-te-rō-SĀ-krul) **ligaments** extend from the lateral surfaces of the uterus to the anterior face of the sacrum, keeping the body of the uterus from moving inferiorly and anteriorly. The **round ligaments** arise on the lateral margins of the uterus just posterior and inferior to the attachments of the uterine tubes. These ligaments extend through the inguinal canal and end in the connective tissues of the external genitalia. (Unlike the inguinal canals in males, these canals in females are very small, containing only the round ligaments and the *ilioinguinal nerves*; this makes inguinal hernias in women very rare.) The round ligaments restrict posterior movement of the uterus. The **cardinal ligaments** extend from the base of the uterus and vagina to the lateral walls of the pelvis. These ligaments tend to prevent inferior movement of the uterus. The muscles and fascia of the pelvic floor provide additional mechanical support.

Gross Anatomy of the Uterus

We divide the uterus into four main anatomical regions (Figure 28–16a). The uterine **body** is the largest portion of the uterus. The **fundus** is the rounded portion of the body superior to the attachment of the uterine tubes. The body ends at a constriction known as the **isthmus** of the uterus. The **cervix** (SER-viks) is the inferior portion of the uterus that extends from the isthmus to the vagina.

+ Clinical Note Pap Smear

For many young women, the **Pap smear** is the reason for a regular visit to the doctor. This important screening test evaluates the health of the *cervix*, the inferior portion of the uterus that projects into the vaginal canal. Early detection of cervical cancer, the most common reproductive cancer in women ages 15–34, is the main goal of the test. Developed by Dr. Georgios Papanikolaou (hence the name of the test), the simple, quick, and inexpensive Pap smear is a form of *exfoliative cytology*. The practitioner opens the patient's vagina with a speculum, and gently scrapes the cervix with a swab to collect epithelial cells. These cells are then studied in the pathology lab for any evidence of cancerous changes.

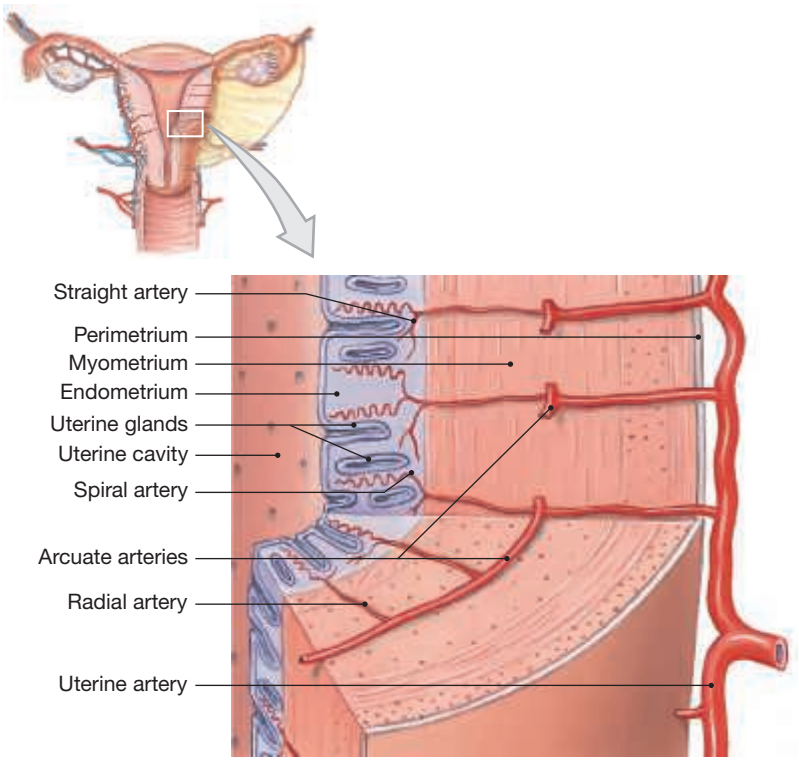
The tubular cervix projects about 1.25 cm (0.5 in.) into the vagina. Within the vagina, the distal end of the cervix forms a curving surface that surrounds the **external os** (*os*, an opening or mouth) of the uterus. The external os leads into the **cervical canal**, a constricted passageway that opens into the **uterine cavity** of the body at the **internal os**.

The uterus receives blood from branches of the **uterine arteries**. These vessels arise from branches of the *internal iliac arteries*, and from the *ovarian arteries*, which arise from the abdominal aorta inferior to the renal arteries. The arteries to the uterus are extensively interconnected, ensuring a reliable flow of blood to the organ despite changes in its position and shape during pregnancy. Numerous veins and lymphatic vessels also drain each portion of the uterus.

The organ is innervated by autonomic fibers from the hypogastric plexus (sympathetic) and from sacral segments S_3 and S_4 (parasympathetic). Sensory information reaches the central nervous system (CNS) within the posterior roots of spinal nerves T_{11} and T_{12}. The most delicate anesthetic procedures used during labor and delivery, known as *segmental blocks*, target only spinal nerves T_{10}–L_1.

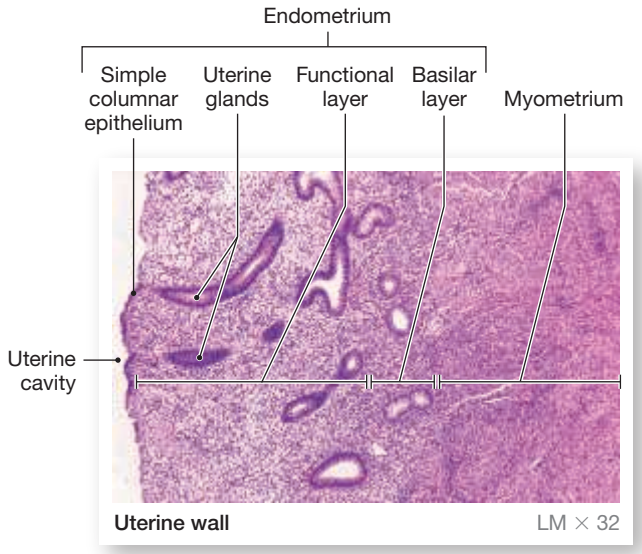
The Uterine Wall

The dimensions of the uterus are highly variable. In women of reproductive age who have not given birth, the uterine wall is about 1.5 cm (0.6 in.) thick.



Layers of the Uterine Wall. The uterine wall is made up of three main layers. The fundus and the posterior surface of the uterine body and isthmus are covered by an outer serous membrane that is continuous with the peritoneal lining. This incomplete serosa is called the **perimetrium**. The wall has a thick, middle, muscular **myometrium** (mī-ō-MĒ-trē-um; *myo-*, muscle + *metra*, uterus) and a thin, inner, glandular **endometrium** (en-dō-MĒ-trē-um) (Figure 28–17a).

The myometrium is the thickest portion of the uterine wall. It makes up almost 90 percent of the mass of the uterus. Smooth muscle in the myometrium is arranged into longitudinal, circular, and oblique layers. The smooth muscle tissue of the myometrium provides much of the force needed to move a fetus out of the uterus and into the vagina.



The endometrium makes up about 10 percent of the mass of the uterus. The glandular and vascular tissues of the endometrium support the physiological demands of the growing fetus. Vast numbers of *uterine glands* open onto the endometrial surface and extend deep into the lamina propria, almost to the myometrium. Under the influence of estrogens, the uterine glands, blood vessels, and epithelium change with the phases of the monthly *uterine cycle*.

Histology of the Uterine Wall. The endometrium is divided into a **functional layer**—the layer closest to the uterine

Figure 28–17 Histology of the Uterine Wall.

a A diagrammatic sectional view of the uterine wall, showing the endometrial regions and the blood supply to the endometrium

b The basic histological structure of the uterine wall

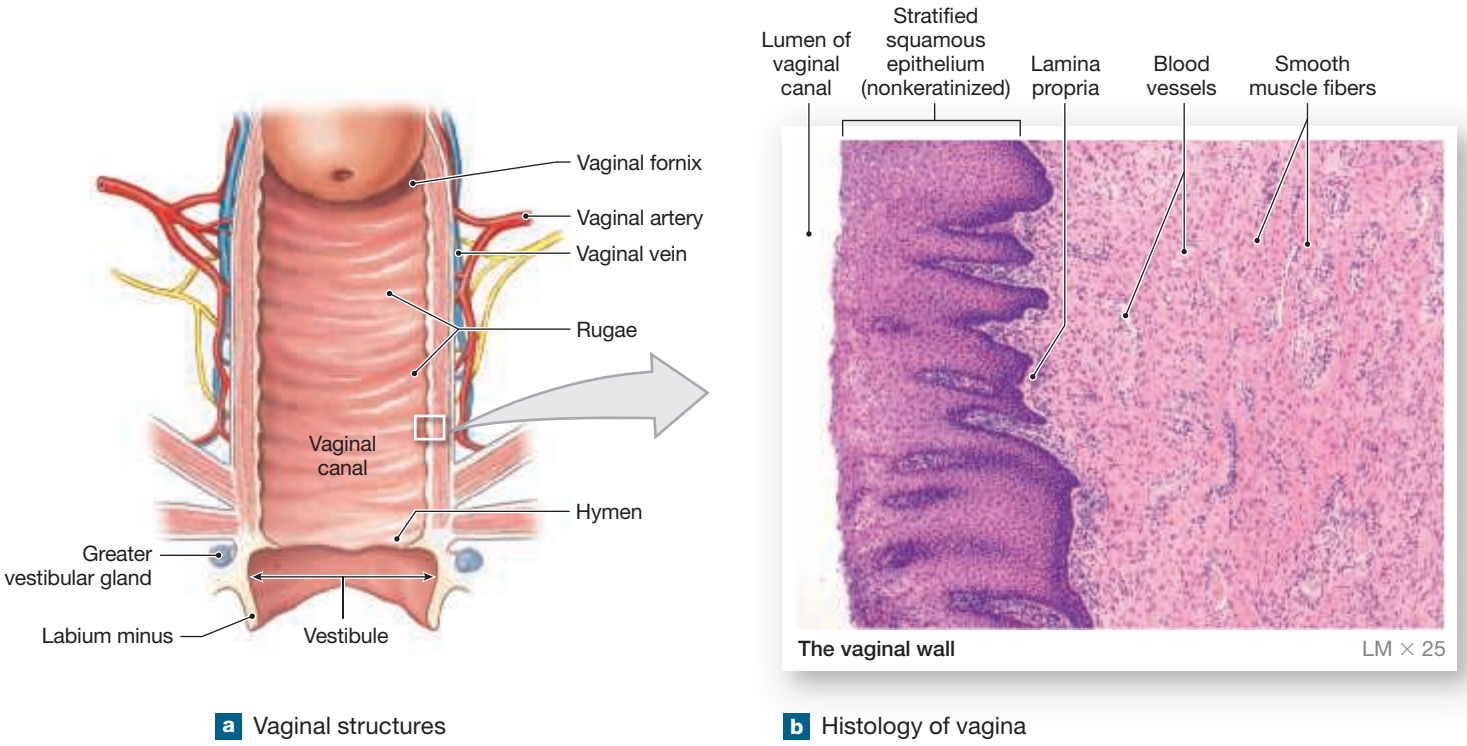
cavity—and a **basal layer**, adjacent to the myometrium (Figure 28–17b). The functional layer contains most of the **uterine glands** and contributes most of the endometrial thickness. This layer undergoes dramatic changes in thickness and structure during the uterine cycle. The basal layer attaches the endometrium to the myometrium and contains the terminal branches of the tubular uterine glands. The structure of the basal layer remains fairly constant over time, but the functional layer undergoes cyclical changes in response to sex hormone levels.

Within the myometrium, branches of the uterine arteries form **arcuate arteries**, which encircle the endometrium (see Figure 28–17a). **Radial arteries** supply **straight arteries**, which deliver blood to the basal layer of the endometrium, and **spiral arteries**, which supply the functional layer.

The Vagina

The **vagina** is an elastic, muscular tube that has three major functions. It (1) is a passageway for the elimination of menstrual fluids; (2) receives the penis during sexual intercourse, and holds sperm prior to their passage into the uterus; and (3) forms the inferior portion of the *birth canal*, through which the fetus passes during delivery.

Gross Anatomy of the Vagina



The vagina extends between the cervix and the body exterior (Figure 28–18a). At the proximal end of the vagina, the cervix projects into the **vaginal canal**. The shallow recess surrounding the cervical protrusion is known as the **vaginal fornix** (FOR-niks). The vagina is typically 7.5–9 cm (3–3.6 in.) long. Its diameter varies because it is highly distensible.

The two *bulbospongiosus* muscles extend along either side of the vaginal entrance. Contractions of the bulbospongiosus muscles constrict the vagina. ↩ p. 407 These muscles cover the **bulb of vestibule**, a mass of erectile tissue on each side of the vagina (Figure 28–19). The bulb of vestibule has the same embryonic origins as the corpus spongiosum of the penis in males.

The vagina opens into the *vestibule*, a space bordered by the female external genitalia (see Figure 28–18a). The **hymen** (HĪ-men) is an elastic epithelial fold of variable size that partially blocks the entrance to the vagina. An intact hymen is typically stretched or torn during first sexual intercourse, tampon use, pelvic examination, or physical activity.

The vagina lies parallel to the rectum, and the two are in close contact posteriorly. Anteriorly, the urethra extends along

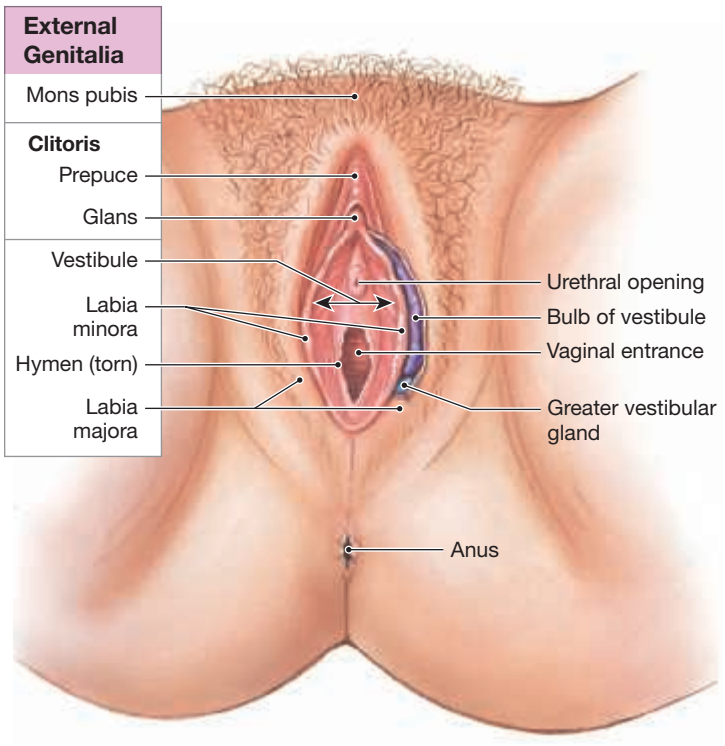


Figure 28–18 Anatomy of the Vagina.

a Vaginal structures

b Histology of vagina

Figure 28–19 Anatomy of the Female External Genitalia.

the superior wall of the vagina from the urinary bladder to the external urethral orifice, which opens into the vestibule.

The primary blood supply of the vagina is by the **vaginal branches** of the internal iliac (or uterine) arteries and veins. Innervation is from the hypogastric plexus, sacral nerves S_2–S_4, and branches of the pudendal nerve. ↩ pp. 497, 810, 817

Histology of the Vagina

In sectional view, the lumen of the vagina appears constricted, forming a rough H-shape. The vaginal walls contain a network of blood vessels and layers of smooth muscle (Figure 28–18b). The lining is moistened by secretions of the cervical glands and by the movement of water across the permeable epithelium.

The vaginal lumen is lined by a nonkeratinized stratified squamous epithelium (see Figure 28–18b). In the relaxed state, this epithelium forms folds called *rugae* (RŪ-gē). The underlying lamina propria is thick and elastic, and it contains small blood vessels, nerves, and lymph nodes. The vaginal mucosa is surrounded by an elastic *muscular* layer consisting of layers of smooth muscle fibers arranged in circular and longitudinal bundles continuous with the uterine myometrium. The portion of the vagina adjacent to the uterus has a serosal covering that is continuous with the pelvic peritoneum. Along the rest of the vagina, the muscular layer is surrounded by an *adventitial layer* of fibrous connective tissue.

The vagina contains a population of resident bacteria, usually harmless, supported by nutrients in the cervical mucus. The metabolic activity of these bacteria creates an acidic environment, which restricts the growth of many pathogens. However, this acidic environment also inhibits the motility of sperm.

Vaginitis (vaj-ih-NĪ-tis), an inflammation of the vagina, is caused by fungal, bacterial, or parasitic infections. In addition to any discomfort that may result, the condition may affect the survival of sperm and thereby reduce fertility.

The hormonal changes associated with the *ovarian cycle*, the monthly cycle that produces an oocyte, also affect the vaginal epithelium. By examining a *vaginal smear*—a sample of epithelial cells shed at the surface of the vagina—a clinician can estimate the corresponding stages in the ovarian and uterine cycles. This diagnostic procedure is an example of *exfoliative cytology*. ↩ p. 172

The Female External Genitalia

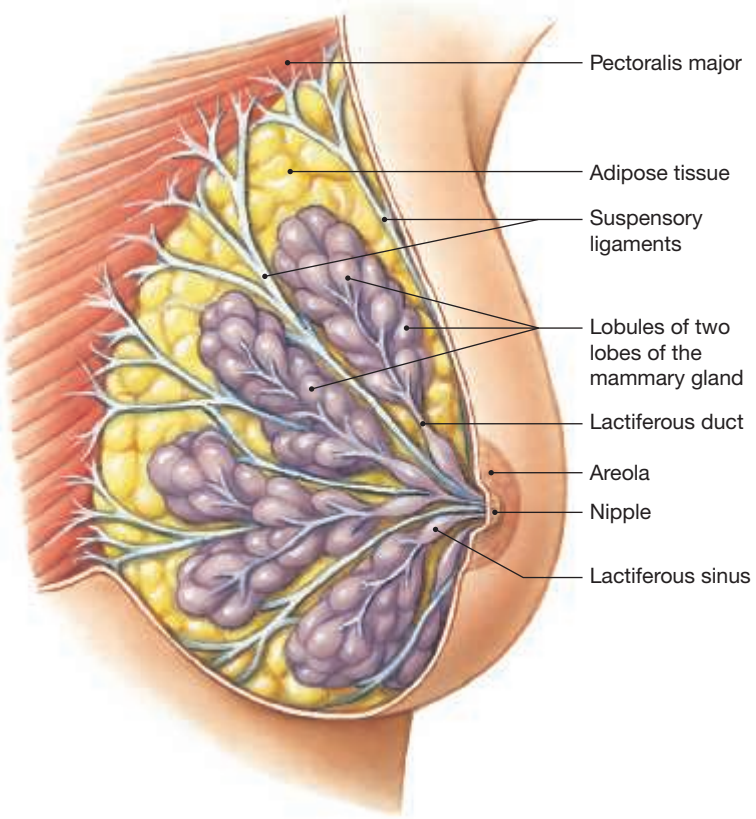
The area containing the female external genitalia is the **vulva** (VUL-vuh), or *pudendum* (pū-DEN-dum; see Figure 28–19). The vagina opens into the **vestibule**, a central space surrounded by small folds known as the **labia minora** (LĀ-bē-uh mi-NOR-uh; singular, *labium minus*). The labia minora are covered with smooth, hairless skin. The urethra opens into the vestibule just anterior to the vaginal entrance. The **urethral glands** discharge into the urethra near the external urethral opening.

Anterior to this opening, the **clitoris** (KLIT-ō-ris) projects into the vestibule. A small, rounded tissue projection, the clitoris is derived from the same embryonic structures as the penis in males, and has a major role in female sexual response. Internally, it contains erectile tissue called **corpus cavernosum of clitoris** (comparable to those structures of the penis) that form its **body**. A small erectile **glans** sits atop the body. The bulb of vestibule along the sides of the vestibule are comparable to the male corpus spongiosum. These erectile tissues engorge with blood during sexual arousal. Extensions of the labia minora encircle the body of the clitoris, forming its **prepuce**.

A variable number of small **lesser vestibular glands** discharge their secretions onto the exposed surface of the vestibule between the orifices of the vagina and urethra. During sexual arousal, the **greater vestibular glands**, located on each side of the distal portion of the vagina, secrete into the vestibule. These mucous glands keep the area moist and lubricated. The vestibular glands have the same embryonic origins as the bulbourethral glands in males.

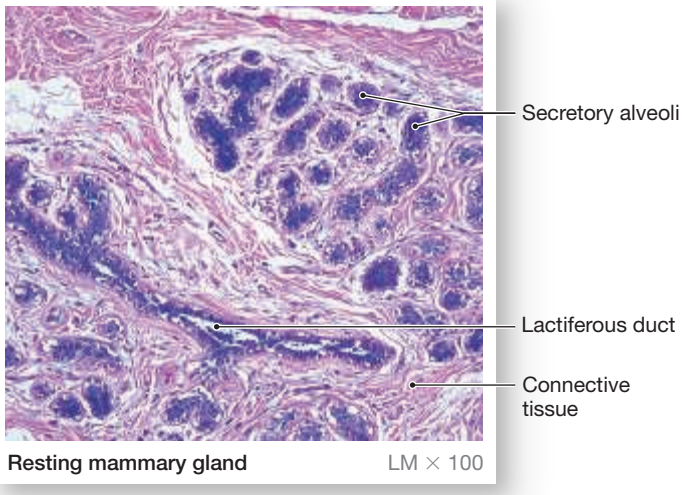
The outer margins of the vulva are formed by the mons pubis and the labia majora. The **mons pubis** is a pad of adipose tissue covering the pubic symphysis. Adipose tissue also accumulates within the **labia majora** (singular, *labium majus*), prominent folds of skin that encircle and partially conceal the labia minora and adjacent structures. The outer margins of the labia majora and the mons pubis are covered with coarse hair, but the inner surfaces of the labia majora are hairless. Sebaceous glands and scattered apocrine sweat glands secrete onto the inner surface of the labia majora, moistening and lubricating them.

The Breasts



Female **breasts** are two projections anterior to the pectoral muscles that include a mammary gland, a variable amount of fat, a nipple, and an areola. Breasts are rudimentary in the male. A newborn infant cannot fend for itself, and several of its key systems have yet to complete development. Over the initial period of adjustment to an independent existence, the infant is nourished from the milk secreted by the maternal **mammary glands**. Milk production, or **lactation** (lak-TĀ-shun), takes place in these glands. In females, mammary glands are specialized organs of the integumentary system that are controlled mainly by hormones of the reproductive system and by the *placenta*, a temporary structure that provides the embryo and fetus with nutrients.

On each side, a mammary gland lies in the subcutaneous tissue of the pectoral **adipose tissue** deep to the skin of the chest (Figure 28–20a). Each breast has a **nipple**, a small conical projection where the ducts of the underlying mammary gland open onto the body surface. The reddish-brown skin around each nipple is the **areola** (a-RĒ-ō-luh). Large sebaceous glands deep to the areolar surface give it a grainy texture.



The glandular tissue of a mammary gland consists of separate lobes, each containing several secretory lobules. Ducts leaving the lobules converge, giving rise to a single **lactiferous** (lak-TIF-er-us) **duct** in each lobe. Near the nipple, that lactiferous duct enlarges, forming an expanded chamber called a **lactiferous sinus**. Typically, 15–20 lactiferous sinuses open onto the surface of each nipple. Dense connective tissue surrounds the duct system and forms partitions that extend between the lobes and the lobules. These bands of connective tissue, the *suspensory ligaments of the breast*, originate in the dermis of the overlying skin. A layer of areolar tissue separates the mammary gland complex from the underlying pectoralis muscles. Branches of the *internal thoracic artery* supply blood to each mammary gland (look back at Figure 21–20, p. 806).

Figure 28–20b,c compares the histology of inactive and active mammary glands. An inactive, or *resting*, mammary gland is dominated by a duct system rather than by active glandular cells. The size of the mammary glands in a nonpregnant woman reflects primarily the amount of adipose tissue present, not the amount of glandular tissue. The secretory apparatus normally does not complete its development unless pregnancy occurs. An active mammary gland is a tubulo-alveolar gland, consisting of multiple glandular tubes that end in secretory alveoli. We will discuss the hormonal mechanisms involved in lactation in Chapter 29.

+ Clinical Note Fibrocystic Disease and Breast Cancer

The uterine cycle also influences cyclical changes in the mammary glands. Occasional discomfort or even inflammation of mammary gland tissues can occur late in the cycle. If inflamed lobules become walled off by scar tissue, **cysts** are created. Clusters of cysts can be felt in the breast as discrete masses, a condition known as **fibrocystic disease**. Because its symptoms are similar to those of breast cancer, biopsies may be needed to distinguish between this benign condition and breast cancer.

Breast cancer is a malignant, metastasizing tumor of the mammary gland. It is the leading cause of death in women between ages 35 and 45, but it is most common in women over age 50. An estimated 12.4 percent of U.S. women will develop breast cancer at some point in their lifetime. The incidence is highest among Caucasian Americans, somewhat lower in Black Americans, and lowest in Asian Americans and Native Americans. Notable risk factors include (1) a family history of breast cancer, (2) a first pregnancy after age 30, and (3) early menarche (first menstruation) or late menopause (end of menstruation).

Despite repeated studies, no links have been proven between breast cancer and birth control pills, fat consumption, or alcohol use. It appears likely that multiple factors are involved. In some families an inherited genetic variation has been linked to higher-than-normal risk of developing the disease. However, most women never develop breast cancer—even women in families with a history of the disease. Mothers who breast-fed (nursed) their babies have a 20 percent lower incidence of breast cancer after menopause than do mothers who did not breast-feed. The reason is not known. Adding to the mystery, nursing does not appear to affect the incidence of premenopausal breast cancer.

+ Clinical Note Laparoscopy

Laparoscopy is a minimally invasive procedure that allows a direct look into the abdominopelvic cavity. The technique is often employed to assess the health of female pelvic structures when another diagnostic test, such as an x-ray, is inconclusive. The surgeon makes a tiny incision through the abdominal wall when the patient is under general anesthesia. Through this opening, carbon dioxide gas is injected into the abdomen in order to spread out the organs and increase visibility. Then the laparoscope is inserted. The scope is a flexible tube bearing a tiny light and an equally tiny camera. The operator can look around, take photos, and collect biopsies. Laparoscopy can determine, for example, the presence of a blocked uterine tube or a cyst on an ovary.

+ Clinical Note Mammoplasty

Mammoplasty includes three types of surgical alteration of the breast. *Breast augmentation* is most frequently desired. In this procedure, the size or contour of the mammary gland is modified by the placement of fluid-filled implants under the skin, and either superficial or deep to the pectoral muscles. The surgeon may be able to insert the implant through an incision along the margin of the areola of the nipple. A second approach is to enter from the axilla. A third option is to make a small incision directly underneath each breast. *Breast reduction* can be performed when a woman desires that cosmetic result, or when she is suffering back and neck pain due to excessive breast size. Finally, women who have undergone surgery for breast cancer may seek *breast reconstruction*. As a case in point, actor and activist Angelina Jolie went public in 2013 with her prophylactic bilateral mastectomy, or removal of the breasts in response to a high risk of breast cancer.

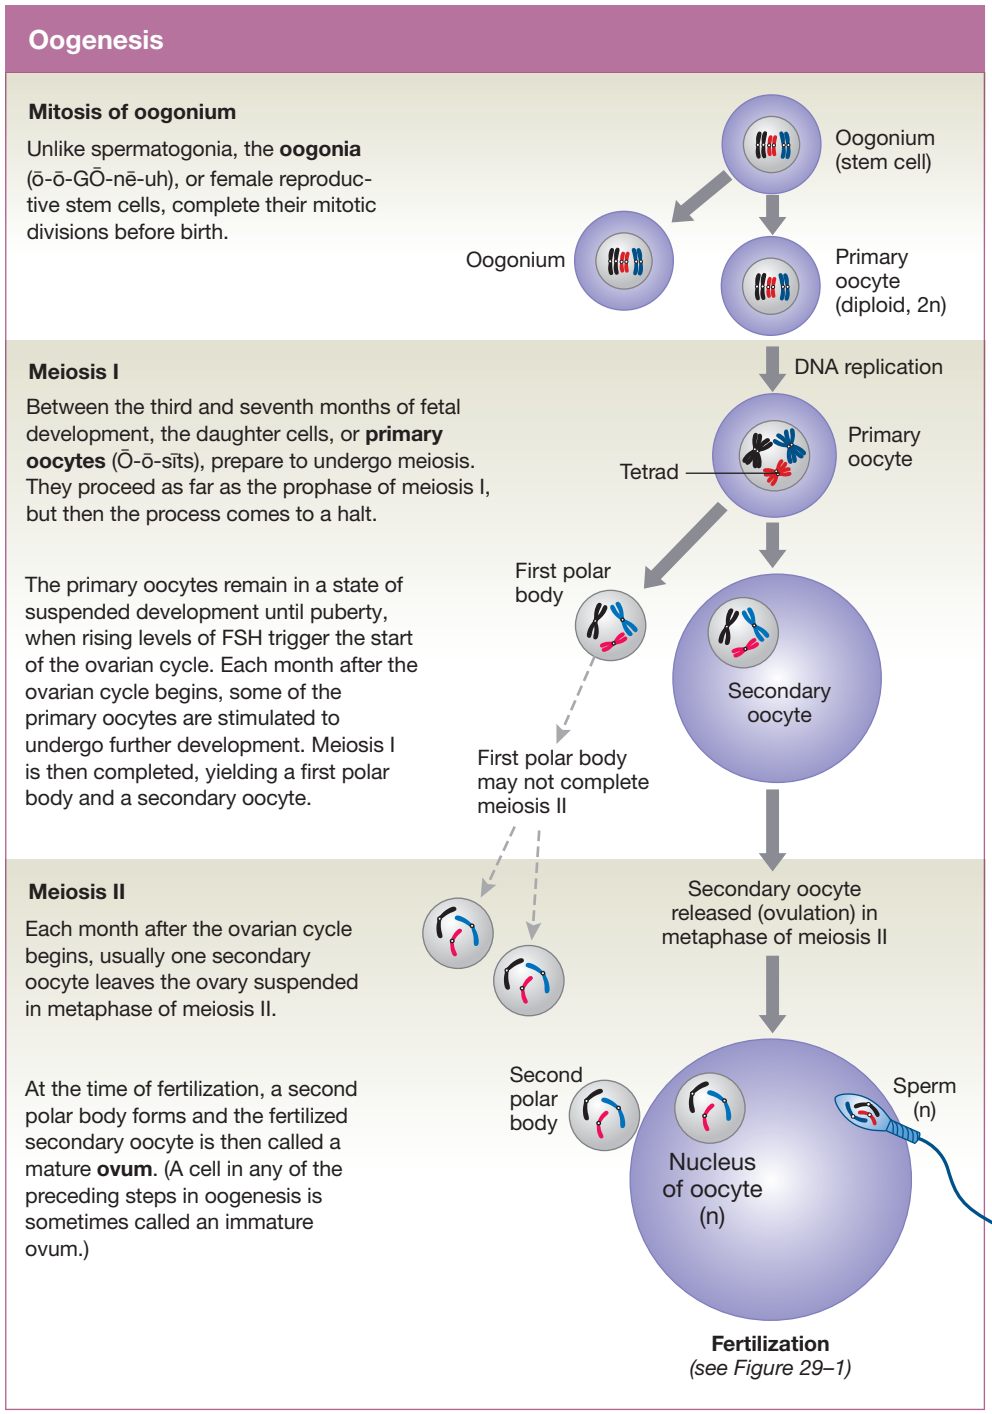
28-5 Oogenesis occurs in the ovaries, and hormones from the hypothalamus, pituitary gland, and ovaries control female reproductive functions

Learning Outcome Describe the ovarian roles in oogenesis, explain the complete ovarian and uterine cycles, and summarize all aspects of the female reproductive cycle.

Three interrelated processes help to ensure the continuation of our species from the female perspective: oogenesis, the ovarian cycle, and the uterine cycle. *Oogenesis* is the production of female gametes called oocytes. Oogenesis takes place in the ovaries within structures called *follicles*. The *ovarian cycle* is the monthly series of events associated with the maturation of an oocyte. The *uterine cycle* involves a series of events that prepares the uterus for implantation of a fertilized oocyte. This section describes these events and how they are influenced by hormones.

Oogenesis



Ovum production, or **oogenesis** (ō-ō-JEN-eh-sis; *oon*, egg), begins before a woman's birth, accelerates at puberty, and ends at *menopause* (end of menstruation). Between puberty and menopause, oogenesis occurs on a monthly basis as part of the ovarian cycle.

Oogenesis is summarized in Figure 28–21. This process begins during fetal development, when female reproductive stem cells called **oogonia** (ō-ō-GŌ-nē-uh; singular, *oogonium*) undergo mitosis, producing diploid **primary oocytes** (2n). After 5 months of development, fetal ovaries contain an estimated 7 million primary oocytes. Not all survive. At birth the ovaries have approximately 2 million primary oocytes. However, most of these primary oocytes do not survive until puberty, degenerating in a process called *atresia* (ah-TRĒ-zē-uh). By puberty, their number has dropped to about 400,000.

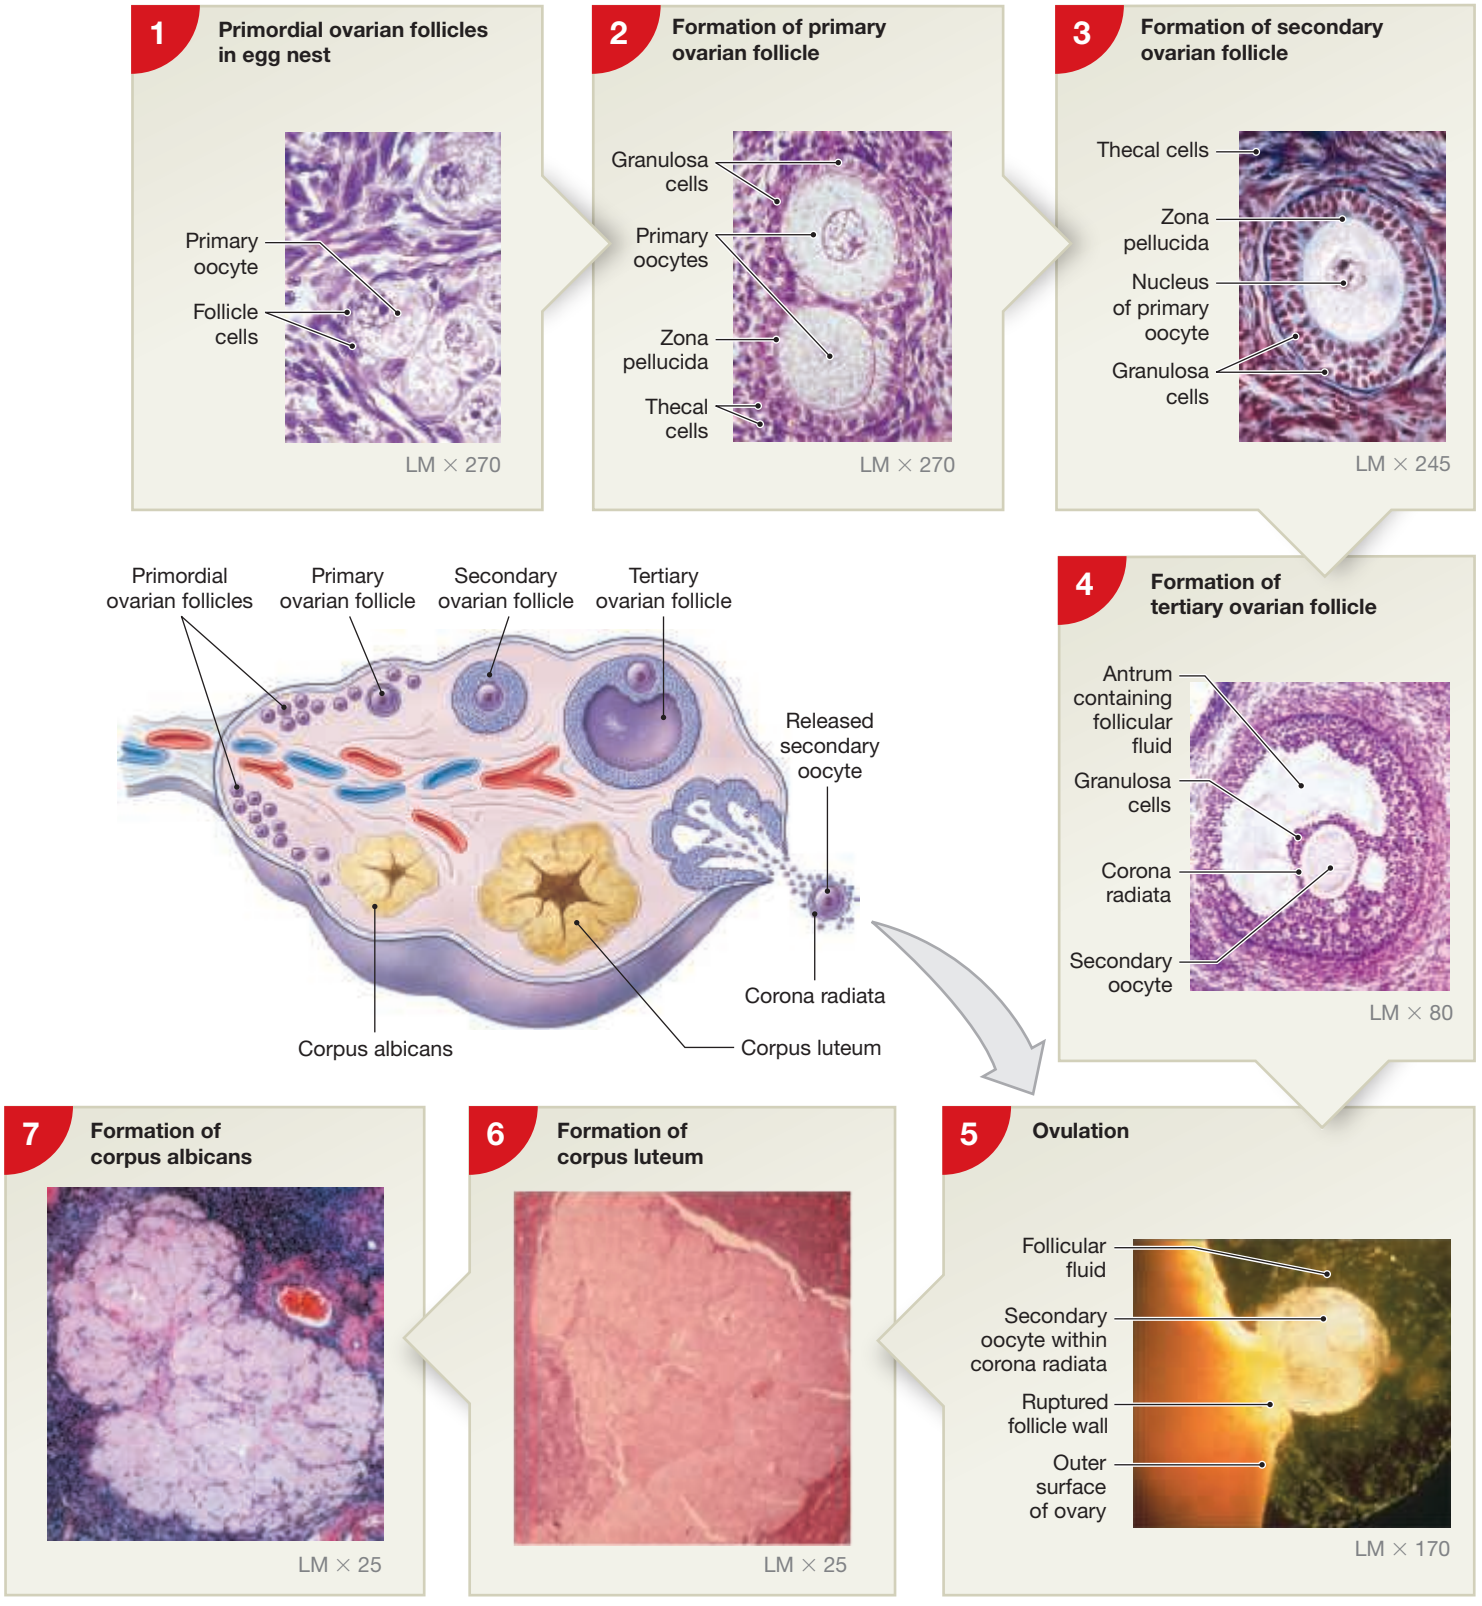
The remaining primary oocytes begin meiosis I, proceed as far as prophase I, and then remain in that state until the female reaches puberty. At that point, some are stimulated to finish meiosis I, producing haploid **secondary oocytes** (n). Note that the cytoplasm of the primary oocyte is unevenly distributed during the two meiotic divisions (see Figure 28–21). Oogenesis produces one secondary oocyte, which contains most of the original cytoplasm, and two or three **polar bodies**, nonfunctional cells that later disintegrate.

The secondary oocyte then begins meiosis II, but is suspended at metaphase II. In the process of *ovulation*, the ovary releases such a secondary oocyte. This secondary oocyte will not complete meiosis II and become a mature ovum unless fertilization occurs.

Figure 28–21 The Process of Oogenesis. For clarity, maternal and paternal chromatids are not identified.

Follicle Development

Specialized structures in the cortex of the ovaries called **ovarian follicles** (ō-VAR-ē-an FOL-i-klz) are the sites of both oocyte growth and meiosis I of oogenesis. Follicle development and the ovarian cycle are shown in Figure 28–22.



1 Primordial Ovarian Follicles in Egg Nest. Primary oocytes are located in the outer portion of the ovarian cortex, near the tunica albuginea, in clusters called *egg nests*. A single squamous layer of *follicle cells* surrounds each primary oocyte within an egg nest. The primary oocyte and its follicle cells form a **primordial ovarian follicle.** At puberty, each ovary contains about 200,000 primordial follicles. Forty years later, few if any primary ovarian follicles remain, although only about 500 secondary oocytes will have been ovulated.

Beginning at puberty, primordial ovarian follicles are continuously activated to join other follicles already in development. The activating mechanism is unknown, but local hormones or growth factors within the ovary may be involved. The activated primordial ovarian follicle will either eventually mature and release a secondary oocyte or degenerate through follicular atresia.

2 Formation of Primary Ovarian Follicle. The preliminary steps in follicle development vary in length but may take almost a year to complete. Follicle development begins with the activation of primordial ovarian follicles into **primary ovarian follicles**. The follicular cells enlarge, divide, and form several layers of cells around the growing primary oocyte. The cells begin to produce sex hormones called estrogens. Microvilli from the surrounding follicle cells intermingle with microvilli originating at the surface of the oocyte. This region is called the **zona pellucida** (ZŌ-na pe-LŪ-sid-uh; *pellucidus*, translucent). The microvilli increase the surface area available for the transfer of materials from the follicular cells to the growing oocyte.

3 Formation of Secondary Ovarian Follicle. Many primordial ovarian follicles develop into primary ovarian follicles, but only a few mature further in the next four months or so. This

Figure 28–22 Follicle Development and the Ovarian Cycle. The photomicrographs show the changes in an ovarian follicle as it develops. It enters the 28-day ovarian cycle as a tertiary ovarian follicle. The drawing of the ovary illustrates the sequence and relative sizes of the various stages in the development, ovulation, and degeneration of an ovarian follicle. Follicles do not physically move around the periphery of the ovary.

? At what stage of development is the oocyte during ovulation?

process is apparently under the control of a growth factor produced by the oocyte. The transformation begins as the wall of the follicle thickens. At this stage, the complex is known as a **secondary ovarian follicle**. The primary oocyte continues to grow slowly.

4 Formation of Tertiary Ovarian Follicle. During the next 2 to 3 months, the follicle wall continues to grow and the deeper follicular cells begin secreting *follicular fluid*. This fluid accumulates in small pockets that gradually expand between the inner and outer cellular layers of the follicle. The secondary ovarian follicle as a whole has doubled in size, and is now called a *tertiary ovarian follicle*. Tertiary ovarian follicles, also called *vesicular follicles*, continue to grow and accumulate follicular fluid.

The Ovarian Cycle

The tertiary follicles are then ready to complete their maturation as part of the 28-day ovarian cycle. The monthly process of the maturation, ovulation, and degeneration of a tertiary ovarian follicle is known as the **ovarian cycle** (see Figure 28–22). We can divide the ovarian cycle into a *follicular phase* (folliculogenesis) and a *luteal phase* (luteogenesis), each lasting about 14 days. The luteal phase involves the follicle after ovulation, when it becomes an endocrine structure called a *corpus luteum* (LŪ-tē-um) that secretes a sex hormone.

The Follicular Phase

In the **follicular phase**, or *preovulatory phase*, a tertiary ovarian follicle is ready to complete its maturation. Ovulation marks the end of this phase.

At the start of each ovarian cycle, an ovary contains only a few tertiary follicles destined for further development. Stimulated by FSH, one of these follicles becomes dominant by day 5 of the cycle and it rapidly increases in size. This remaining **tertiary ovarian follicle**, also called a *mature graafian* (GRAF-ē-an) *follicle*, is roughly 15–20 mm (0.6–0.8 in) in diameter. It is formed by days 10–14 of the ovarian cycle. Its large size creates a prominent bulge in the surface of the ovary. The oocyte and its covering of follicular cells projects into the expanded central chamber of the follicle, the **antrum** (AN-trum). The antrum is surrounded by a mass of **granulosa cells**. As the granulosa cells enlarge and multiply, adjacent cells in the ovarian stroma form a layer of **thecal endocrine cells** (*theca*, a box) around the follicle. Thecal endocrine cells and granulosa cells work together to produce the sex hormones called **estrogens**.

Until this time, the primary oocyte has been suspended in prophase of meiosis I. As the development of the remaining tertiary ovarian follicle ends, rising LH levels prompt the primary oocyte to complete meiosis I. The completion of the first meiotic division produces a secondary oocyte and a small, nonfunctional polar body (see Figure 28–21). The secondary oocyte begins meiosis II but stops short of dividing. Meiosis II will not be completed unless fertilization occurs.

Generally, on day 14 of a 28-day ovarian cycle, the secondary oocyte and its surrounding follicular cells lose their connections with the follicular wall and drift free within the antrum. The granulosa cells still associated with the secondary oocyte form a protective layer known as the **corona radiata** (kō-RŌ-nuh rā-dē-AH-tuh).

5 Ovulation. At **ovulation** (ōv-ū-LĀ-shun), the tertiary follicle releases the secondary oocyte. The distended follicular wall then ruptures, releasing the follicular contents, including the secondary oocyte, into the pelvic cavity. The sticky follicular fluid keeps the corona radiata attached to the surface of the ovary near the ruptured wall of the follicle. The oocyte is then moved into the uterine tube by contact with the fimbriae that extend from the tube's funnel-like opening (look back at Figure 28–14a), or by fluid currents produced by the cilia that line the tube.

Usually only a single oocyte is released into the pelvic cavity at ovulation, although many primordial ovarian follicles may have developed into primary ovarian follicles, and several primary ovarian follicles may have been converted to secondary ovarian follicles. These follicles undergo follicular atresia.

The Luteal Phase

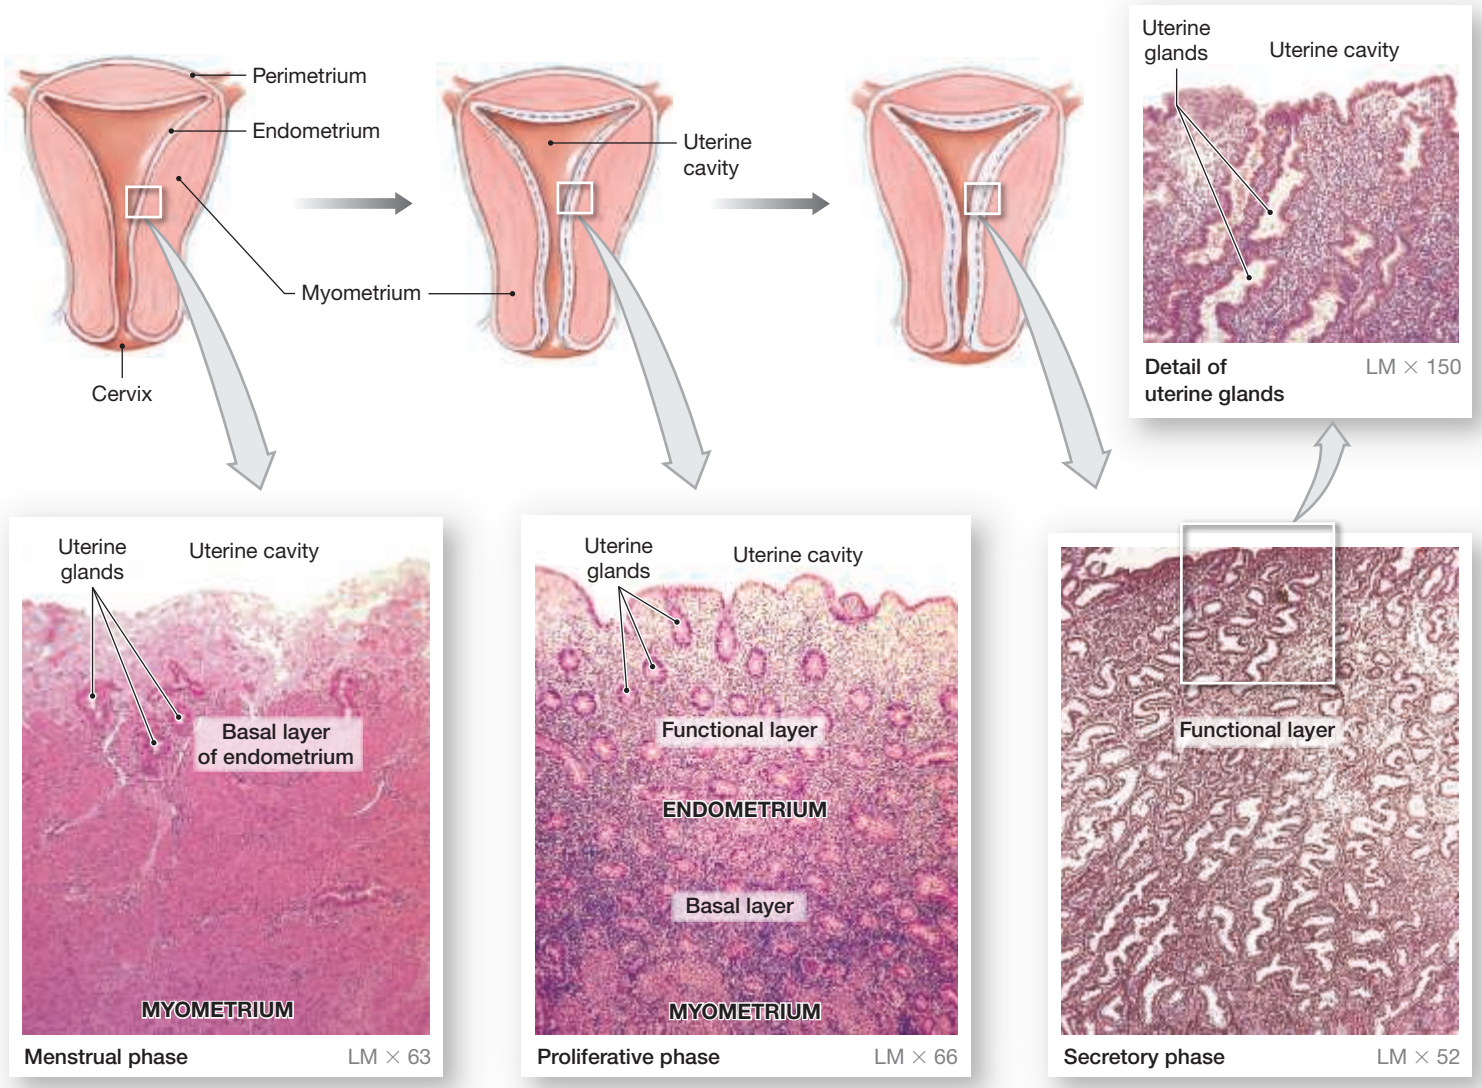
After ovulation occurs, the **luteal phase**, or *postovulatory phase*, begins. This phase ends with the degeneration of the corpus luteum.

6 Formation of Corpus Luteum. The empty tertiary ovarian follicle initially collapses, and ruptured vessels bleed into the antrum. Under the stimulation of LH, the remaining granulosa cells then invade the area and proliferate to create the **corpus luteum**.

The corpus luteum is so named (*lutea*, yellow) because this is the color of the cholesterol it contains. This cholesterol is used to manufacture the steroid hormone **progesterone** (prō-JES-ter-ōn). Progesterone is the main hormone during the luteal phase. Progesterone's primary function is to prepare the uterus for pregnancy by stimulating the maturation of the uterine lining and the secretions of uterine glands. The corpus luteum also secretes moderate amounts of estrogens, but levels are not as high as they were at ovulation.

7 Formation of Corpus Albicans. The corpus luteum begins to degenerate about 12 days after ovulation (unless fertilization takes place). Progesterone and estrogen levels then decline markedly. Fibroblasts invade the nonfunctional corpus luteum, producing a knot of pale scar tissue called a **corpus albicans** (AL-bi-kanz).

The disintegration of the corpus luteum marks the end of the ovarian cycle. A new ovarian cycle then begins with another group of tertiary ovarian follicles.



The Uterine (Menstrual) Cycle

The **uterine cycle**, or *menstrual* (MEN-strū-ul) *cycle*, is a repeating series of changes in the structure of the endometrium (Figure 28–23). The uterine cycle averages 28 days in length, but it can range from 21 to 35 days in healthy women of reproductive age.

The uterine cycle begins at puberty. The first cycle, known as *menarche* (me-NAR-kē; *men*, month + *arche*, beginning), typically occurs at age 11–12. The cycles continue until *menopause* (MEN-ō-pawz), the termination of the uterine cycle, at age 45–55. Over the interim, the regular appearance of uterine cycles is interrupted only by circumstances such as illness, stress, starvation, or pregnancy.

The uterine cycle is divided into three phases: (1) the *menstrual phase*, (2) the *proliferative phase*, and (3) the *secretory phase*. The phases take place in response to hormones associated with the regulation of the ovarian cycle. The menstrual and proliferative phases occur during the follicular phase of the ovarian cycle. The secretory phase corresponds to the luteal phase of the ovarian cycle.

Figure 28–23 A Comparison of the Structure of the Endometrium during the Phases of the Uterine Cycle.

a The endometrium during the menstrual phase of the uterine cycle

b The endometrium during the proliferative phase of the uterine cycle

c The endometrium during the secretory phase of the uterine cycle

? Which layer of the endometrium is affected most during the uterine cycle?

Tips & Tools

Progesterone literally means a steroid *(-**one**)* that favors *(**pro**-)* gestation *(-**gest**)*.

Menstrual Phase

The uterine cycle begins with the **menstrual phase**. This phase is marked by the degeneration and sloughing (shedding) of the endometrial functional layer, leading to **menstruation** (men-strū-Ā-shun), also called **menses** (MEN-sēz) (see Figure 28–23a). Endometrial degeneration occurs in patches. It is caused by constriction of the spiral arteries, which reduces blood flow to areas of the endometrium. Deprived of oxygen and nutrients, the secretory glands and other tissues in the functional layer begin to deteriorate. Eventually, the weakened arterial walls rupture, and blood pours into the connective tissues of the functional layer. Blood cells and degenerating tissues then break away and enter the uterine cavity, to be shed as they pass through the external os and into the vagina. Only the functional layer is affected, because the deeper, basal layer receives blood from the straight arteries, which remain unconstricted.

The sloughing of tissue is gradual, and repairs begin almost immediately at each site. Nevertheless, before menstruation has ended, the entire functional layer has been lost. The menstrual phase generally lasts from 1 to 7 days. During this time about 35–50 mL (1.2–1.7 oz) of blood are lost.

The process can be relatively painless. However, painful menstruation, or **dysmenorrhea**, can result from myometrial contractions ("cramps"), uterine inflammation, or from conditions involving adjacent pelvic structures.

The Proliferative Phase

The basal layer, including the basal parts of the uterine glands, survives menstruation intact. In the days after menstruation, the epithelial cells of the uterine glands multiply and spread across the endometrial surface, restoring the uterine epithelium (see Figure 28–23b). Further growth and vascularization completely restore the functional layer.

During this reorganization, the endometrium is in the **proliferative phase**. Restoration takes place at the same time as the tertiary ovarian follicles enlarge in the ovary. Estrogens secreted by the developing ovarian follicles stimulate and sustain the proliferative phase.

By the time ovulation occurs, the functional layer is several millimeters thick. Prominent mucous glands extend to its border with the basal layer. At this time, the uterine glands are manufacturing mucus that is rich in glycogen. This specialized mucus appears to be essential for the survival of the fertilized ovum through its earliest developmental stages. (We consider these stages in Chapter 29.) The entire functional layer is highly vascularized, with small arteries spiraling toward the endometrial surface from larger arteries in the myometrium.

The Secretory Phase

During the **secretory phase** of the uterine cycle, the uterine glands enlarge, accelerating their rates of secretion. The arteries that supply the uterine wall elongate and spiral through the tissues of the functional layer (see Figure 28–23c). This activity occurs under the combined stimulatory effects of progesterone and estrogens from the corpus luteum. The secretory phase begins at the time of ovulation and persists as long as the corpus luteum remains intact.

Secretory activities peak about 12 days after ovulation. Over the next day or two, the glands become less active. The uterine cycle ends as the corpus luteum stops producing stimulatory hormones. A new uterine cycle then begins with the onset of menstruation and the disintegration of the functional layer.

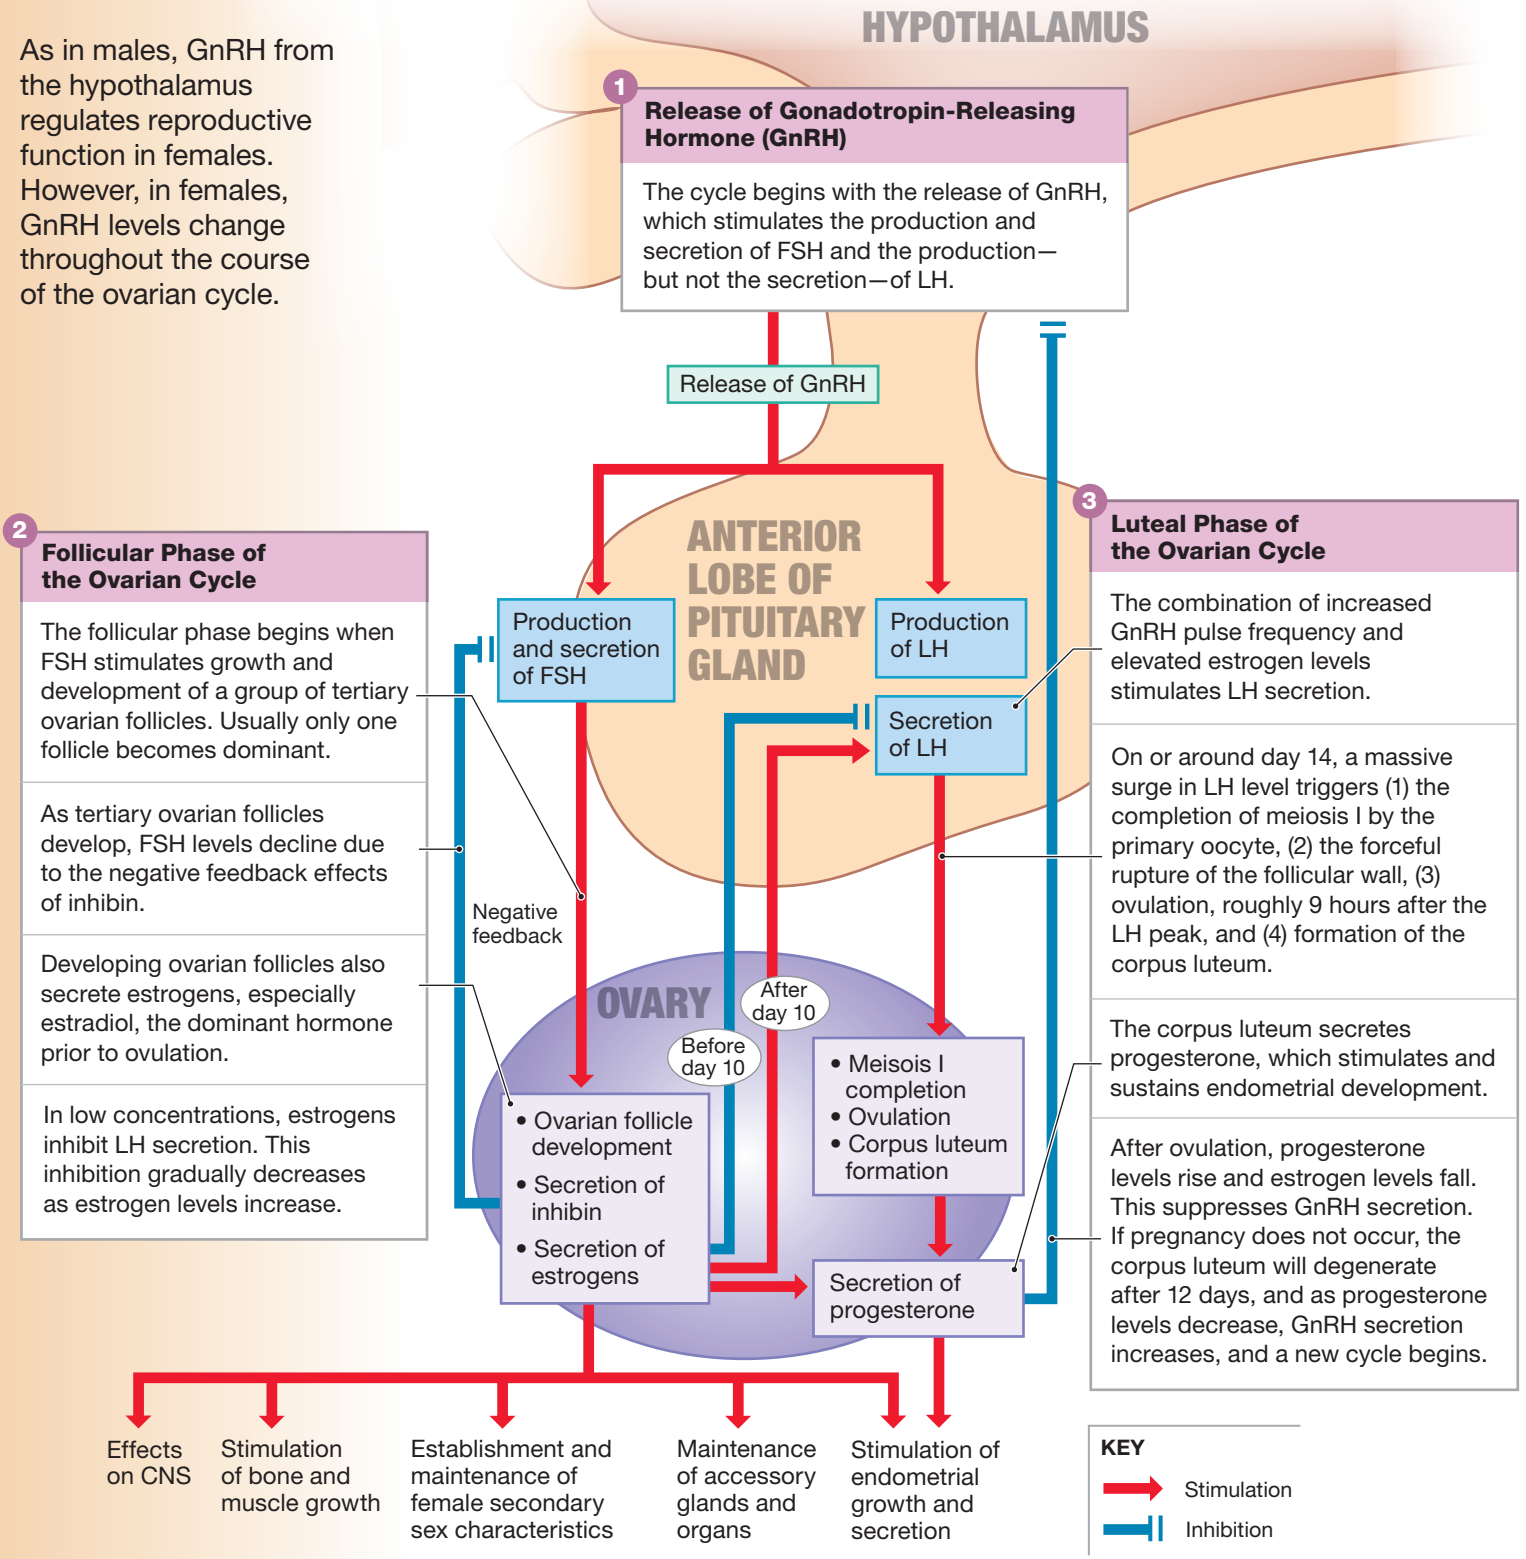
The secretory phase generally lasts 14 days. For this reason, you can identify the date of ovulation by counting backward 14 days from the first day of menstruation.

Hormonal Coordination of the Ovarian and Uterine Cycles

The female reproductive tract is under hormonal control that involves interplay between secretions of both the pituitary gland and the gonads. Circulating hormones control the **female reproductive cycle**, coordinating the ovarian and uterine cycles for proper reproductive function. If the two cycles are not properly coordinated, *infertility*, the inability to conceive or carry a pregnancy to term, results.

As in males, GnRH from the hypothalamus regulates reproductive function in females. However, in females, the GnRH pulse frequency and amplitude (amount secreted per pulse) change throughout the ovarian cycle. If the hypothalamus were a radio station, the pulse frequency would correspond to the radio frequency it is transmitting on, and the amplitude would be the volume. We will consider changes in pulse frequency, because their effects are both dramatic and reasonably well understood. Circulating levels of estrogens and progesterone primarily control changes in GnRH pulse frequency. Estrogens increase the GnRH pulse frequency, and progesterone decreases it.

The endocrine cells of the anterior lobe of the pituitary gland respond as if each group of endocrine cells is monitoring different frequencies. As a result, each group of cells is sensitive to some GnRH pulse frequencies and insensitive to others. For example, consider the *gonadotropes*, the cells that produce FSH and LH. At one pulse frequency, the gonadotropes respond preferentially and secrete FSH, but at another frequency, these cells release primarily LH. FSH and LH production also occurs in pulses that follow the rhythm of GnRH pulses. If GnRH is absent or is supplied at a constant rate (without pulses), FSH and LH secretion stops in a matter of hours.



Spotlight Figure 28–24 shows the changes in circulating hormone levels that accompany the ovarian and uterine cycles.

SPOTLIGHT

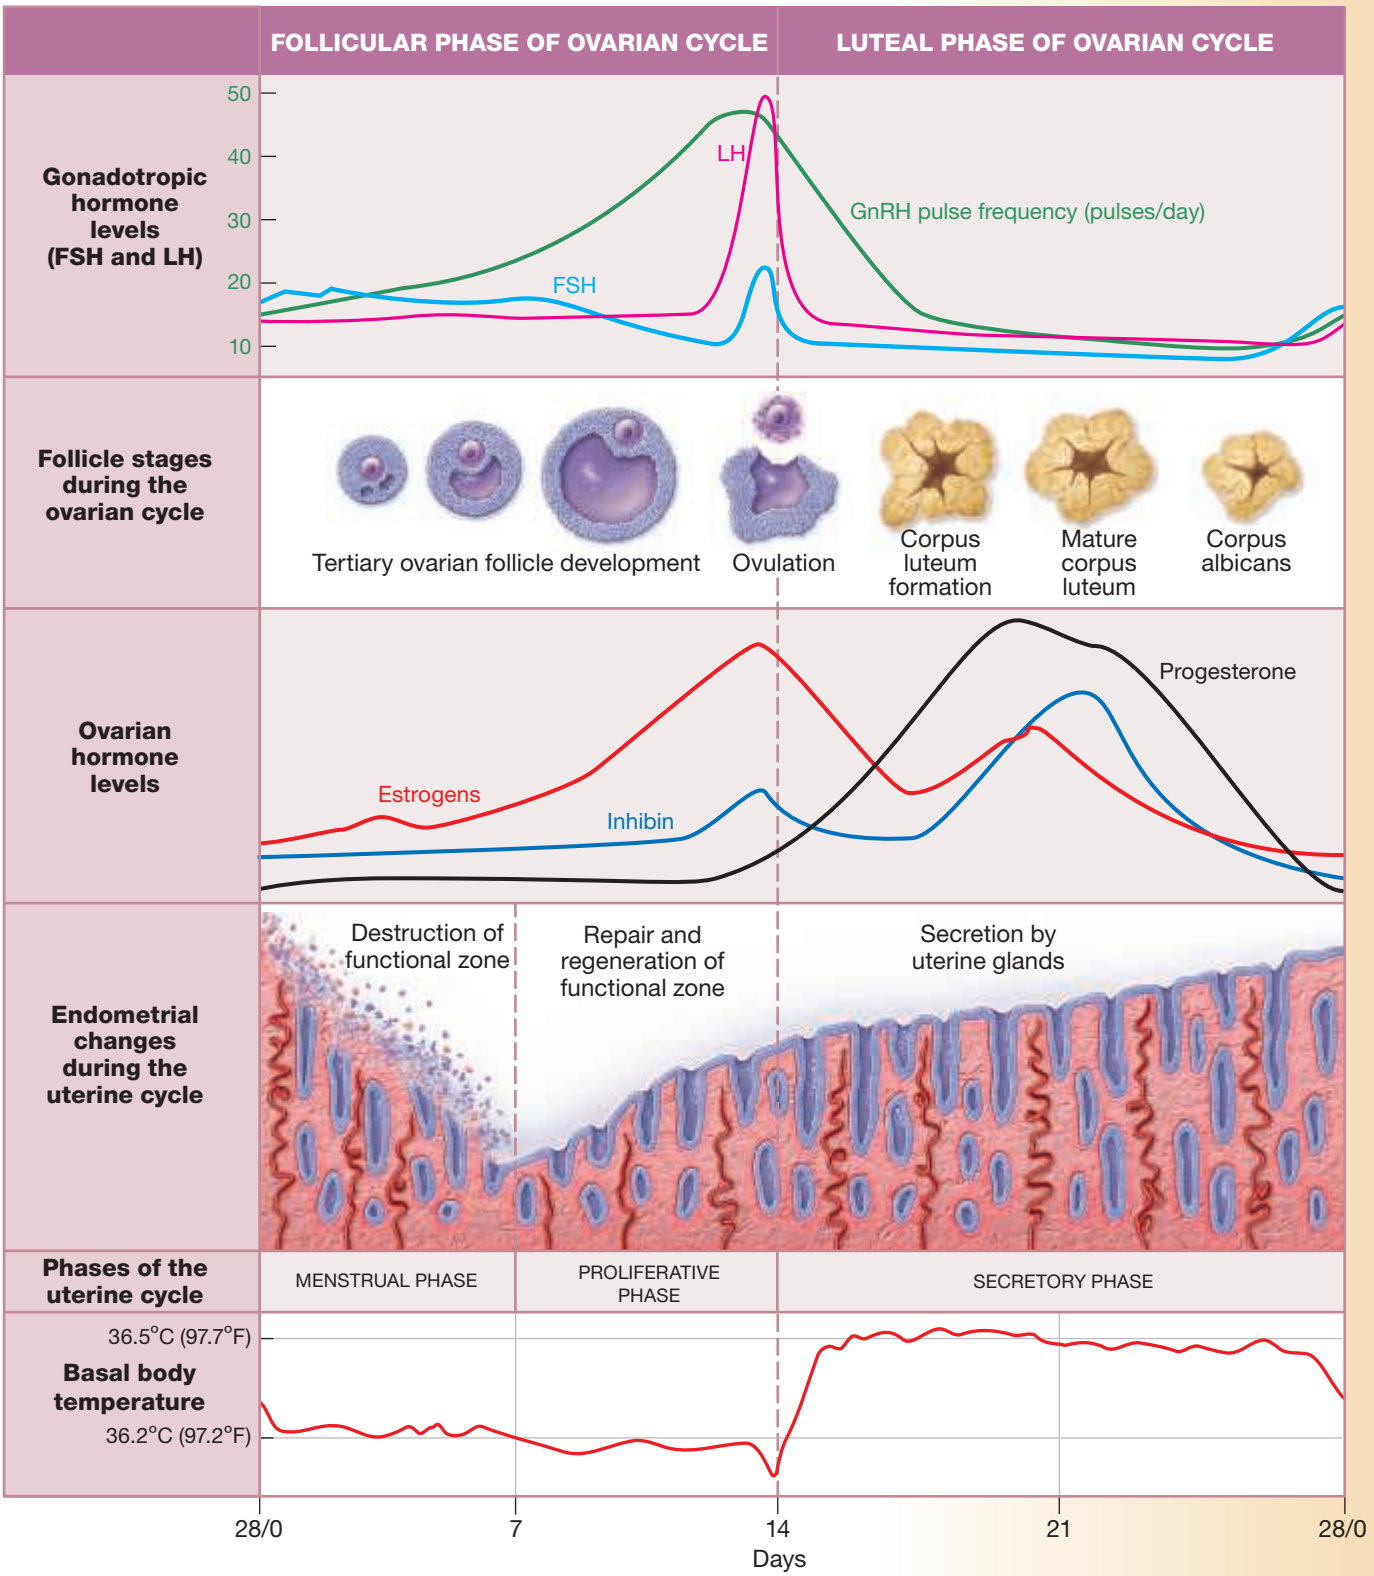


Figure 28–24
Hormonal Regulation of Female Reproduction

The ovarian and uterine cycles must operate in synchrony to ensure proper reproductive function. If the two cycles are not properly coordinated, infertility results. A female who doesn't ovulate cannot conceive, even if her uterus is perfectly normal. A female who ovulates normally, but whose uterus is not ready to support an embryo, will also be infertile.

As in males, GnRH from the hypothalamus regulates reproductive function in females. However, in females, GnRH levels change throughout the course of the ovarian cycle.

This illustration combines the key events in the ovarian and uterine cycles. The monthly hormonal fluctuations cause physiological changes that affect core body temperature. During the follicular phase—when estrogens are the dominant hormones—the **basal body temperature**, or the resting body temperature measured upon awakening in the morning, is about 0.3°C (0.5°F) lower than it is during the luteal phase, when progesterone dominates.

Early in the follicular phase of the ovarian cycle and prior to day 10, the levels of estrogens are low and the GnRH pulse frequency is 16–24 per day (one pulse every 60–90 minutes). At this frequency, FSH is the dominant hormone released by the anterior lobe of the pituitary gland. The estrogens released by developing follicles inhibit LH secretion. As tertiary ovarian follicles develop, the FSH level decreases due to the negative feedback effects of inhibin. Follicular development and maturation continue, however, supported by the combination of estrogens, FSH, and LH.

As one of the tertiary ovarian follicles becomes dominant, the concentration of circulating estrogens rises steeply. As a result, the GnRH pulse frequency increases to about 36 per day (one pulse every 30–60 minutes). The increased pulse frequency stimulates LH secretion. In addition, around day 10 of the cycle, the effect of estrogen on LH secretion changes from inhibition to stimulation. The switchover takes place only after the levels of estrogens have risen above a specific threshold value for about 36 hours. (The threshold value and the time required vary among individuals.) High levels of estrogens also increase gonadotrope sensitivity to GnRH. At about day 14, the estrogen levels have peaked, the gonadotropes are at maximum sensitivity, and the GnRH pulses are arriving about every 30 minutes. The result is a massive release of LH from the anterior lobe of the pituitary gland. This sudden surge in LH concentration triggers (1) the completion of meiosis I by the primary oocyte, (2) the forceful rupture of the follicular wall, and (3) ovulation. Typically, ovulation occurs 34–38 hours after the LH surge begins, roughly 9 hours after the LH peak.

Hormonal Regulation of the Ovarian Cycle

The phases of the ovarian cycle are regulated by various hormones. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are the main hormones influencing the follicular phases. Progesterone is the dominant hormone directing the luteal phase. If implantation does not occur, the menstrual cycle begins. This section describes the hormonal regulation of the ovarian cycle.

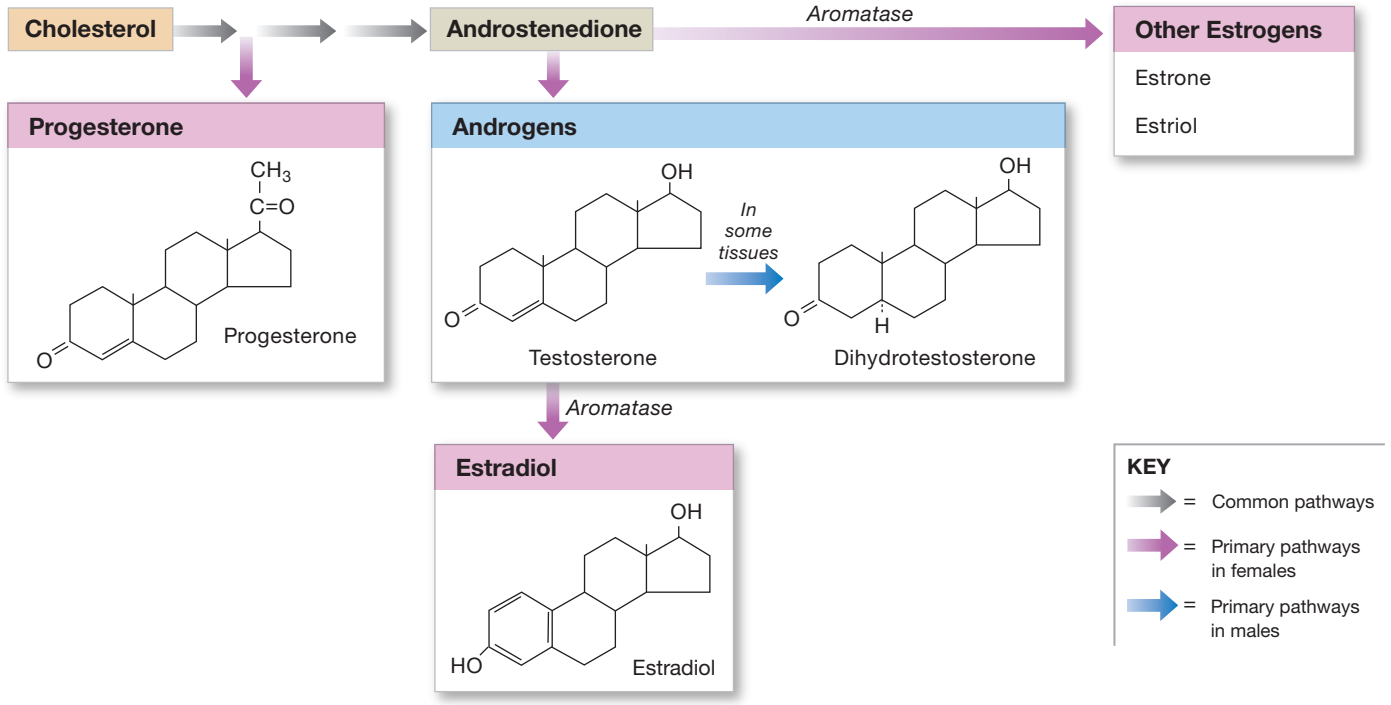
Regulation of the Follicular Phase. Follicular development begins under FSH stimulation. Each month some of the tertiary ovarian follicles begin to grow but only one will become dominant. As the follicles enlarge, thecal endocrine cells start producing *androstenedione*, a steroid hormone that is a key intermediate in the synthesis of estrogens and androgens. The granulosa cells absorb androstenedione and convert it to estrogens. In addition, thecal endocrine cells scattered throughout the ovarian stroma secrete small quantities of estrogens. Circulating estrogens are bound primarily to albumins, with lesser amounts carried by gonadal steroid-binding globulin (GBG).

Of the three estrogens circulating in the bloodstream—*estradiol*, *estrone*, and *estriol*—**estradiol** (es-tra-DĪ-ol) is the most abundant and has the most pronounced effects on target tissues. It is the dominant hormone prior to ovulation. In estradiol synthesis, androstenedione is first converted to testosterone, which the enzyme aromatase converts to estradiol (Figure 28–25). The synthesis of both estrone and estriol proceeds directly from androstenedione.

Estrogens have multiple functions that affect the activities of many tissues and organs throughout the body. Among the important general functions of estrogens are (1) stimulating bone and muscle growth; (2) maintaining female secondary sex characteristics, such as body hair distribution and the location of adipose tissue deposits; (3) affecting CNS activity, especially in the hypothalamus, where estrogens increase the sexual drive; (4) maintaining functional accessory reproductive glands and organs; and (5) initiating the repair and growth of the endometrium.

Regulation of the Luteal Phase. The high LH level that triggers ovulation also promotes progesterone secretion and the formation of the corpus luteum. As the progesterone level rises and the levels of estrogens fall, the GnRH pulse frequency decreases sharply, soon reaching 1–4 pulses per day. This frequency of GnRH pulses stimulates LH secretion more than it does FSH secretion, and the LH maintains the structure and secretory function of the corpus luteum.

The corpus luteum secretes moderate amounts of estrogens, but progesterone is the main hormone of the luteal phase. Its primary function is to continue the preparation of the uterus for pregnancy. Progesterone enhances the blood supply to the functional layer and stimulates the secretion of uterine glands. The progesterone level remains high for the next week, but unless pregnancy occurs, the corpus luteum begins to degenerate.



Approximately 12 days after ovulation, the corpus luteum becomes nonfunctional, and progesterone and estrogen levels fall markedly. The blood supply to the functional layer is restricted, and the endometrial tissues begin to deteriorate. As progesterone and estrogen levels drop, the GnRH pulse frequency increases, stimulating FSH secretion by the anterior lobe of the pituitary gland, and the ovarian cycle begins again.

The hormonal changes involved with the ovarian cycle in turn affect the activities of other reproductive tissues and organs. At the uterus, the hormonal changes maintain the uterine cycle.

Hormonal Regulation of the Uterine Cycle

Spotlight Figure 28–24 also shows the changes in the endometrium during a single uterine cycle. Progesterone and estrogen levels decrease as the corpus luteum degenerates, resulting in menstruation. The shedding of endometrial tissue continues for several days, until rising levels of estrogens stimulate the repair and regeneration of the functional layer of the endometrium. The proliferative phase then continues until a rising progesterone level marks the arrival of the secretory phase. The combination of estrogen and progesterone then causes the uterine glands to enlarge and increase their secretions.

Figure 28–25 Pathways of Steroid Hormone Synthesis in Males and Females. All gonadal steroids are derived from cholesterol. In men, the pathway ends with the synthesis of testosterone, which may subsequently be converted to dihydrotestosterone. In women, an additional step after testosterone synthesis leads to estradiol synthesis. The synthesis of progesterone and estrogens other than estradiol involves alternative pathways.

? What is the precursor for all steroid hormones in both males and females?

28-6 The autonomic nervous system influences male and female sexual function

Learning Outcome Discuss the physiology of sexual intercourse in males and females.

Sexual intercourse introduces semen into the female reproductive tract. The process, in which the autonomic nervous system plays a critical part, affects both the male and female reproductive systems.

Sexual intercourse can lead to several consequences, including pregnancy (both wanted and unintended) and sexually transmitted infections. We also discuss these subjects in this section.

Human Sexual Function

Human sexual function refers to how the body reacts during the sexual response.

Male Sexual Function

Complex neural reflexes coordinate sexual function in males. The reflex pathways use the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS). During sexual **arousal**, erotic thoughts, the stimulation of sensory nerves in the genital region, or both lead to an increase in parasympathetic outflow over the pelvic nerves. This outflow in turn leads to **erection** of the penis. The parasympathetic innervation of the penile arteries involves neurons that release nitric oxide at their axon terminals. The smooth muscles in the arterial walls relax when nitric oxide is released. At that time, the vessels dilate, blood flow increases, and the vascular channels become

engorged with blood. The skin covering the glans penis contains numerous sensory receptors, and erection tenses the skin and increases sensitivity. Subsequent stimulation can initiate the secretion of the bulbo-urethral glands, providing **lubrication** for the spongy urethra and the surface of the glans penis.

During intercourse, the sensory receptors of the penis are rhythmically stimulated. This stimulation eventually results in the coordinated processes of emission and ejaculation. **Emission** occurs under sympathetic stimulation. The process begins when the peristaltic contractions of the ampullae of the ductus deferentia push seminal fluid and sperm into the prostatic urethra. The seminal glands then begin contracting, and the contractions increase in force and duration over the next few seconds. Peristaltic contractions also appear in the walls of the prostate. The combination moves the seminal mixture into the membranous and penile portions of the urethra. As the contractions proceed, sympathetic commands also cause the contraction of the urinary bladder and the internal urethral sphincter. The combination of elevated pressure inside the bladder and the contraction of the sphincter effectively prevent semen from passing into the bladder.

Ejaculation occurs as powerful, rhythmic contractions appear in the *ischiocavernosus* and *bulbospongiosus*, two pairs of superficial skeletal muscles of the pelvic floor. The ischiocavernosus muscles insert along the sides of the penis. Their contractions serve primarily to stiffen that organ. The bulbospongiosus muscles wrap around the base of the penis. The contraction of these muscles pushes semen toward the external urethral opening. The contractions of both muscles are controlled by somatic motor neurons in the inferior lumbar and superior sacral segments of the spinal cord. (The positions of these muscles are shown in Figure 11–13b, p. 406.) Contraction of the smooth muscle within the prostate acts to pinch off the urethra, preventing urine from passing through the erect penis.

Ejaculation is associated with intensely pleasurable sensations associated with perineal muscle contraction, an experience known as male **orgasm** (OR-gazm). Several other noteworthy physiological changes take place at this time, including pronounced but temporary increases in heart rate and blood pressure. After orgasm, a **resolution** phase occurs as heart rate and blood pressure decrease and blood begins to leave the erectile tissue and the erection begins to subside. This process of losing an erection, called **detumescence** (dē-tū-MES-ens), is mediated by the sympathetic nervous system. A *refractory period* occurs during the initial period of resolution in which it is generally impossible for another orgasm to occur.

In sum, arousal, erection, emission, ejaculation, orgasm, and resolution are controlled by a complex interplay between the sympathetic and parasympathetic divisions of the ANS. Higher centers, including the cerebral cortex, can facilitate or inhibit many of the important reflexes, modifying sexual function.

Any physical or psychological factor that affects a single component of the system can result in male sexual dysfunction. **Erectile dysfunction (ED)**, or *impotence*, is an inability to achieve or maintain an erection. Various physical causes may be responsible for ED, because erection involves vascular changes as well as neural commands. For example, low blood pressure in the arteries supplying the penis, due to a circulatory blockage such as a plaque, will reduce the ability to attain an erection. Drugs, alcohol, trauma, or illnesses that affect the ANS or the CNS can have the same effect. But male sexual performance can also be strongly affected by the psychological state of the individual. Temporary periods of erectile dysfunction are fairly common in healthy individuals who are experiencing severe stresses or emotional problems. Depression, anxiety, and fear of ED are examples of emotional factors that can result in sexual dysfunction. Prescription drugs, which enhance and prolong the effects of nitric oxide on the erectile tissue of the penis, have proven useful in treating many cases of erectile dysfunction.

Female Sexual Function

The events in female sexual function are largely comparable to those of male sexual function. During sexual arousal, parasympathetic activation leads to engorgement of the erectile tissues of the clitoris and vestibular bulbs, and increased secretion from cervical mucous glands and greater vestibular glands. Clitoral erection increases the receptors' sensitivity to stimulation, and the cervical and vestibular glands lubricate the vaginal walls. A network of blood vessels in the vaginal walls becomes filled with blood at this time, and the vaginal surfaces are also moistened by fluid that moves across the epithelium from underlying connective tissues. (This process accelerates during intercourse as the result of mechanical stimulation.) Parasympathetic stimulation also causes contraction of subcutaneous smooth muscle of the nipples, making them more sensitive to touch and pressure.

During sexual intercourse, rhythmic contact of the penis with the clitoris and vaginal walls—reinforced by touch sensations from the breasts and other stimuli (visual, olfactory, and auditory)—provides stimulation that can lead to orgasm. Female orgasm is accompanied by peristaltic contractions of the uterine and vaginal walls and, through impulses traveling over the pudendal nerves, rhythmic contractions of the bulbospongiosus and ischiocavernosus muscles. The latter contractions give rise to the intensely pleasurable sensations of orgasm. Unlike resolution and the refractory period in men, women may have little delay in achieving further orgasms.

Contraception and Infertility

Many different methods can be used to promote or avoid pregnancy. For example, at the time of ovulation, the basal body temperature (BBT) decreases noticeably, making the rise

in temperature over the next day even more noticeable (see Spotlight Figure 28–24). Urine tests that detect LH are available, and testing daily for several days before expected ovulation can detect the LH surge more reliably than the BBT changes. Because fertilization typically occurs within a day of ovulation, this information can be used to time intercourse according to the wishes of the couple. Using this to avoid conception is called the *rhythm method*.

Other forms of **contraception** (methods to prevent pregnancy) include abstinence, barrier methods, intrauterine devices, chemical methods such as "the pill," and surgical methods.

Some couples find they have the opposite problem, and they are unable to conceive. **Infertility** is defined as the inability to conceive or carry a pregnancy to term after 1 year of unprotected intercourse. Infertility, which affects about 10 percent of the U.S. population, can happen in both males and females.

For men, the most common issues are low sperm count and motility. Most males with lower sperm counts are infertile, because too few sperm survive the ascent of the female reproductive tract to perform fertilization. A low sperm count may reflect inflammation of the epididymis, ductus deferens, or prostate. Common abnormalities in sperm are malformed heads and "twin" sperm that did not separate at the time of spermiation.

For women, all of their reproductive organs and hormonal regulation must work properly to conceive and carry a pregnancy to term. If menarche does not appear by age 16, or if the normal uterine cycle of an adult woman is interrupted for 6 months or more, the condition of **amenorrhea** (ā-men-ō-RĒ-uh) exists. *Primary amenorrhea* is the failure to initiate menstruation. This condition may indicate developmental abnormalities, such as nonfunctional ovaries, the absence of a uterus, or an endocrine or genetic disorder. It can also result from malnutrition: Puberty is delayed if the leptin level is too low. ↩ p. 692

Severe physical or emotional stresses can cause transient *secondary amenorrhea*. In effect, the reproductive system gets "switched off." Factors associated with amenorrhea include drastic weight loss, anorexia nervosa, and severe depression or grief. Amenorrhea has also been observed in marathon runners and other women engaged in training programs that require sustained high levels of exertion, which severely reduce body lipid reserves.

Sexually Transmitted Diseases (STDs)

Sexual activity carries with it the risk of infection with a variety of microorganisms. The consequences of such an infection may range from merely inconvenient to potentially lethal. **Sexually transmitted diseases (STDs)**, also called **sexually transmitted infections (STIs)**, are transferred from individual to individual, primarily or exclusively by sexual intercourse. At least two dozen bacterial, viral, and fungal infections are currently recognized as STIs. The bacterium *Chlamydia* can cause **pelvic inflammatory disease (PID)** and infertility. The *Zika virus* (*ZIKV*) is a cause of fetal brain defects, including microcephaly. Recent evidence indicates it can be spread through sexual contact. AIDS, caused by a virus, is deadly.

The incidence of STDs is a significant health challenge in the United States. According to the Centers for Disease Control and Prevention (CDC), an estimated 20 million new cases occur each year, almost 50 percent in people aged 15–24.

28-7 Changes in levels of reproductive hormones cause functional changes throughout the life span

Learning Outcome Describe the reproductive system changes that occur with development and aging.

Sex hormones have widespread effects on the body and begin early in development. They affect brain development and behavioral drives, muscle mass, bone mass and density, body proportions, and the patterns of hair and body fat distribution. As noted earlier in the chapter, these systems become fully functional at puberty. At puberty, secretion of sex hormones in both sexes accelerates markedly, initiating sexual maturation and the appearance of secondary sex characteristics. Later on, the aging process affects all body systems, including the reproductive systems of both men and women.

Development of the Genitalia

Male and female reproductive systems develop from an embryonic aggregation of cells, termed *primordial cells*. Primordial cells form the first trace of an organ. Both reproductive systems follow a similar pattern of development from the same primordial tissues. They become distinct from each other because of the influence of sex hormones.

Around weeks 5–6 of embryonic development, an embryo is said to be *sexually indifferent*, because the gonads and other

internal and external reproductive structures are similar in both sexes. Whether male or female gonads develop depends on the embryo's genetic makeup. (We discuss the basis of sex determination in Chapter 29.) The male gonads begin to form during week 7. Female gonads begin forming about a week later. Once the testes have formed, they begin to secrete testosterone continuously throughout fetal development and until a few days after birth. Testosterone stimulates the differentiation and development of male reproductive structures. Without testosterone, the sexually indifferent embryo will develop female reproductive structures.

The development of male and female genitalia from a sexually indifferent stage is shown in **Figure 28–26**. At week 4 of development, a temporary cloacal opening marks the site of the future genitalia (**Figure 28–26a**). A *cloaca* is a cavity or chamber at the end of the digestive tract open to both excretory and reproductive products. By week 6, the cloacal opening becomes subdivided, thus isolating the digestive tract from future urogenital structures. An anterior urogenital membrane will eventually form the urethra and urinary bladder. The genital tubercle present in the sexually indifferent stage will give rise to the penis in the male and clitoris in the female (see **Figure 28–26b,c**).

During fetal development, the testes form inside the body cavity adjacent to the kidneys. A bundle of connective tissue fibers—called the *gubernaculum testis* (gū-bur-NAK-ū-lum TES-tis; plural, *gubernacula*)—extends from each testis to the posterior wall of a small anterior and inferior pocket of the peritoneum. As the fetus grows, the gubernacula do not get any longer, so they lock the testes in position. As a result, the position of each testis changes as the body enlarges. The testis gradually moves inferiorly and anteriorly toward the anterior abdominal wall. During the seventh developmental month, fetal growth continues rapidly, and circulating hormones stimulate a contraction of the gubernaculum testis. During this time, each testis moves through the abdominal musculature, along with small pockets of the peritoneal cavity. This process is called the *descent of the testes* into the scrotum (see **Figure 28–26b**). Descent of the female gonads is much less than that in males. The ovaries come to lie below the rim of the true pelvis. They are held in place by the suspensory ligament, ovarian ligament, and round ligament of the uterus (see **Figure 28–16**).

In *cryptorchidism* (krip-TOR-ki-dizm; *crypto*, hidden + *orchis*, testis), one or both of the testes have not descended into the scrotum by the time of birth. Typically, the cryptorchid (abdominal) testes are lodged in the abdominal cavity or within the inguinal canal. Cryptorchidism occurs in about 3 percent of full-term deliveries and in about 30 percent of premature births. In most instances, normal descent takes place a few weeks later.

The condition can be surgically corrected if it persists. Corrective measures should be taken before *puberty* (sexual maturation), because a cryptorchid testis will not produce sperm. If both testes are cryptorchid, the male will be *sterile (infertile)* and unable to father children. If the testes cannot be moved into the scrotum, they will usually be removed. This surgical procedure to remove the testes is called an *orchiectomy* (or-kē-EK-tō-mē). About 10 percent of males with uncorrected cryptorchid testes eventually develop testicular cancer.

As each testis moves through the body wall, the ductus deferens and the testicular blood vessels, nerves, and lymphatic vessels accompany it. Together, these structures form the body of the spermatic cord (see **Figure 28–2**, p. 1104).

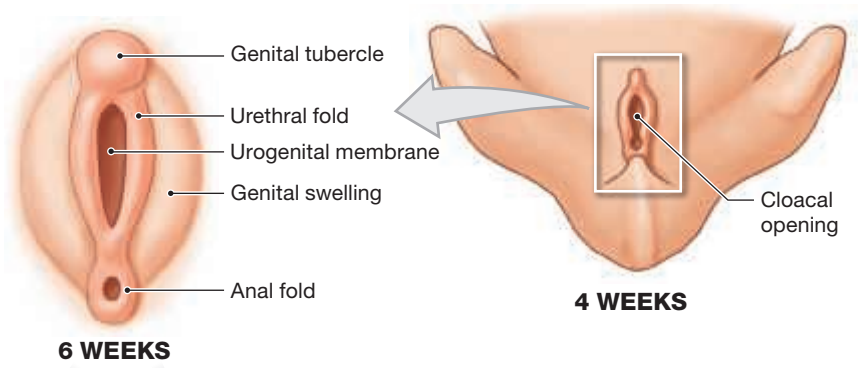
Effects of Aging

As aging occurs, reductions in sex hormone levels affect appearance, strength, and a variety of physiological functions. The most striking age-related changes in the female reproductive system occur at menopause. Comparable age-related changes in the male reproductive system occur more gradually and over a longer period of time.

The Male Climacteric

Changes in the male reproductive system take place more gradually than do those in the female reproductive system. The period of declining reproductive function, which corresponds to perimenopause in women, is known as the **male climacteric** or *andropause*. The level of circulating testosterone begins to decrease between the ages of 50 and 60, and levels of circulating FSH and LH increase. Although sperm production continues (men well into their 80s can father children), older men experience a gradual reduction in sexual activity. This decrease may be linked to the declining testosterone level. Some clinicians suggest the use of testosterone replacement therapy to enhance the libido (sexual drive) of elderly men, but this may increase the risk of prostate disease.

Menopause



Menopause is usually defined as the time when ovulation and menstruation cease. Menopause typically occurs at age 45–55, but in the years immediately preceding it, an interval called *perimenopause*, the ovarian and uterine cycles become irregular. A shortage of primordial ovarian follicles is the underlying cause of the irregular cycles. With the arrival of perimenopause, the number of primordial ovarian follicles responding each month begins to decrease markedly. As their numbers decrease, the levels of estrogens decrease and may not increase enough to trigger ovulation. By age 50, there are often no primordial ovarian follicles left to respond to FSH. In **premature menopause**, this depletion occurs before age 40.

Menopause is accompanied by a decrease in circulating concentrations of estrogens and progesterone, and a sharp and sustained increase in the production of GnRH, FSH, and LH. The decrease in the levels of estrogens leads to reductions in

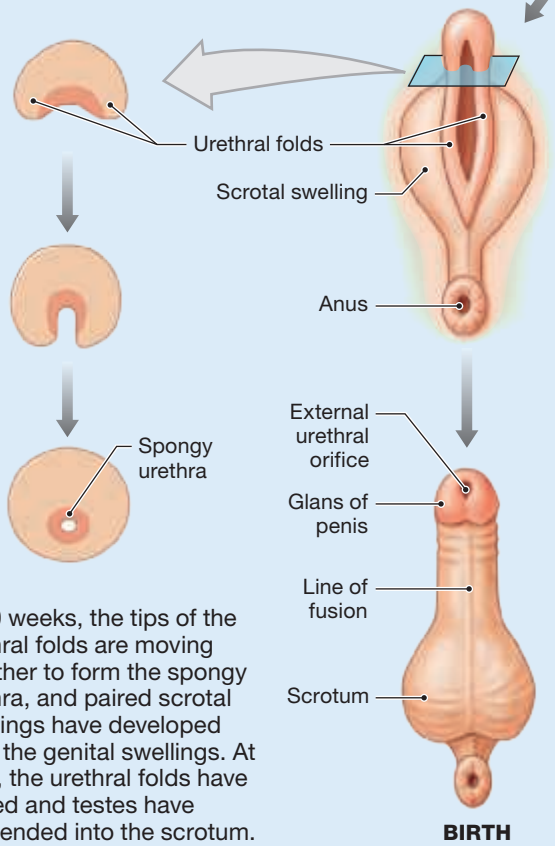


Figure 28–26 The Development of Male and Female Genitalia.

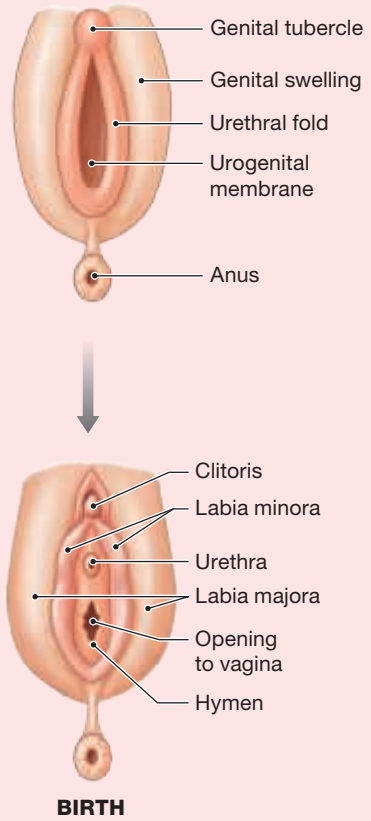
a

By 6 weeks, the cloacal opening has been subdivided into a posterior anal membrane and an anterior urogenital membrane. Urethral folds develop and prominent genital swellings form lateral to each urethral fold. The genital tubercle will develop into either the penis in males, or clitoris in females, depending on the presence or absence of testosterone.



b **Development of the Male Genitalia**

At 10 weeks, the tips of the urethral folds are moving together to form the spongy urethra, and paired scrotal swellings have developed from the genital swellings. At birth, the urethral folds have closed and testes have descended into the scrotum.

c **Development of the Female Genitalia**

In the female, the urethral folds do not fuse; they develop into the labia minora. The genital swellings will form the labia majora. The genital tubercle develops into the clitoris. The urethra opens to the exterior immediately posterior to the clitoris. The hymen remains as an elaboration of the urogenital membrane.

COMPARISON OF MALE AND FEMALE GENITALIA

MALE	FEMALE
Penis	Clitoris
Corpora cavernosa	Erectile tissue
Corpus spongiosum	Bulbs of vestibule
Proximal shaft of penis	Labia minora
Spongy urethra	Vestibule
Bulbo-urethral glands	Greater vestibular glands
Scrotum	Labia majora

the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal epithelia. The decreased concentrations of estrogens have also been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate. A variety of neural effects are reported as well, including "hot flashes," anxiety, and depression. Hot flashes typically begin while the levels of estrogens are decreasing, and cease when the levels of estrogens reach minimal values. These intervals of increased body temperature are associated with surges in LH production. The hormonal mechanisms involved in other CNS effects of menopause are poorly understood. In addition, the risks of atherosclerosis and other forms of cardiovascular disease increase after menopause.

Some women experience only mild symptoms, but some experience acutely unpleasant symptoms in perimenopause or during or after menopause. For most of those women, hormone replacement therapy (HRT) involving a combination of estrogens and progesterone can control the unpleasant neural and vascular changes associated with menopause. The hormones are administered as pills, by injection, or by transdermal "estrogen patches." However, recent studies suggest that taking estrogen replacement therapy for more than 5 years increases the risk of heart disease, breast cancer, Alzheimer's disease, blood clots, and stroke. HRT should be used only after a full discussion and assessment of the potential risks and benefits, and taken for as short a time as possible.

28-8 The reproductive system secretes hormones affecting growth and metabolism of all body systems

Learning Outcome Give examples of interactions between the reproductive system and each of the other organ systems.

Normal human reproduction is a complex process that involves multiple systems. The hormones discussed in this chapter play a major role in coordinating reproductive events (**Table 28–1**). Physical factors also play a role. The man's sperm count must be adequate, the semen must have the correct pH and nutrients, and erection and ejaculation must occur in the proper sequence. The woman's ovarian and uterine cycles must be properly coordinated; ovulation and oocyte transport must occur normally. Her reproductive tract must provide a hospitable environment

Table 28–1 Hormones of the Reproductive System

Hormone	Source	Regulation of Secretion	Primary Effects
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	*Males:* inhibited by testosterone and possibly by inhibin *Females:* GnRH pulse frequency increased by estrogens, decreased by progesterone	*Males:* stimulates FSH secretion and LH synthesis *Females:* stimulates FSH secretion and LH synthesis
Follicle-stimulating hormone (FSH)	Anterior lobe of the pituitary gland	*Males:* stimulated by GnRH, inhibited by inhibin *Females:* stimulated by GnRH, inhibited by inhibin	*Males:* stimulates spermatogenesis and spermiogenesis through effects on nurse cells *Females:* stimulates follicle development, estrogen production, and oocyte maturation
Luteinizing hormone (LH)	Anterior lobe of the pituitary gland	*Males:* stimulated by GnRH *Females:* production stimulated by GnRH, secretion by the combination of high GnRH pulse frequencies and high estrogen levels	*Males:* stimulates interstitial cells to secrete testosterone *Females:* stimulates ovulation, formation of corpus luteum, and progesterone secretion
Androgens (primarily testosterone and dihydrotestosterone)	Interstitial endocrine cells of testes	Stimulated by LH	Establish and maintain male secondary sex characteristics and sexual behavior; promote maturation of sperm; inhibit GnRH secretion
Estrogens (primarily estradiol)	Granulosa and thecal endocrine cells of developing follicles; corpus luteum	Stimulated by FSH	Stimulate LH secretion (at high levels); establish and maintain female secondary sex characteristics and sexual behavior; stimulate repair and growth of endometrium; increase frequency of GnRH pulses
Progesterone	Granulosa cells from midcycle through functional life of corpus luteum	Stimulated by LH	Stimulate endometrial growth and glandular secretion; reduce frequency of GnRH pulses
Inhibin	Nurse cells of testes and granulosa cells of ovaries	Stimulated by factors released by developing sperm (male) and developing follicles (female)	Inhibits secretion of FSH (and possibly of GnRH)

Build Your Knowledge

Figure 28–27 Integration of the REPRODUCTIVE system with the other body systems presented so far.

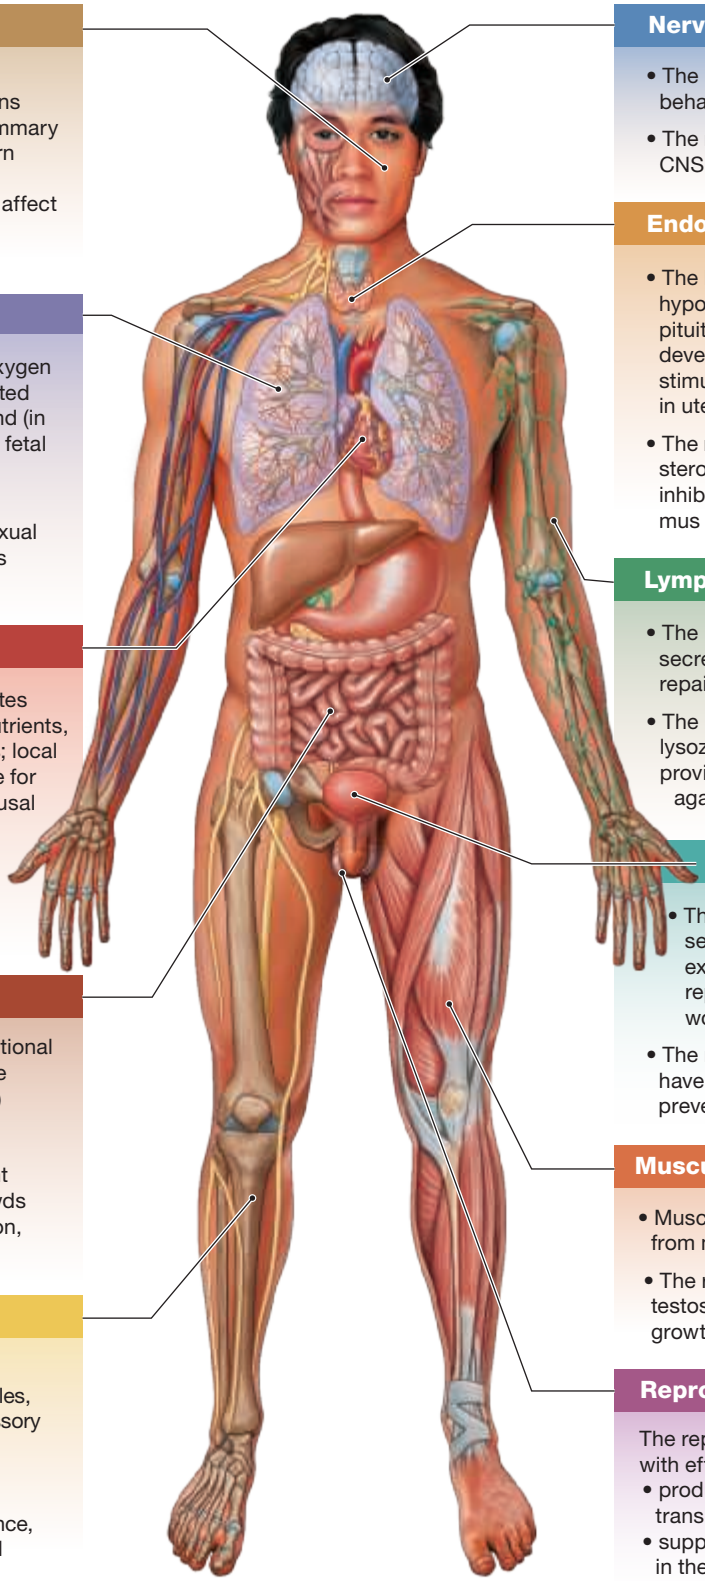
Integumentary System

- The Integumentary System covers external genitalia; provides sensations that stimulate sexual behaviors; mammary gland secretions nourish the newborn
- The reproductive system hormones affect the distribution of body hair and subcutaneous fat

Respiratory System

- The Respiratory System provides oxygen and removes carbon dioxide generated by tissues of reproductive system and (in pregnant women) by embryonic and fetal tissues
- The reproductive system changes respiratory rate and depth during sexual arousal, under control of the nervous system

Cardiovascular System



- The Cardiovascular System distributes reproductive hormones; provides nutrients, oxygen, and waste removal for fetus; local blood pressure changes responsible for physical changes during sexual arousal
- The reproductive system produces estrogens that may help maintain healthy vessels and slow development of atherosclerosis

Digestive System

- The Digestive System provides additional nutrients required to support gamete production and (in pregnant women) embryonic and fetal development
- The reproductive system in pregnant women with a developing fetus crowds digestive organs, causes constipation, and increases appetite

Skeletal System

- The Skeletal System (pelvic girdle) protects reproductive organs of females, portion of ductus deferens and accessory glands in males
- The reproductive system hormones stimulate bone growth and maintenance, and at puberty accelerate growth and closure of epiphyseal cartilages

Nervous System

- The Nervous System controls sexual behaviors and sexual function
- The reproductive system hormones affect CNS development and sexual behaviors

Endocrine System

- The Endocrine System produces hypothalamic regulatory hormones and pituitary hormones that regulate sexual development and function; oxytocin stimulates smooth muscle contractions in uterus and mammary glands
- The reproductive system produces steroid sex hormones and inhibin that inhibit secretory activities of hypothalamus and pituitary gland

Lymphatic System

- The Lymphatic System provides IgA for secretions by epithelial glands; assists in repairs and defense against infection
- The reproductive system secretes lysozymes and bactericidal chemicals that provide innate (nonspecific) defense against reproductive tract infections

Urinary System

- The Urinary System in males carries semen to exterior in urethra; kidneys excrete wastes generated by reproductive tissues and (in pregnant women) by a growing embryo and fetus
- The reproductive system secretions may have antibacterial activity that helps prevent urethral infections in males

Muscular System

- Muscular System contractions eject semen from male reproductive tract
- The reproductive system hormone testosterone accelerates skeletal muscle growth

Reproductive System

The reproductive system secretes hormones with effects on growth and metabolism. It:

- produces, stores, nourishes, and transports male and female gametes
- supports the developing embryo and fetus in the uterus

for the survival and movement of sperm, and for the subsequent fertilization of the oocyte. For these steps to occur, the reproductive, digestive, endocrine, nervous, cardiovascular, and urinary systems must all be functioning normally.

Even when all else is normal and fertilization occurs at the proper time and place, a healthy infant will not be produced unless the **zygote**—the union of an ovum with a sperm forming a single cell the size of a pinhead—manages to develop into a full-term fetus that typically weighs about 3 kg (6.6 lb). In Chapter 29 we will consider the process of development, focusing on the mechanisms that determine both the structure of the body and the distinctive characteristics of each individual.

Even though the reproductive system's primary function—producing offspring—doesn't play a role in maintaining homeostasis, reproduction depends on a variety of physical, physiological, and psychological factors. Many of these factors require intersystem cooperation. In addition, the hormones that control and coordinate sexual function have direct effects on the organs and tissues of other systems. For example, testosterone and estradiol affect both muscular development and bone density. Build Your Knowledge **Figure 28–27** summarizes the functional relationships between the reproductive system and other body systems.

28 Chapter Review

Study Outline

An Introduction to the Reproductive System p. 1102

1. The *reproductive system* is the only system that is not essential to the life of an individual, but it ensures continuation of our species.

28-1 Male and female reproductive system structures produce gametes that combine to form a new individual p. 1102

2. The human **reproductive system** produces, stores, nourishes, and transports functional **gametes** (reproductive cells). **Fertilization** is the fusion of male and female gametes.
3. The reproductive system includes **gonads** (**testes** or **ovaries**), ducts, accessory glands and organs, and the **external genitalia**.
4. In males, the testes produce **sperm**, which are expelled from the body in **semen** during *ejaculation*. The ovaries of a sexually mature female produce **oocytes** (immature **ova**) that travel along *uterine tubes* toward the *uterus*. The *vagina* connects the uterus with the exterior of the body.

28-2 The structures of the male reproductive system consist of the testes, duct system, accessory glands, and penis p. 1103

5. Sperm travel along the *epididymis*, the *ductus deferens*, the *ejaculatory duct*, and the *urethra* before leaving the body. Accessory organs (notably the *seminal glands*, *prostate*, and *bulbo-urethral gland*) secrete fluids into the ejaculatory ducts and the urethra. The *scrotum* encloses the testes, and the *penis* is an erectile organ. *(Figure 28–1)*
6. The **raphe** marks the boundary between the two chambers in the **scrotum**. *(Figure 28–3)*

- A&P Flix
- Interactive Physiology IP2
- PhysioEx PhysioEx 9.1

7. The **dartos** muscle tightens the scrotum, giving it a wrinkled appearance as it elevates the testes. The **cremaster** has skeletal muscle fibers that pull the testes close to the body.
8. The **tunica albuginea** surrounds each testis. Septa extend from the tunica albuginea to the region of the testis closest to the entrance to the epididymis, creating a series of **lobules**. *(Figure 28–3)*
9. **Seminiferous tubules** within each lobule are the sites of sperm production. From there, sperm pass through the **rete testis**. Seminiferous tubules connect to a **straight tubule**. **Efferent ductules** connect the rete testis to the epididymis. Between the seminiferous tubules are **interstitial cells**, which secrete sex hormones. *(Figures 28–3, 28–4)*
10. From the testis, the sperm enter the **epididymis**, an elongated tubule with **head**, **body**, and **tail** regions. The epididymis monitors and adjusts the composition of the fluid in the seminiferous tubules, serves as a recycling center for damaged sperm, stores and protects sperm, and facilitates their functional maturation. *(Figure 28–5)*
11. The **ductus deferens**, or *vas deferens*, begins at the epididymis and passes through the inguinal canal as part of the spermatic cord. Near the prostate, the ductus deferens enlarges to form

the **ampulla of ductus deferens**. The junction of the base of the seminal gland and the ampulla creates the **ejaculatory duct**, which empties into the urethra. *(Figures 28–5, 28–6)*

12. The **urethra** extends from the urinary bladder to the tip of the penis. The urethra can be divided into *prostatic*, *membranous*, and *spongy regions.*
13. Each **seminal gland (seminal vesicle)** is an active secretory gland that contributes about 60 percent of the volume of semen. Its secretions contain fructose (which is easily metabolized by sperm), bicarbonate ions, prostaglandins, and fibrinogen. The **prostate** secretes slightly acidic **prostatic fluid.** Alkaline mucus secreted by the **bulbo-urethral glands** has lubricating properties. *(Figures 28–6, 28–7)*
14. A typical ejaculation releases 2–5 mL of semen (**ejaculate**), which contains 20–100 million sperm per milliliter. The fluid component of semen is **seminal fluid**.
15. The skin overlying the **penis** resembles that of the scrotum. Most of the **body** of the penis consists of three masses of **erectile tissue**. Beneath the superficial fascia are two **corpora cavernosa** and a single **corpus spongiosum**, which surrounds the urethra. Dilation of the blood vessels within the erectile tissue produces an **erection**. *(Figure 28–7)*

28-3 Spermatogenesis occurs in the testes, and hormones from the hypothalamus, pituitary gland, and testes control male reproductive functions p. 1111

16. Seminiferous tubules contain **spermatogonia**, stem cells involved in **spermatogenesis** (the production of sperm).
17. **Nurse** (Sertoli) **cells** sustain and promote the development of sperm. *(Figures 28–8, 28–9, 28–10)*
18. Each **sperm** has a **head** capped by an **acrosome**, a **middle piece**, and a **tail**. *(Figure 28–11)*
19. Important regulatory hormones include **FSH** *(follicle-stimulating hormone)*, **LH** *(luteinizing hormone)*, and **GnRH** *(gonadotropin-releasing hormone)*. *Testosterone* is the most important androgen. *(Spotlight Figure 28–12)*

28-4 The structures of the female reproductive system consist of the ovaries, uterine tubes, uterus, vagina, and external genitalia p. 1118

20. Principal organs of the female reproductive system include the *ovaries*, *uterine tubes*, *uterus*, *vagina*, and external genitalia. *(Figure 28–13)*
21. The ovaries, uterine tubes, and uterus are enclosed within the **broad ligament**. The **mesovarium** supports and stabilizes each ovary. *(Figure 28–14)*
22. The ovaries are held in position by the **ovarian ligament** and the **suspensory ligament**. Major blood vessels enter the ovary at the **ovarian hilum**. Each ovary is covered by a **tunica albuginea**. *(Figure 28–14)*
23. Each **uterine tube** has an **infundibulum** with **fimbriae** (fingerlike projections), an **ampulla**, and an **isthmus**. Each uterine tube opens into the *uterine cavity.* For fertilization to occur, a secondary oocyte must encounter sperm during the first 12–24 hours of its passage from the infundibulum to the uterus. *(Figure 28–15)*
24. *Peg cells* lining the uterine tube secrete a fluid that completes the capacitation of sperm.
25. The **uterus** provides mechanical protection, nutritional support, and waste removal for the developing embryo and fetus. Normally, the uterus bends anteriorly near its base (*anteflexion*). The **broad ligament**, **uterosacral ligaments**, **round ligaments**, and **lateral ligaments** stabilize the uterus. *(Figure 28–16)*
26. Major anatomical landmarks of the uterus include the **body**, **isthmus**, **cervix**, **external os** *(external orifice)*, **uterine cavity**, **cervical canal**, and **internal os** *(internal orifice)*. The uterine wall consists of an inner **endometrium**, a muscular **myometrium**, and a superficial **perimetrium** (an incomplete serous layer). *(Figures 28–16, 28–17)*
27. The **vagina** is a muscular tube extending between the uterus and the external genitalia; it is lined by a nonkeratinized stratified squamous epithelium. A thin epithelial fold, the **hymen**, partially blocks the entrance to the vagina until physical distortion ruptures the membrane. *(Figures 28–18, 28–19)*
28. The components of the **vulva** are the **vestibule**, **labia minora**, **urethral glands**, **clitoris**, **mons pubis, labia majora**, and **lesser** and **greater vestibular glands**. *(Figure 28–19)*
29. A newborn infant is nourished from milk secreted by the maternal **mammary gland** in each breast. *(Figure 28–20)*

28-5 Oogenesis occurs in the ovaries, and hormones from the hypothalamus, pituitary gland, and ovaries control female reproductive functions p. 1128

30. Ovaries are the site of **oogenesis** (ovum production), which occurs in **ovarian follicles**. Follicle development proceeds from **primordial ovarian follicles** through **primary**, **secondary**, and **tertiary ovarian follicles**. A dominant tertiary ovarian follicle forms during the **ovarian cycle**. The **ovarian cycle** is divided into a **follicular** *(preovulatory)* **phase** and a **luteal** *(postovulatory)* **phase**. *(Figures 28–21, 28–22)*
31. At **ovulation**, a **secondary oocyte** and the attached follicular cells of the **corona radiata** are released through the ruptured ovarian wall. The follicular cells remaining within the ovary form the **corpus luteum**, which later degenerates into scar tissue called a **corpus albicans**. *(Figure 28–22)*
32. A typical 28-day **uterine**, or *menstrual*, **cycle** begins with the onset of menstruation, also called **menses**, and the destruction of the **functional layer** of the endometrium. This process of **menstruation** continues from 1 to 7 days. *(Figure 28–23)*
33. After the **menstrual phase**, the **proliferative phase** begins, and the functional layer thickens and undergoes repair. The proliferative phase is followed by the **secretory phase**, during which uterine glands enlarge. Menstruation begins at **menarche** and continues until **menopause**. *(Figure 28–23)*
34. Hormonal regulation of the **female reproductive cycle** involves the coordination of the ovarian and uterine cycles. *(Spotlight Figure 28–24)*
35. **Estradiol**, the most important *estrogen*, is the dominant hormone of the follicular phase. Ovulation occurs in response to a midcycle surge in LH. *(Spotlight Figure 28–24; Figure 28–25)*
36. The hypothalamic secretion of GnRH occurs in pulses that trigger the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian interstitial cells produce estrogens. High estrogen levels stimulate LH secretion, increase pituitary sensitivity to GnRH, and increase the GnRH pulse frequency. **Progesterone** is the main hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for maintaining the uterine cycle. *(Spotlight Figure 28–24)*

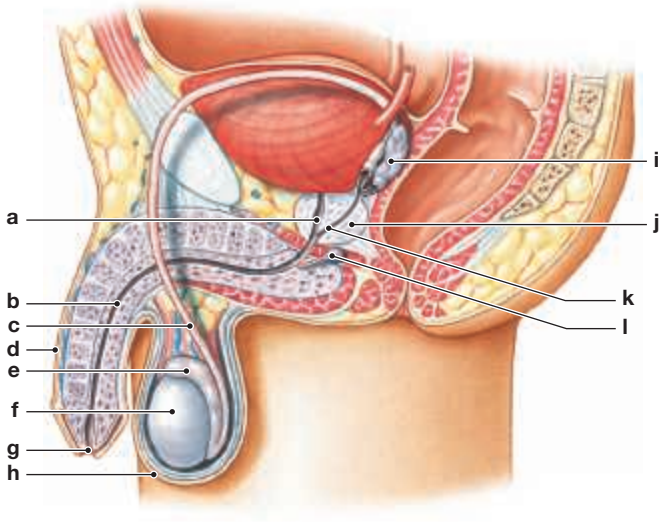
28-6 The autonomic nervous system influences male and female sexual function p. 1137

37. During sexual **arousal** in males, erotic thoughts, sensory stimulation, or both lead to parasympathetic activity that produces erection. Stimuli accompanying **sexual intercourse** lead to **emission** and **ejaculation**. Contractions of the bulbospongiosus muscles are associated with **orgasm**. During **resolution**, the heart rate and blood pressure decrease and blood begins to leave the erectile tissue and the erection begins to subside.
38. The events of female sexual function resemble those of male sexual function, with parasympathetic arousal and skeletal muscle contractions associated with orgasm.
39. **Infertility** is the inability to conceive or carry a pregnancy to term after 1 year of unprotected intercourse.

28-7 Changes in levels of reproductive hormones cause functional changes throughout the life span p. 1139

40. At weeks 5–6 of embryonic development, an embryo is said to be **sexually indifferent**, because the gonads and other internal and external reproductive structures are similar in both sexes. The presence of testosterone stimulates the differentiation and development of male reproductive structures. Without testosterone, the sexually indifferent embryo will develop female reproductive structures. *(Figure 28–26)*
41. The **descent of the testes** through the *inguinal canals* begins during the seventh month of fetal development.
42. During the **male climacteric**, at ages 50–60, circulating testosterone levels decrease, and FSH and LH levels increase.
43. Menopause (the time that ovulation and menstruation stop) typically occurs at ages 45–55. The production of GnRH, FSH, and LH rises, whereas circulating concentrations of estrogen and progesterone decrease.

28-8 The reproductive system secretes hormones affecting growth and metabolism of all body systems p. 1142



44. Normal human reproduction depends on a variety of physical, physiological, and psychological factors, many of which require intersystem cooperation. *(Figure 28–27; Table 28–1)*

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. All of the following structures are part of the spermatic cord *except* the **(a)** ductus deferens, **(b)** pampiniform plexus, **(c)** genitofemoral nerve, **(d)** testicular artery, **(e)** epididymis.
2. The uterus **(a)** undergoes the uterine cycle every month, **(b)** has a thick, muscular myometrium, **(c)** has a tubular cervix that projects into the vagina, **(d)** does/has all of these.
3. In meiosis, sister chromatids separate during **(a)** prophase I, **(b)** metaphase I, **(c)** anaphase I, **(d)** anaphase II.
4. Gonadotropin-releasing hormone **(a)** stimulates FSH secretion and LH synthesis in only males, **(b)** stimulates FSH secretion and LH synthesis in only females, **(c)** stimulates FSH secretion and LH synthesis in both males and females, **(d)** is produced in the ovaries.
5. The main hormone of the postovulatory phase is **(a)** progesterone, **(b)** estradiol, **(c)** estrogen, **(d)** luteinizing hormone.
6. Which accessory structures contribute to the composition of semen? What are the functions of each structure?
7. What types of cells in the testes are responsible for functions related to reproductive activity? What are the functions of each cell type?
8. Which part of the nervous system controls sexual arousal?
9. List the functions of testosterone in males.
10. List and summarize the important steps in the ovarian cycle.
11. Describe the histology of the uterine wall.
12. What is the role of the clitoris in the female reproductive system?
13. Trace the path of milk flow from its site of production to outside the female.
14. Identify the main structures of the male reproductive system in the diagram on the right.

(a)_____ **(b)**_____ **(c)**_____
(d)_____ **(e)**_____ **(f)**_____
(g)_____ **(h)**_____ **(i)**_____
(j)_____ **(k)**_____ **(l)**_____

LEVEL 2 Reviewing Concepts

15. The immune system does not identify the developing sperm as a foreign matter because of the **(a)** blood testis barrier, **(b)** capacitation of sperm, **(c)** secretion of dehydroepiandrosterone, **(d)** secretion of inhibin, **(e)** formation of acrosome.
16. Summarize the roles of the hormones in the ovarian and uterine cycles.
17. Compare the fates of parent cells undergoing meiosis in males and females.
18. Describe the erectile tissues of the penis. How does erection occur?
19. Describe each of the three phases of a typical 28-day uterine cycle.
20. Describe the hormonal events associated with the ovarian cycle.
21. Describe the hormonal events associated with the uterine (menstrual) cycle.
22. What is meant by the descent of the testes? Is there a comparable process in females?
23. How does the aging process affect the reproductive systems of men and women?

LEVEL 3 Critical Thinking and Clinical Applications

24. Andrew is 75 and is in good health. But he has recently started to experience lower back pain and painful urination. A rectal examination reveals an enlargement of the prostate. Explain why it is not unusual for elderly men to develop this condition.
25. In a condition known as endometriosis, endometrial cells are believed to migrate from the body of the uterus into the uterine tubes or by way of the uterine tubes into the peritoneal cavity, where they become established. A major symptom of endometriosis is periodic pain. Why does such pain occur?
26. Birth control pills contain estradiol and progesterone, or progesterone alone, administered at programmed doses during the ovarian cycle to prevent tertiary ovarian follicle maturation and ovulation. Explain how such pills are effective.
27. Female bodybuilders and women with eating disorders such as anorexia nervosa commonly experience amenorrhea. What does this fact suggest about the relationship between body fat and menstruation? What effect would amenorrhea have on achieving a successful pregnancy?

CLINICAL CASE Wrap-Up And Baby Makes Three?

A basic rule of thumb is that a couple that has been trying to get pregnant for 1 year is a candidate for a fertility work-up. Fertility problems can originate in the female, in the male, in both, or for unknown reasons.

A woman's ability to get pregnant decreases with increasing age. Her fertility depends on how many oocytes she has left in her ovaries, how healthy the oocytes are, and—most importantly—if they are being released from the ovary. A healthy reproductive tract is needed for the oocyte to unite with a sperm, and then for the fertilized ovum to be conveyed to a healthy uterus to implant and complete gestation.

Is Susan ovulating? That is the first thing to check, as it is the most common reason for female infertility. At home she can take her morning temperature, which should spike with ovulation at day 14 and stay high through day 28 of her cycle under the influence of progesterone. Is her reproductive tract blocked by scarring from her earlier STI? If so, surgery can open a blocked uterine tube.

A man's infertility is most often due to problems with his sperm. The count may be too low or the motility of the sperm may be poor. Checking the quantity and quality of Tim's sperm is simple. He can provide a sample for analysis in the lab. Tim can change his running gear from briefs to boxers in order to provide a cooler environment in the testes for sperm production.

The Millers have youth and general good health on their side. However, they do have risk factors for infertility that need to be addressed. Baby Miller may yet join the family!

1. Trace the path of Susan's oocyte to meet Tim's sperm. Where will a fertilized ovum travel next?
2. When should Susan expect ovulation to occur during her cycle? How can we verify that she has ovulated?

See the blue Answers tab at the back of the book.

Related Clinical Terms

cervical dysplasia: Abnormal growth of epithelial cells in the uterine cervix; may progress to cancer.
endometriosis: The growth of endometrial tissue outside the uterus.
genital herpes: A sexually transmitted disease caused by a herpes virus and characterized by painful blisters in the genital area.
gonorrhea: A sexually transmitted bacterial disease caused by *Neisseria gonorrhoeae.* Commonly called "the clap."
gynecology: The branch of medicine that deals with the functions and diseases specific to women and girls affecting the reproductive system.
hydrocele: The accumulation of serous fluid in any body sac, but especially in the tunica vaginalis of the testis or along the spermatic cord.
hysterectomy: The surgical removal of the uterus.
menorrhagia: The condition of experiencing extremely heavy bleeding at menstruation.
oophorectomy: The surgical removal of one or both ovaries.
orchitis: Inflammation of one or both testicles.
ovarian cyst: A condition (usually harmless) in which fluid-filled sacs develop in or on the ovary.

polycystic ovary syndrome (PCOS): A condition in women that is characterized by irregular or no menstrual periods, acne, obesity, and excessive hair growth.

premature ejaculation: A common complaint of ejaculating semen sooner than the man desires while achieving orgasm during intercourse. An estimated 30 percent of men regularly experience the problem.

premenstrual dysphoric disorder (PMDD): A collection of physical and emotional symptoms that occurs 5 to 11 days before a woman's period begins, and goes away once menstruation starts. Over 150 signs and symptoms have been associated with the condition.

premenstrual syndrome: A condition occurring in the last half of the menstrual cycle after ovulation that is a combination of physical and mood disturbances that normally end with the onset of the menstrual flow.

salpingitis: Inflammation of a uterine tube.

uterine fibroids (leiomyomas): Benign tumors of the uterus composed of smooth muscle tissue that grows in the wall of the uterus of some women. Although not usually dangerous they can cause problems such as very heavy menstrual periods and pain.

uterine prolapse: Condition that occurs when a woman's pelvic floor muscles and ligaments stretch and weaken and provide inadequate support for the uterus, which then descends into the vaginal canal.

vasectomy: The surgical removal of a segment of each ductus (vas) deferens, making it impossible for sperm to reach the distal portions of the male reproductive tract.

vulvovaginal candidiasis: A common female vaginal infection caused by the yeast *Candida*, usually *Candida albicans.*

29 Development and Inheritance

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

29-1 ■ Explain the relationship between differentiation and development, and specify the various stages of development. p. 1150

29-2 ■ Describe the process of fertilization, and explain how developmental processes are regulated. p. 1151

29-3 ■ List the three stages of prenatal development, and describe the major events of each. p. 1153

29-4 ■ Explain how the three germ layers are involved in forming the extra-embryonic membranes, and discuss the importance of the placenta as an endocrine organ. p. 1153

29-5 ■ List several fetal changes that occur during the second and third trimesters. p. 1161

29-6 ■ Describe the interplay between the maternal organ systems and the developing fetus, and discuss the structural and functional changes in the uterus during gestation. p. 1163

29-7 ■ List and discuss the events that occur during labor and delivery. p. 1169

29-8 ■ Identify the features and physiological changes of the postnatal stages of life. p. 1172

29-9 ■ Relate basic principles of genetics to the inheritance of human traits. p. 1177

CLINICAL CASE The Twins That Looked Nothing Alike

Annie and her twin, Ruth, are in Twinsburg, Ohio, for the Twins Day Festival, the largest annual celebration of twins in the world. There are thousands of identical twins in attendance, and a healthy representation of fraternal twins as well. Annie and Ruth are amazed to see so many twins who not only look alike but also move alike, sound alike, and smile alike.

As they walk through the festival grounds, Annie and Ruth notice tents set up to recruit twins for everything from FBI face-recognition software development to fingerprint and handwriting analysis. The festival is a popular event for "nature vs. nurture" researchers who are looking for twins to enlist in their studies.

Another centerpiece of the festival is the awarding of medals to twins in various categories, including the oldest twins, the youngest twins, the "most-alike" twins, and the "least-alike" twins. This year, the "least-alike" twins medals are awarded to two boys, one who is short and Caucasian-with blonde hair, the other who is tall and of African descent, with black hair. **Annie elbows Ruth and asks, "What do you think is the story with these twins?" To find out, turn to the Clinical Case Wrap-Up on p. 1189.**

An Introduction to Development and Inheritance

The physiological processes we have studied so far are relatively brief. Many last only a fraction of a second, and others may take hours. But some important processes are measured in months, years, or even decades. In the process of **development**, a human being forms in the womb for 9 months, and grows to maturity in 15 to 20 years. He or she may live the better part of a century, in that time always changing. Birth, growth, maturation, aging, and death are all parts of a single, continuous process. That process does not end with the individual, because humans can pass at least some of their characteristics on to their offspring. Each generation gives rise to a new generation that will repeat the cycle.

In this chapter, we explore how genetics, environmental factors, and various physiological processes affect the events following the union of male and female *gametes*—sperm and oocytes. The explanation begins with development before birth and continues through childhood and adolescence and into maturity and *senescence*, or aging.

29-1 Directed by inherited genes, a fertilized ovum differentiates during prenatal development to form an individual; postnatal development brings that individual to maturity

29

Learning Outcome Explain the relationship between differentiation and development, and specify the various stages of development.

The gradual modification of anatomical structures and physiological characteristics that occurs before birth is referred to as **prenatal** (*natus*, birth) **development**. **Postnatal development** begins at birth and continues to **maturity**, the state of full development or completed growth.

Prenatal development, the primary focus of this chapter, begins at *fertilization*, or *conception*, when the male gamete (a sperm) and the female gamete (oocyte) fuse. We divide development into stages characterized by specific anatomical changes. **Pre-embryonic development** involves the processes that occur in the first 2 weeks after fertilization, producing an *embryo*. **Embryonic development** includes the events during the third through eighth weeks. The study of these events is called **embryology** (em-brē-OL-ō -jē). The development of the **fetus**, or **fetal development**, begins at the start of the ninth week and continues until birth.

The changes that occur during development are truly remarkable. In a mere nine months, all the tissues, organs, and organ systems we have studied so far take shape and begin to function. What begins as a single egg cell slightly larger than the period at the end of this sentence becomes an individual like yourself whose body contains trillions of cells organized into a complex array of highly specialized structures. The formation of the different types of cells required in this process is called **differentiation**.

Differentiation occurs through selective changes in genetic activity. As development proceeds, some genes are turned off and others are turned on. Exactly which genes are turned off and on varies from one type of cell to another, and the patterns change over time.

All humans go through the same developmental stages, but this process produces individuals with distinctive characteristics. The term **inheritance**, or **heredity**, refers to the transfer of genetically determined characteristics from generation to generation. The study of the mechanisms responsible for inheritance is called **genetics**. In this chapter, we consider basic genetics as it applies to inherited characteristics, such as sex, hair color, and various diseases.

A basic understanding of human development gives important insights into anatomical structures. In addition, many of the processes of development and growth are similar to those that repair injuries. In this chapter, we focus on major aspects of development. We consider highlights of the developmental process rather than examine the events in great detail. We also consider the regulatory mechanisms involved, and how developmental patterns can be modified.

Checkpoint

1. Define *differentiation*.
2. What event marks the onset of development?
3. Define *inheritance*.

See the blue Answers tab at the back of the book.

29-2 Fertilization—the fusion of a secondary oocyte and a sperm—forms a zygote

Learning Outcome Describe the process of fertilization, and explain how developmental processes are regulated.

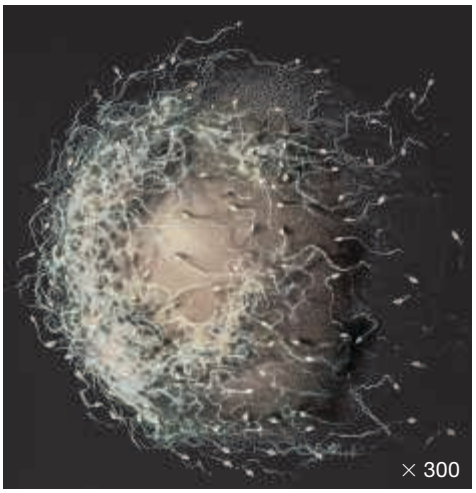
Fertilization involves the fusion of two haploid (n) gametes, each containing 23 chromosomes. This process produces a **zygote** that contains 46 chromosomes, the normal diploid (2n) number in a human somatic cell. Fertilization typically takes place near the junction between the ampulla and isthmus of the uterine tube. It generally occurs within a day after ovulation. Let's look at how this process takes place, and the different roles of the male and female gametes.

The Secondary Oocyte and Sperm before Fertilization

The functional roles and contributions of the male and female gametes are very different. The **sperm** delivers the paternal (father's) chromosomes to the site of fertilization. It is small, highly streamlined, and driven by a flagellum. In contrast, the female **oocyte** provides all the cellular organelles and inclusions, nourishment, and genetic programming necessary to support development of the embryo for nearly a week after conception. For this reason, the volume of this gamete is much greater than that of the sperm. At fertilization, the diameter of the secondary oocyte is more than twice the entire length of the sperm (Figure 29–1a). The ratio of their volumes is even more striking—approximately 2000:1.

Recall from Chapter 28 that ovulation releases a **secondary oocyte**. The secondary oocyte is surrounded by a thick, glycoprotein-rich envelope called the *zona pellucida*. Outside of that envelope is a protective layer of follicle cells called the **corona radiata** (Figure 29–1b). The cells of the corona radiata protect the secondary oocyte as it passes through the ruptured follicular wall, across the surface of the ovary, and into the infundibulum of the uterine tube. The oocyte then generally travels a few centimeters into the ampulla toward the isthmus.

The secondary oocyte begins meiosis II in the tertiary ovarian follicle, but the process is suspended in metaphase of meiosis II. The secondary oocyte is then ovulated in this state. The cell's metabolic operations await the stimulus of fertilization for further development. If fertilization does not take place, the oocyte disintegrates without completing meiosis.



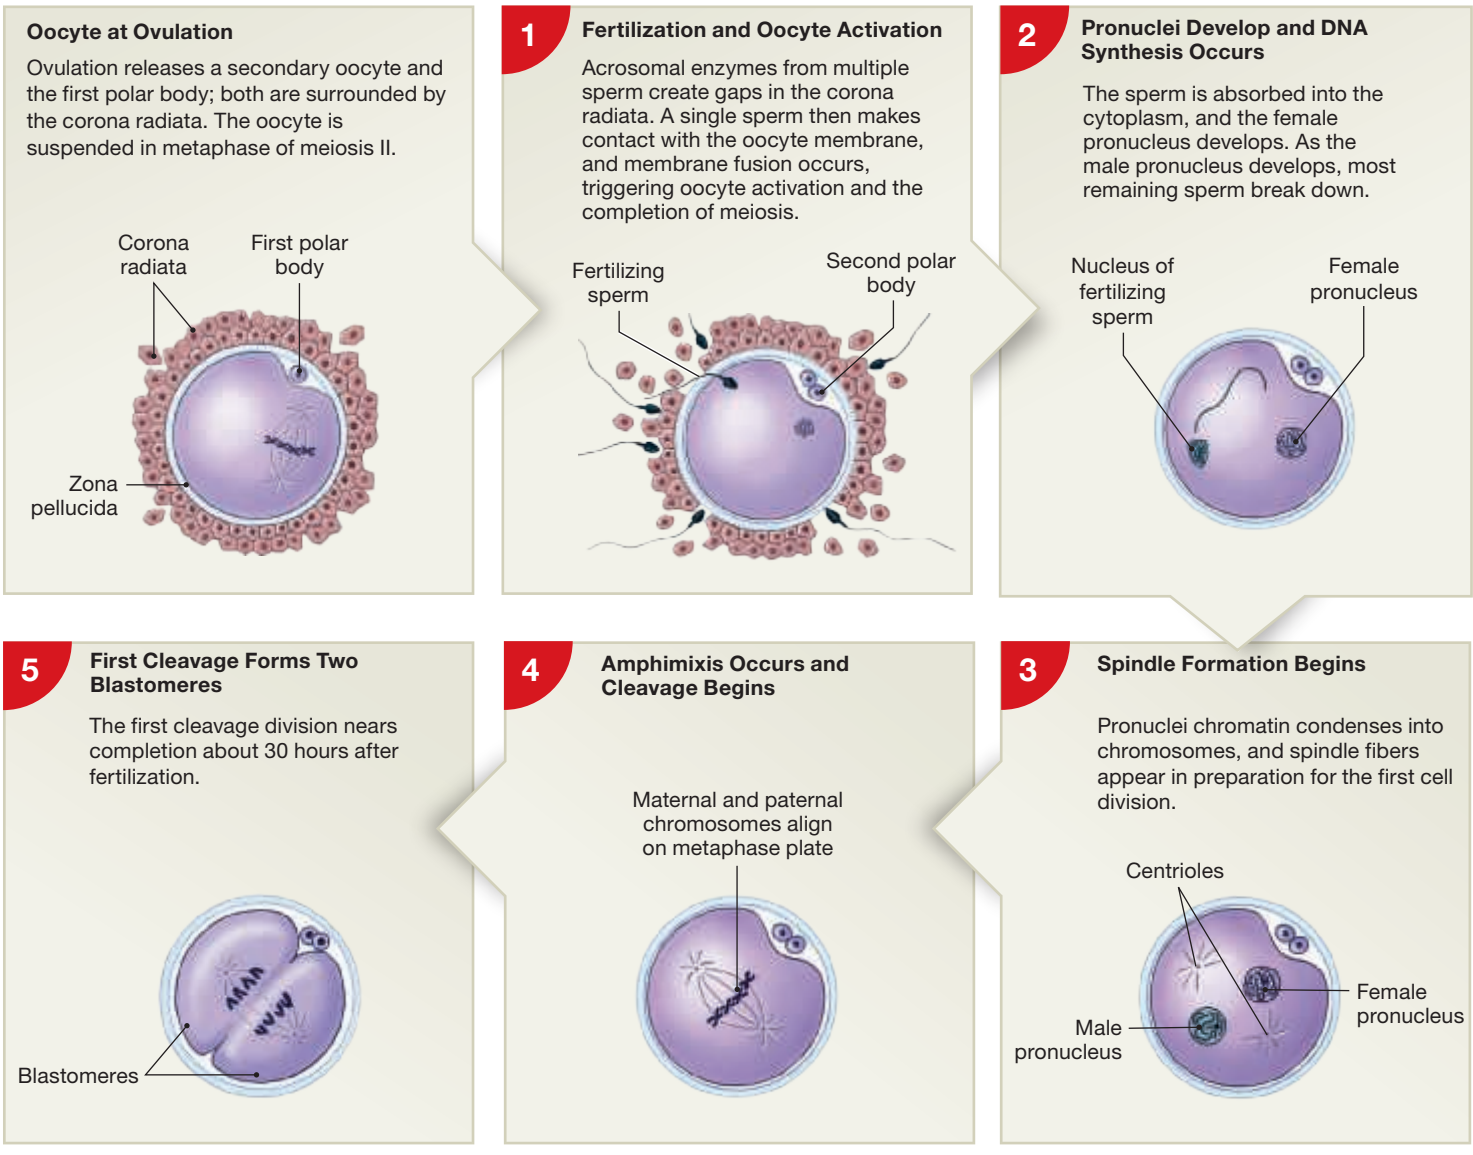
To have a chance of fertilizing a secondary oocyte, sperm must travel the relatively long distance between the vagina and the ampulla of the uterine tube. The sperm deposited in the vagina are already motile, as a result of contact with secretions of the seminal glands—the first step of *capacitation*. p. 1116 Capacitation is the functional maturation of the sperm in which the receptors are uncovered when the glycoprotein layer of the sperm membrane is removed. This also alters the acrosome, enabling the acrosome reaction, and allowing the sperm to penetrate and fertilize an oocyte. (An unidentified substance secreted by the epididymis appears to prevent premature capacitation.) The sperm, however, cannot accomplish fertilization until they have been exposed to conditions in the female reproductive tract. Uterine tube peg cell secretions help with capacitation, but the exact mechanism responsible for capacitation remains unknown. Furthermore, how sperm "find" the oocyte remains a rich field of investigation. A sperm can propel itself at speeds of only about 34 µm per second, or about 12.5 cm (5 in.) per hour. In theory it should take sperm several hours to reach the upper portions of the uterine tubes. The actual time, however, ranges from 2 hours to as little as 30 minutes. Contractions of the uterine musculature and ciliary currents in the uterine tubes may help the sperm travel from the vagina to the site of fertilization.

Of the nearly 200 million sperm introduced into the vagina in a typical ejaculation, only about 10,000 enter the uterine tube, and fewer than 100 reach the isthmus. In general, a male with a sperm count below 20 million per milliliter is functionally sterile because too few sperm survive to reach and fertilize an oocyte. While it is true that only one sperm fertilizes an oocyte, dozens of sperm are required for successful fertilization, as we will learn next.

The Process of Fertilization

Fertilization and the events that follow are diagrammed in Figure 29–1b. Before the physical process of fertilization can occur, a sperm must penetrate the corona radiata. This is aided by the *acrosome reaction*, which frees the enzymes contained in the acrosome of each sperm, including **hyaluronidase** (hī -uh-lū-RON-i-dās). Hyaluronidase breaks down the bonds between adjacent follicle cells. Dozens of sperm must release

Figure 29–1 Fertilization.



a A secondary oocyte and numerous sperm at the time of fertilization. Notice the difference in size between the gametes.

hyaluronidase before the connections between the follicle cells of the corona radiata break down enough to allow an intact sperm to reach the oocyte.

No matter how many sperm slip through the gap in the corona radiata, only a single sperm fertilizes the oocyte (1, Figure 29–1b). That sperm must have an intact acrosome. The first step is the binding of the sperm to *sperm receptors* in the zona pellucida. This binding triggers the rupture of the acrosome. The hyaluronidase and **acrosin**, another protein-digesting enzyme, then digest a path through the zona pellucida toward the surface of the oocyte. When the sperm contacts the oocyte membrane, the sperm and oocyte membranes begin to fuse.

Events after Fertilization

The fusion of these membranes triggers **oocyte activation**, which involves a series of changes in the metabolic activity of the oocyte. This process leads to increased permeability of the oocyte membrane to sodium ions; the entry of sodium ions causes the membrane to depolarize. This depolarization in turn causes the release of calcium ions from the smooth endoplasmic reticulum into the oocyte cytoplasm.

b Fertilization and the preparations for cleavage.

The sudden increase in the calcium ion level has important effects, including the following:

- *Exocytosis of Vesicles Adjacent to the Oocyte Membrane.* This process, called the *cortical reaction*, releases enzymes called *zonal inhibiting proteins*, or *ZIPs*, that both inactivate the sperm receptors and harden the zona pellucida. This combination that prevents fertilization by more than one sperm is known as the **block to polyspermy**. Polyspermy would create a zygote incapable of normal development. (Prior to completion of the cortical reaction, depolarization of the oocyte membrane probably prevents fertilization by any other sperm that penetrate the zona pellucida.)
- *Completion of Meiosis II and Formation of the Second Polar Body.* Once the sperm enters the secondary oocyte, the oocyte can complete meiosis II. The fertilized oocyte is now called an **ovum**.
- *Activation of Enzymes That Cause a Rapid Increase in the Ovum's Metabolic Rate.* The cytoplasm of the ovum contains a large number of mRNA strands that have been inactivated by special proteins. The mRNA strands are now activated, so protein synthesis accelerates quickly. Most of the proteins synthesized are required for development to proceed.

After oocyte activation and the completion of meiosis, the nuclear material remaining within the ovum reorganizes into the **female pronucleus**. While these changes are under way, the nucleus of the sperm swells. As it forms the **male pronucleus**, the rest of the sperm breaks down (except for its centrosome). DNA synthesis then takes place in both the male and female pronuclei (2, Figure 29–1b). The male and female pronuclei move toward each other, their chromatin begins to condense into chromosomes (each consisting of two duplicate chromatids), and the male-donated centrioles duplicate and begin to form spindle fibers (3). The pronuclei membranes dissolve and their maternal and paternal chromosomes all line up on the metaphase plate. The combining of the male and female chromosomes is called *amphimixis* (am-fi-MIK-sis; "both mixed together") (4). The cell is now a zygote that contains the normal diploid complement of 46 chromosomes, and fertilization is complete. This is the "moment of conception." The first cleavage yields two daughter cells called *blastomeres* (5). The cell divisions of cleavage subdivide the cytoplasm of the zygote.

Checkpoint

4. **Name two sperm enzymes important to secondary oocyte penetration.**
5. **How many chromosomes are contained within a human zygote?**

See the blue Answers tab at the back of the book.

29-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters

Learning Outcome List the three stages of prenatal development, and describe the major events of each.

The time spent in prenatal development is known as **gestation** (jes-TĀ-shun). For convenience, we usually think of the gestation period as three integrated **trimesters**, each lasting 3 months:

1. The **first trimester** is the period of pre-embryonic, embryonic, and early fetal development. During this time, the beginnings of all the major organ systems appear.
2. The **second trimester** is dominated by the development of fetal organs and organ systems. This process nears completion by the end of the sixth month. During this time, body shape and proportions change. By the end of this trimester, the fetus looks distinctively human.
3. The **third trimester** is characterized by rapid fetal growth and deposition of adipose tissue. Early in the third trimester, most of the fetus's major organ systems become fully functional. An infant born 1 month or even 2 months prematurely has a reasonable chance of survival.

Checkpoint

6. **Define *gestation*.**
7. **Characterize the key features of each trimester.**

See the blue Answers tab at the back of the book.

29-4 The first trimester includes pre-embryonic and embryonic development, involving the processes of cleavage, implantation, placentation, and embryogenesis

Learning Outcome Explain how the three germ layers are involved in forming the extra-embryonic membranes, and discuss the importance of the placenta as an endocrine organ.

At the moment of conception, the fertilized ovum is a single cell about 0.135 mm (0.005 in.) in diameter. It weighs approximately 150 µg. By convention, pregnancies are clinically dated from the last menstrual period (LMP), which is usually 2 weeks before ovulation and conception. At the end of the first trimester (12 weeks from LMP, but only 10 developmental weeks), the fetus is almost 75 mm (3 in.) long and weighs perhaps 14 g (0.5 oz).

Many important and complex developmental events occur during the first trimester. Here we focus on four general processes: Two occur in the pre-embryonic period (cleavage and

implantation) and two occur in the embryonic period (placentation and embryogenesis).

1. **Cleavage** (KLĒV-ij) is a sequence of cell divisions that begins immediately after fertilization (Figure 29–1b). During cleavage, the zygote becomes a **pre-embryo**, which develops into a multicellular complex known as a *blastocyst.* Cleavage ends when the blastocyst first contacts the uterine wall.
2. **Implantation** begins when the blastocyst attaches to the endometrium of the uterus. The process continues as the blastocyst invades maternal tissues. Important events during implantation set the stage for the formation of vital embryonic structures.
3. **Placentation** (plas-en-TĀ-shun) occurs as blood vessels form around the periphery of the blastocyst, and as the placenta develops. The **placenta** is a complex organ that permits exchange between maternal and embryonic blood. It supports the early fetus from its formation in the first trimester until just after birth, when the placenta stops functioning and is expelled from the uterus. From that point on, the newborn is physically independent of the mother.
4. **Embryogenesis** (em-brē-ō-JEN-e-sis) is the formation of a viable **embryo**. This process establishes the foundations for all major organ systems.

These processes are both complex and vital to the survival of the embryo. Perhaps because the events in the first trimester are so complex, it is the most dangerous prenatal stage. Only about 40 percent of conceptions produce embryos that survive the first trimester. For that reason, pregnant women are warned to avoid drugs, alcohol, tobacco, and other disruptive stresses during the first trimester, in the hope of preventing an error in the intricate processes that are under way. Let's look at each of these stages in turn.

The Pre-Embryonic Period

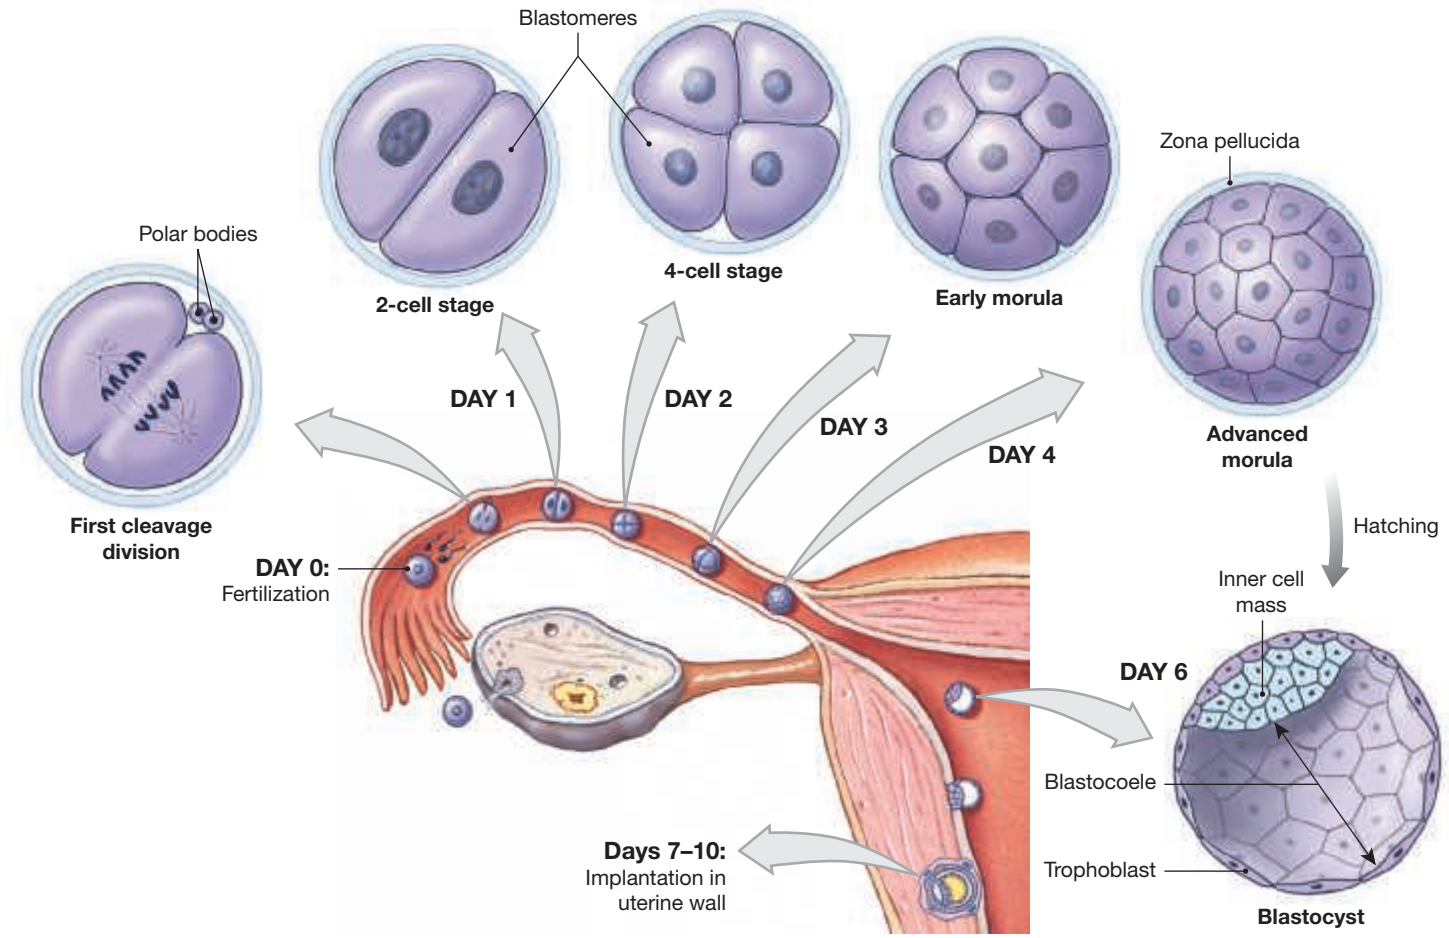
The pre-embryonic period is the first 14 days after fertilization, before implantation in the uterus. At this stage, tissue differentiation has not occurred.

Cleavage and Blastocyst Formation

Cleavage is a series of cell divisions that subdivides the cytoplasm of the zygote, producing an ever-increasing number of smaller and smaller daughter cells (Figure 29–2). Soon after the secondary oocyte completes meiosis, the chromosomes line up along a metaphase plate, and the cell prepares to divide. The first cleavage division is completed about 30 hours after fertilization. The first cleavage produces a pre-embryo consisting of two identical cells called **blastomeres** (see day 0 in Figure 29–2). Subsequent divisions take place at intervals of 10–12 hours. During the initial divisions, all the blastomeres divide simultaneously. As the number of blastomeres increases, the timing becomes less predictable.

After 3 days of cleavage, the pre-embryo is a solid ball of cells resembling a mulberry. This stage is called the **morula** (MOR-yū-luh; *morus*, mulberry) (see days 1–3). The morula typically reaches the uterus on day 4 or 5. Over the next 2 days, the blastomeres in the morula form a **blastocyst**, a hollow ball with an inner cavity known as the **blastocoele** (BLAS-tō-sēl) (see day 6). The blastomeres are now no longer identical in size and shape. The outer layer of cells is called the **trophoblast** (TRŌ-fō-blast). As the word *trophoblast* implies (*trophos*, food + *blast*, precursor), cells in this layer provide nutrients to the developing embryo. The trophoblast also releases enzymes that erode an opening in the zona pellucida, which is then shed in a process known as *hatching* (see Figure 29–2). In the blastocyst, a second group of cells, the **inner cell mass**, lies clustered at one end. These cells are exposed only to the blastocoele and insulated from contact with the outside uterine environment by the trophoblast. In time, the inner cell mass will form the embryo.

Implantation



Once the blastocyst is hatched, it is freely exposed to glycogen-rich fluid within the uterine cavity. The uterine glands secrete this fluid. Throughout the previous few days, the pre-embryo and early blastocyst had been absorbing fluid and nutrients from their surroundings. The process now accelerates, and the blastocyst enlarges. When fully formed, the blastocyst contacts the endometrium, and implantation takes place (Figure 29–3).

Implantation begins as the surface of the blastocyst closest to the inner cell mass adheres to the uterine lining (see day 7 in Figure 29–3). At the point of contact, the trophoblast cells divide rapidly, making the trophoblast several layers thick. The cells closest to the interior of the blastocyst remain intact, forming an inner cellular layer of the trophoblast called the **cytotrophoblast**. Near the endometrial wall, however, the plasma membranes separating the trophoblast cells disappear, creating a layer of cytoplasm with multiple nuclei (day 8). This outer layer is called the **syncytiotrophoblast**.

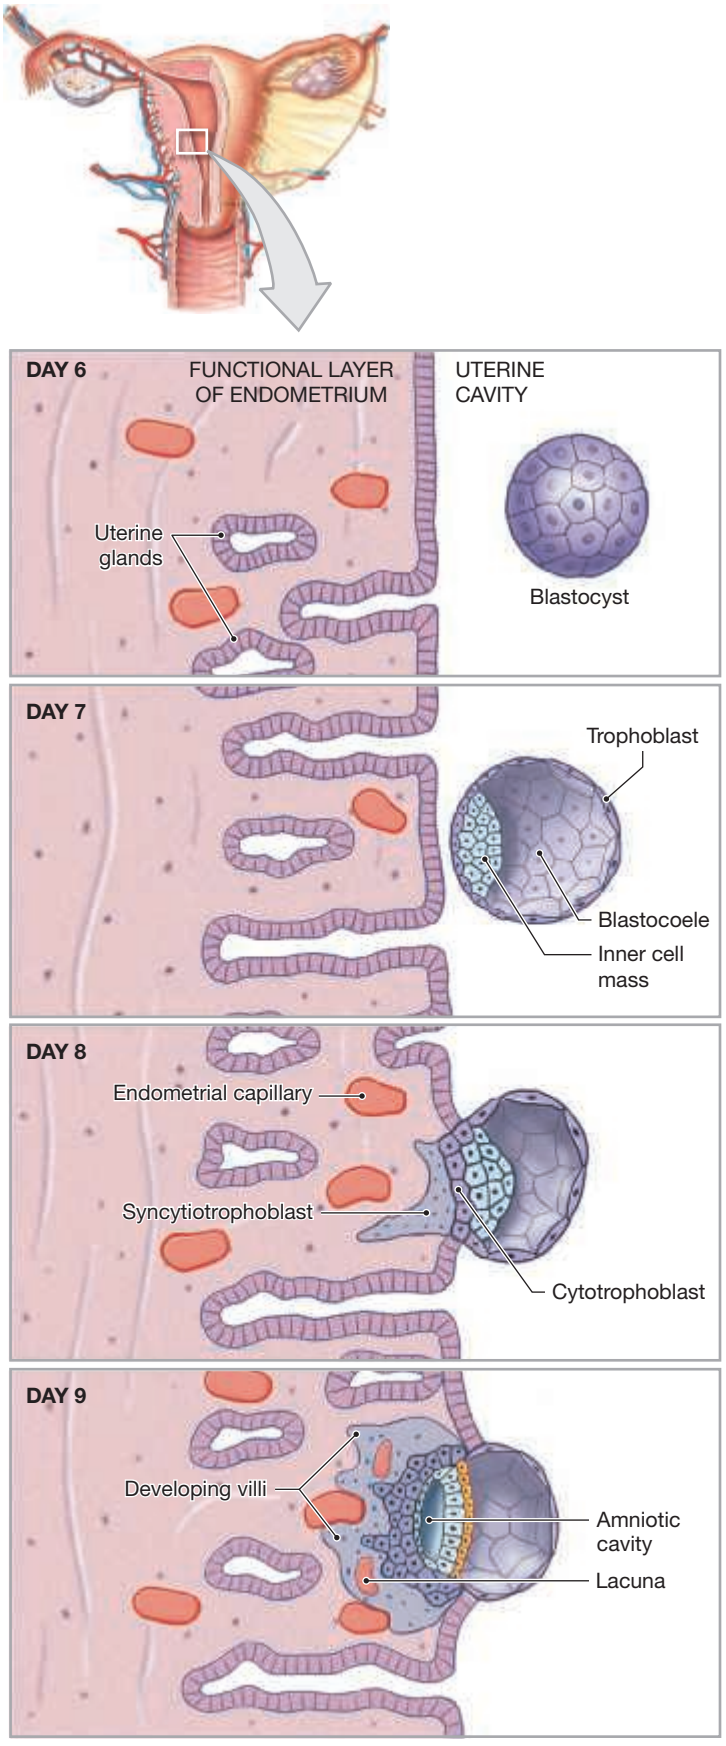
The syncytiotrophoblast erodes a path through the uterine epithelium by secreting hyaluronidase. This enzyme dissolves the proteoglycans between adjacent epithelial cells, just as hyaluronidase released by sperm dissolved the connections between cells of the corona radiata. At first, the erosion creates a gap in the uterine lining, but maternal epithelial cells migrate and divide and soon repair the surface. Once the blastocyst has lost contact with the uterine cavity, its further development occurs entirely within the functional layer of the endometrium.

As implantation proceeds, the syncytiotrophoblast continues to enlarge and spread into the surrounding endometrium (see day 9, Figure 29–3). The erosion of uterine glands releases nutrients that are absorbed by the syncytiotrophoblast. They

Figure 29-2 Cleavage and Blastocyst Formation.

? What is the name and function of the outer cell layer of a blastocyst?

then diffuse through the underlying cytotrophoblast to the inner cell mass. These nutrients provide the energy needed for the early stages of embryo formation. Trophoblastic extensions grow around endometrial capillaries. As the capillary walls are destroyed, maternal blood begins to percolate through trophoblastic channels known as **lacunae** (*lacuna*, singular). Fingerlike **villi** extend away from the trophoblast into the surrounding endometrium, gradually increasing in size and complexity until about day 21. As the syncytiotrophoblast spreads, it begins breaking down larger endometrial veins and arteries, and blood flow through the lacunae accelerates.



The inner cell mass has little apparent organization early in the blastocyst stage. Yet by the time of implantation, the inner cell mass has separated from the trophoblast. The separation gradually increases, creating a fluid-filled chamber called the **amniotic** (am-nē-OT-ik) **cavity** (see day 9 in Figure 29–3). When the amniotic cavity first appears, the cells of the inner cell mass are organized into an oval sheet that is two layers thick. A superficial layer faces the amniotic cavity, and a deeper layer is exposed to the fluid contents of the blastocoele.

In most cases, implantation occurs in the fundus or in the body of the uterus. In an **ectopic pregnancy**, implantation occurs somewhere other than within the uterus, such as in one of the uterine tubes. Approximately 0.6 percent of pregnancies are ectopic pregnancies. They do not produce a viable embryo and can be life threatening to the mother.

The Embryonic Period

The embryonic period comprises the events from implantation to week 9. During this time, hormonal changes that help maintain the pregnancy are occurring: Trophoblast cells and later the chorion secrete human chorionic gonadotropin (hCG), the corpus luteum secretes progesterone and estrogen, and by the end of the second month, the placenta begins secreting progesterone and estrogen.

Figure 29-3 Stages in Implantation.

Regulation of Differentiation

During prenatal development, a single cell ultimately forms a 3–4-kg (6.6–8.8-lb) infant. One of the most fascinating aspects of development is its apparent order. Continuity exists at all levels and at all times. Nothing "leaps" into existence without apparent precursors. Differentiation and increasing structural complexity take place hand in hand.

Differentiation involves changes in the genetic activity of some cells but not others. A continuous exchange of information takes place between the nucleus and the cytoplasm in a cell. Activity in the nucleus varies in response to chemical messages that arrive from the surrounding cytoplasm. In turn, ongoing nuclear activity alters conditions within the cytoplasm by directing the synthesis of specific proteins. In this way, the nucleus can affect enzyme activity, cell structure, and membrane properties.

In development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. These changes in turn lead to further alterations in the cytoplasm, and the process continues in a sequence. But if all the cells of the embryo are derived from cell divisions of a zygote, how do the cytoplasmic differences originate? What sets the process in motion? The important first step occurs before fertilization, while the oocyte is in the ovary.

Before ovulation, the growing oocyte accepts amino acids, nucleotides, and glucose, as well as more complex materials such as phospholipids, mRNA molecules, and proteins, from the surrounding granulosa cells. The contents of the cytoplasm are not evenly distributed because not all follicle cells manufacture and deliver the same nutrients and instructions to the oocyte. After fertilization, the zygote divides into ever-smaller cells that differ from one another in cytoplasmic composition. These differences alter the genetic activity of each cell, creating cell lines with increasingly diverse fates.

As development proceeds, some of the cells release chemical substances, including RNA molecules, polypeptides, and small proteins that affect the differentiation of other embryonic cells. This type of chemical interplay among developing cells is called *induction* (in-DUK-shun). It works over very short distances, such as when two types of cells are in direct contact. It may also operate over longer distances, with the inducing chemicals functioning as hormones.

This type of regulation, which involves an integrated series of interacting steps, can control highly complex processes. The mechanism is not always error free, however. An abnormal or inappropriate inducer can change the course of development.

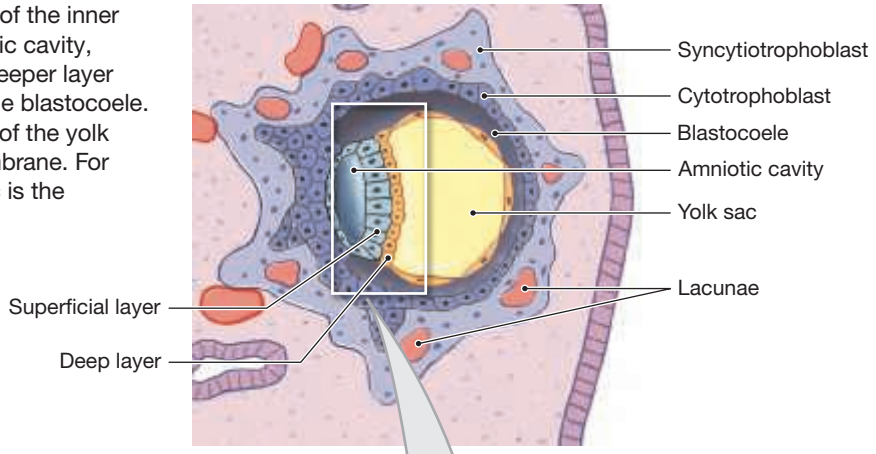
Early Embryogenesis: Formation of the Germ Layers and Extra-Embryonic Membranes

Embryogenesis is a phase of prenatal development in which embryonic structures are formed. It is usually regarded as the time from the end of the second week, when the embryonic disc is formed from the inner cell mass, to the end of the eighth

week, when the embryo becomes a fetus. In week 3, the two-layered embryonic disc becomes a three-layered embryo as the primary germ layers (ectoderm, mesoderm, and endoderm) and the extra-embryonic membranes develop.

Gastrulation and Germ Layer Formation. Around day 15, a third layer of cells begins to form between the superficial and deep layers of the inner cell mass through a cell migration process called **gastrulation** (gas-trū-LĀ-shun) (Figure 29–4). Together, the three layers of cells are called **germ layers**. The layers are known as the **ectoderm**, **mesoderm**, and **endoderm**. The germ layers separate the trophoblast from the amniotic cavity.

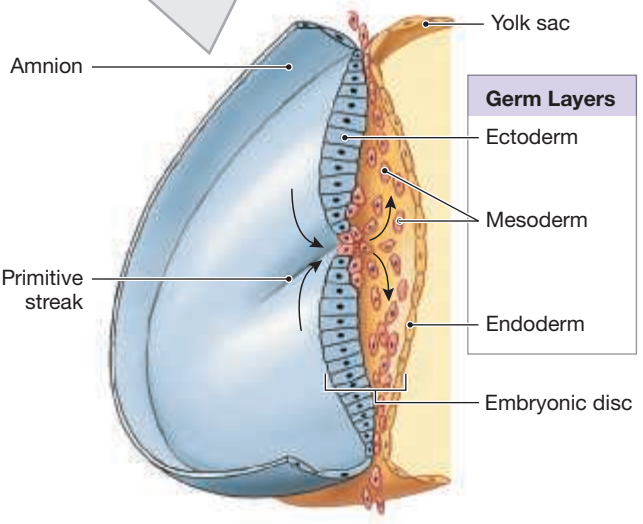
Table 29–1 contains a listing of the contributions each germ layer makes to form the body systems described in earlier chapters.



The **embryonic disc** becomes an oval, three-layered sheet during gastrulation. This disc will form the body of the embryo, whereas all other cells of the blastocyst will be part of the *extra-embryonic membranes*.

Shortly after gastrulation begins, the body of the embryo begins to separate itself from the rest of the embryonic disc. The body of the embryo and its internal organs now start to form. This process, embryogenesis, begins as folding and differential growth of the embryonic disc produce a bulge that projects into the amniotic cavity (Spotlight Figure 29–5, step 2).

Figure 29-4 The Inner Cell Mass and Gastrulation.



Day 10: Yolk Sac Formation

While cells from the superficial layer of the inner cell mass migrate around the amniotic cavity, forming the amnion, cells from the deeper layer migrate around the outer edges of the blastocoele. This is the first step in the formation of the yolk sac, a second extra-embryonic membrane. For about the next 2 weeks, the yolk sac is the primary nutrient source for the inner cell mass; it absorbs and distributes nutrients released into the blastocoele by the cytotrophoblast.

Day 15: Gastrulation

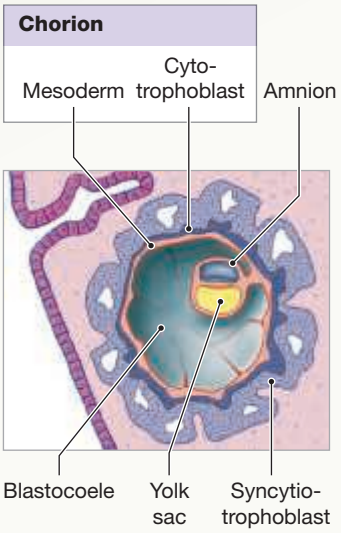
By day 15, superficial cells of the two-layered embryonic disc have begun to migrate toward a central line known as the **primitive streak**. Here, the migrating cells leave the surface and move between the two existing layers. This movement creates three distinct embryonic layers: (1) the **ectoderm**, consisting of superficial cells that did not migrate into the interior of the embryonic disc; (2) the **endoderm**, consisting of the cells that face the yolk sac; and (3) the **mesoderm**, consisting of the poorly organized layer of migrating cells between the ectoderm and the endoderm. Collectively, these three embryonic layers are called **germ layers**, and the migration process is called **gastrulation**. Through gastrulation, the **embryonic disc** becomes an oval, three-layered sheet. This disc will form the body of the embryo, whereas all other cells of the blastocyst will be part of the extra-embryonic membranes.

? What is the name of the the third germ layer that forms during gastrulation?

SPOTLIGHT

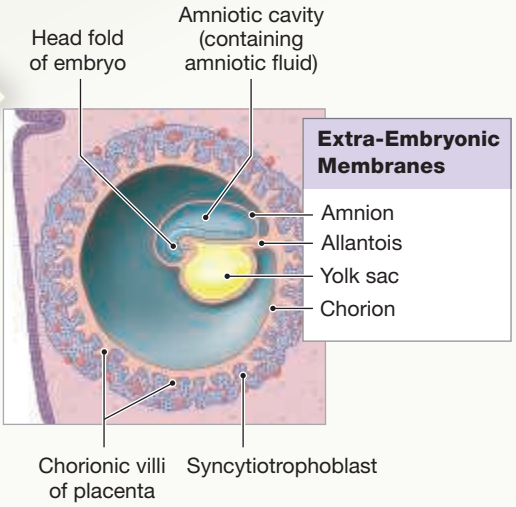
Figure 29-5
Extra-Embryonic Membranes and Placenta Formation

The germ layers introduced in Figure 29–4 also form four **extra-embryonic membranes**: **(1)** The **yolk sac** (endoderm and mesoderm), **(2)** the **amnion** (ectoderm and mesoderm), **(3)** the **allantois** (endoderm and mesoderm), and (4) the **chorion** (mesoderm and trophoblast). These membranes support embryonic and fetal development, but few traces of their existence remain in adults.



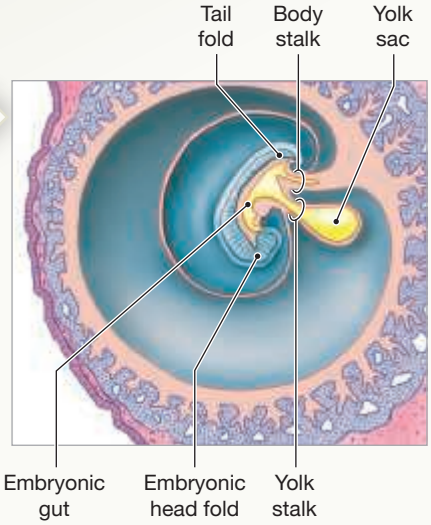
Yolk sac
The yolk sac begins as a layer of cells spreads out around the outer edges of the blastocoele to form a complete pouch. It is the primary nutrient source for early embryonic development, and becomes an important site for blood cell formation.

Amnion
Ectodermal cells spread over the inner surface of the amniotic cavity, soon followed by mesodermal cells. Amniotic fluid is produced, which cushions the developing embryo.



1 **Week 2**

Migration of mesoderm around the inner surface of the cytotrophoblast forms the chorion. Mesodermal migration around the outside of the amniotic cavity, between the ectodermal cells and the trophoblast, forms the amnion. Mesodermal migration around the endodermal pouch forms the yolk sac.



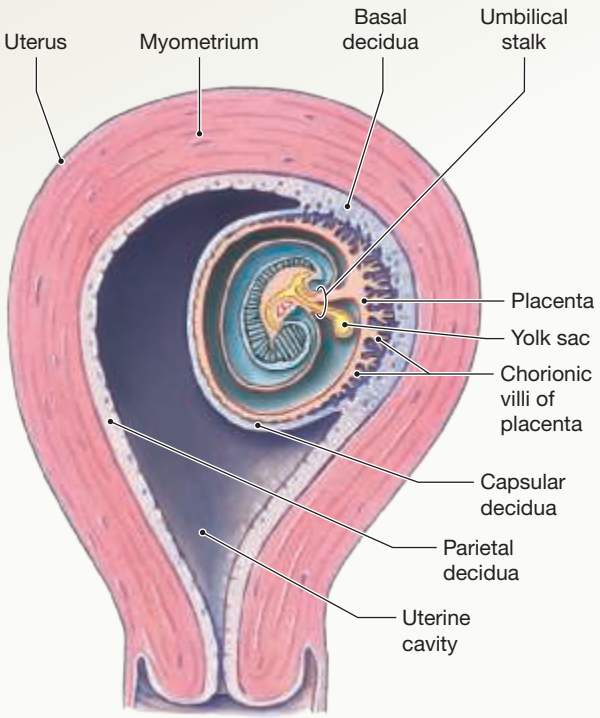
2 **Week 3**

The embryonic disc bulges into the amniotic cavity at the head fold. The allantois, an endodermal extension surrounded by mesoderm, extends toward the trophoblast.

3 **Week 4**

The embryo now has a head fold and a tail fold. Constriction of the connections between the embryo and the surrounding trophoblast narrows the yolk stalk and body stalk.

Allantois



The allantois begins as an outpocket of the endoderm near the base of the yolk sac. The free endodermal tip then grows toward the wall of the blastocyst, surrounded by a mass of mesodermal cells. The base of the allantois eventually gives rise to the urinary bladder.

Chorion

The mesoderm associated with the allantois spreads around the entire blastocyst, separating the cytotrophoblast from the blastocoele. The appearance of blood vessels in the chorion is the first step in the creation of a functional placenta. By the third week of development, the mesoderm extends along the core of each trophoblastic villus, forming chorionic villi in contact with maternal tissues and blood vessels. These villi continue to enlarge and branch forming the placenta, the exchange platform between mother and fetus for nutrients, oxygen, and wastes.

4 **Week 5**

The developing embryo and extra-embryonic membranes bulge into the uterine cavity. The cytotrophoblast pushing out into the uterine cavity remains covered by endometrium but no longer participates in nutrient absorption and embryo support. The embryo moves away from the placenta, and the body stalk and yolk stalk fuse to form an umbilical stalk.

5 **Week 10**

The amnion has expanded greatly, filling the uterine cavity. The fetus is connected to the placenta by an elongated umbilical cord that contains a portion of the allantois, blood vessels, and the remnants of the yolk stalk. A mucus plug forms, preventing bacteria from entering the uterus.

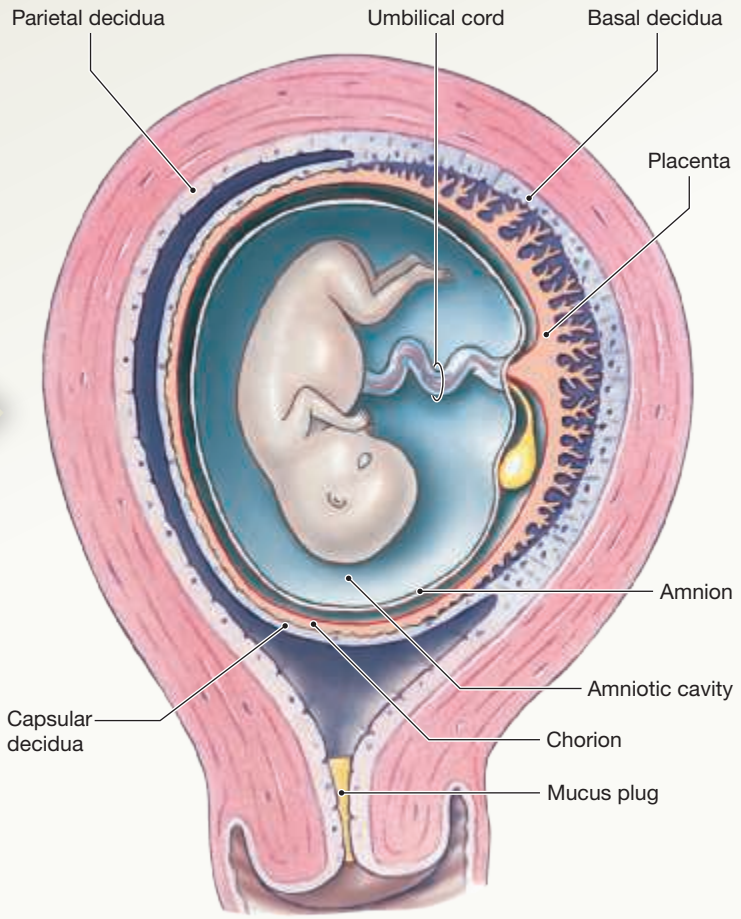


Table 29-1 The Fates of the Germ Layers

Ectodermal Contributions
Integumentary system: epidermis, hair follicles and hairs, nails, and glands communicating with the skin (sweat glands, mammary glands, and sebaceous glands)
Skeletal system: pharyngeal cartilages and their derivatives in adults (portion of sphenoid, the auditory ossicles, the styloid processes of the temporal bones, the cornu and superior rim of the hyoid bone)*
Nervous system: all neural tissue, including brain and spinal cord
Endocrine system: pituitary gland and adrenal medullae
Respiratory system: mucous epithelium of nasal passageways
Digestive system: mucous epithelium of mouth and anus, salivary glands
Mesodermal Contributions
Integumentary system: dermis and subcutaneous layer (hypodermis)
Skeletal system: all structures except some pharyngeal derivatives
Muscular system: all structures
Endocrine system: adrenal cortex, endocrine tissues of heart, kidneys, and gonads
Cardiovascular system: all structures
Lymphatic system: all structures
Urinary system: the kidneys, including the nephrons and the initial portions of the collecting system
Reproductive system: the gonads and the adjacent portions of the duct systems
Miscellaneous: the lining of the pleural, pericardial, and peritoneal cavities and the connective tissues that support all organ systems
Endodermal Contributions
Endocrine system: thymus, thyroid gland, and pancreas
Respiratory system: respiratory epithelium (except nasal passageways) and associated mucous glands
Digestive system: mucous epithelium (except mouth and anus), exocrine glands (except salivary glands), liver, and pancreas
Urinary system: urinary bladder and distal portions of the duct system
Reproductive system: distal portions of the duct system, stem cells that produce gametes

*The neural crest is derived from ectoderm and contributes to the formation of the skull and the skeletal derivatives of the embryonic pharyngeal arches.

This projection is the **head fold**. Similar movements lead to the formation of a **tail fold** (see Spotlight Figure 29–5, step 3).

Formation of the Extra-Embryonic Membranes. The germ layers also form four **extra-embryonic membranes**: the **yolk sac**, **amnion** (AM-nē-on), **allantois** (ah-LAN-tō-is), and **chorion** (KŌ-rē-on). Spotlight Figure 29–5 illustrates and describes the developmental processes of these extra-embryonic membranes. Please study this figure before reading on.

Let's focus more on the chorion here because of its early role in the maternal–embryo exchange of nutrients, gases, and wastes. When implantation first occurs, the nutrients absorbed by the trophoblast can easily reach the inner cell mass by simple diffusion. But as the embryo and the trophoblast enlarge, the distance between them increases, so diffusion alone can no longer keep pace with the demands of the developing embryo. Blood vessels now begin to develop within the mesoderm of the chorion. The appearance of these blood vessels is the first step in the formation of a functional placenta, a rapid-transit system for nutrients that links the embryo with the trophoblast.

Placentation

Placentation is the formation of the placenta from embryonic and maternal tissues. Embryonic tissues form the chorion and chorionic villi. The maternal endometrial tissues that surround the blood-filled lacunae become restricted to a specialized region. The placenta is fully formed and functional by the end of the third month.

Formation of the Placenta. By the third week of development (see Spotlight Figure 29–5, step 2), the mesoderm extends along the core of each trophoblastic villus, forming **chorionic villi** in contact with maternal tissues and blood vessels. Chorionic villi continue to enlarge and branch, creating an intricate network within the endometrium. Embryonic blood vessels develop within each villus. Blood flow through those chorionic vessels begins early in the third week of development, when the embryonic heart starts beating. The blood supply to the chorionic villi arises from the allantoic arteries and veins.

At first, the entire blastocyst is surrounded by chorionic villi. The chorion continues to enlarge, expanding like a balloon within the endometrium. By week 4, the embryo, amnion,

and yolk sac are suspended within an expansive, fluid-filled chamber (see Spotlight Figure 29–5, step 3). The **body stalk**, the connection between embryo and chorion, contains the distal portions of the allantois and blood vessels that carry blood to and from the placenta. The narrow connection between the endoderm of the embryo and the yolk sac is called the **yolk stalk**.

As the chorionic villi enlarge, more maternal blood vessels are eroded. The placenta does not continue to enlarge indefinitely. Regional differences in placental organization begin to develop as expansion of the placenta creates a prominent bulge in the endometrial surface. This relatively thin portion of the endometrium, called the **capsular decidua** (dē-SID-yū-uh; *deciduus*, a falling off), or *decidua capsularis*, no longer exchanges nutrients, and the chorionic villi in the region disappear (see Spotlight Figure 29–5, step 4), and Figure 29–6a). Placental functions are now concentrated in a disc-shaped area in the deepest portion of the endometrium, a region called the **basal decidua (***decidua basalis*). The rest of the uterine endometrium, which has no contact with the chorion, is called the **parietal decidua (***decidua parietalis*).

As the end of the first trimester approaches, the fetus moves farther from the placenta (see Spotlight Figure 29–5, steps 4 and 5). The fetus and placenta remain connected by the **umbilical cord**, which contains the allantois, the placental blood vessels, and the yolk stalk.

Tips & Tools

Like a deep-sea diver's air hose or a space-walking astronaut's tether, the umbilical cord supplies the fetus with life-sustaining substances and removes wastes.

Placental Circulation. Figure 29–6a illustrates placental circulation at the end of the first trimester. Blood flows from the fetus to the placenta through the paired **umbilical arteries** and returns in a single **umbilical vein**. ↩ p. 821

The chorionic villi provide the surface area for active and passive exchanges of gases, nutrients, and wastes between the fetal and maternal bloodstreams. The blood in the umbilical arteries is deoxygenated and contains wastes generated by fetal tissues. Maternal blood moves slowly through complex lacunae lined by the syncytiotrophoblast. Chorionic blood vessels pass close by, and gases and nutrients diffuse between the embryonic and maternal circulations across the layers of the trophoblast. Recall that fetal hemoglobin has a higher affinity for oxygen than does maternal hemoglobin, enabling fetal hemoglobin to strip oxygen from maternal hemoglobin. ↩ p. 912 At the placenta, oxygen supplies are replenished, nutrients added, and carbon dioxide and other wastes removed. Maternal blood then reenters the venous system of the mother through the broken walls of small uterine veins. No mixing of maternal and fetal blood takes place, because layers of trophoblast always separate the two.

The placenta places a considerable demand on the maternal cardiovascular system, and blood flow to the uterus and placenta is extensive. If the placenta is torn or otherwise damaged, the consequences may prove fatal to both fetus and mother.

Late Embryogenesis and Organogenesis

At about week 4 of development, the embryo is physically as well as developmentally distinct from the embryonic disc and the extra-embryonic membranes. The definitive orientation of the embryo can now be seen, complete with posterior and anterior surfaces and left and right sides. The changes in proportions and appearance that occur between the second developmental week and the end of the first trimester are summarized in Figure 29–7.

The first trimester is a critical period for development, because events in the first 12 weeks establish the basis for **organogenesis**, the process of organ formation. The rudiments of all the major organ systems have formed by the end of the first trimester. Table 29–2 provides an overview of the development of the major organs and body systems in the first trimester (as well as subsequent development).

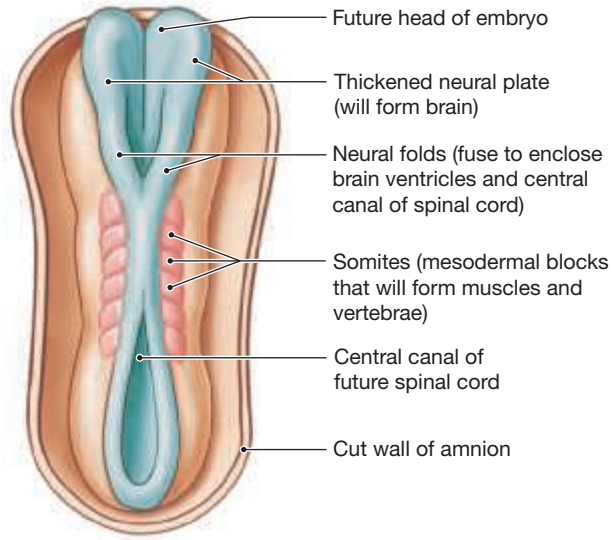
29-5 During the second and third trimesters, fetal development involves growth and organ function

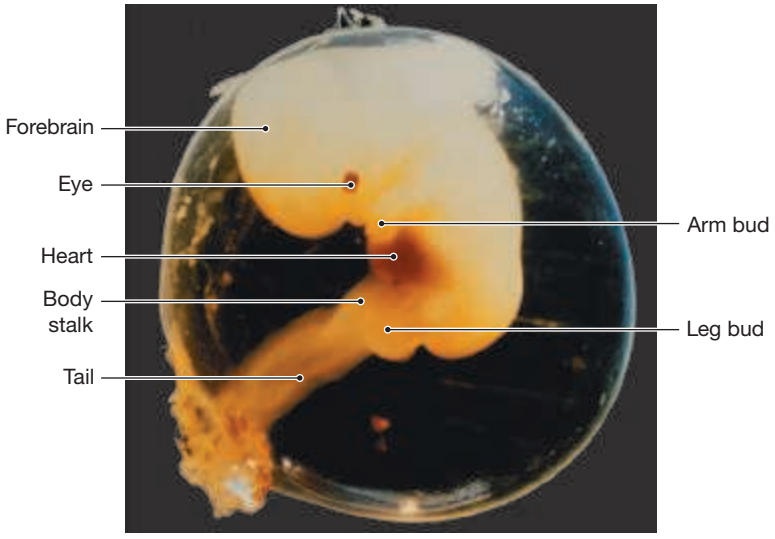
Learning Outcome List several fetal changes that occur during the second and third trimesters.

Over the second trimester, the fetus grows to a weight of about 0.6 kg (1.32 lb). Encircled by the amnion, the fetus grows faster than the surrounding placenta during this period. When the mesoderm on the outer surface of the amnion contacts the mesoderm on the inner surface of the chorion, these layers fuse, creating a compound *amniochorionic membrane*. Figure 29–8a shows a 4-month-old fetus, while Figure 29–8b shows a 6-month-old fetus.



During the third trimester, most organ systems become ready for normal functioning without maternal assistance. The rate of growth starts to slow, but weight gain is the greatest

Figure 29–6 Anatomy of the Placenta after the First Trimester.



a Placental circulation at the end of the first trimester. Arrows in the enlarged view indicate the direction of blood flow. Blood flows into the placenta through ruptured maternal arteries and then flows around chorionic villi, which contain fetal blood vessels.

Hormonal Regulation during Gestation

In addition to its role in the nutrition of the fetus, the placenta acts as an endocrine organ. Several hormones—including *human chorionic gonadotropin*, *human placental lactogen*, *placental prolactin*, *relaxin*, *progesterone*, and *estrogens*—are synthesized by the syncytiotrophoblast and released into the maternal bloodstream.

Human Chorionic Gonadotropin

The hormone **human chorionic gonadotropin (hCG)** appears in the maternal bloodstream soon after implantation. The presence of hCG in blood or urine samples is a reliable indication of pregnancy. Home pregnancy tests detect the presence of hCG in the urine.

In function, hCG resembles luteinizing hormone (LH), because it maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone. As a result, the endometrial lining remains perfectly functional, and menstruation does not normally occur. Without hCG, the pregnancy ends, because another uterine cycle begins and the functional layer of the endometrium disintegrates.

With hCG, the corpus luteum persists for 3 to 4 months before gradually decreasing in size and secretory function. These changes do not trigger the return of uterine cycles, because by the end of the first trimester, the placenta actively secretes both estrogens and progesterone.

Human Placental Lactogen and Placental Prolactin

Human placental lactogen (hPL) helps prepare the mammary glands for milk production. It also has a stimulatory effect on other maternal tissues comparable to that of growth hormone (GH), ensuring that glucose and protein are available for the fetus. At the mammary glands, the conversion from inactive to active status requires placental hormones (hPL, **placental prolactin**, estrogens, and progesterone) and several maternal hormones (GH, prolactin, and thyroid hormones).

Relaxin

Relaxin is a peptide hormone secreted by the placenta and the corpus luteum during pregnancy. Relaxin (1) increases the flexibility of the pubic symphysis, permitting the pelvis to expand during delivery; (2) causes the cervix to dilate, making it easier for the fetus to enter the vaginal canal; and (3) suppresses the release of oxytocin by the hypothalamus and delays the onset of labor contractions.

Progesterone and Estrogens

After the first trimester, the placenta produces sufficient amounts of progesterone to maintain the endometrial lining and continue the pregnancy. As the end of the third trimester approaches, estrogen production by the placenta accelerates. As we will see in Section 29-7, the increasing levels of estrogens play a role in stimulating labor and delivery.

Changes in Maternal Organ Systems

Pregnancy affects the maternal respiratory, cardiovascular, digestive, and urinary systems. The tidal volume increases, blood volume and blood pressure increase, morning sickness and constipation are common, and urine production increases due to increased metabolism and fetal wastes.

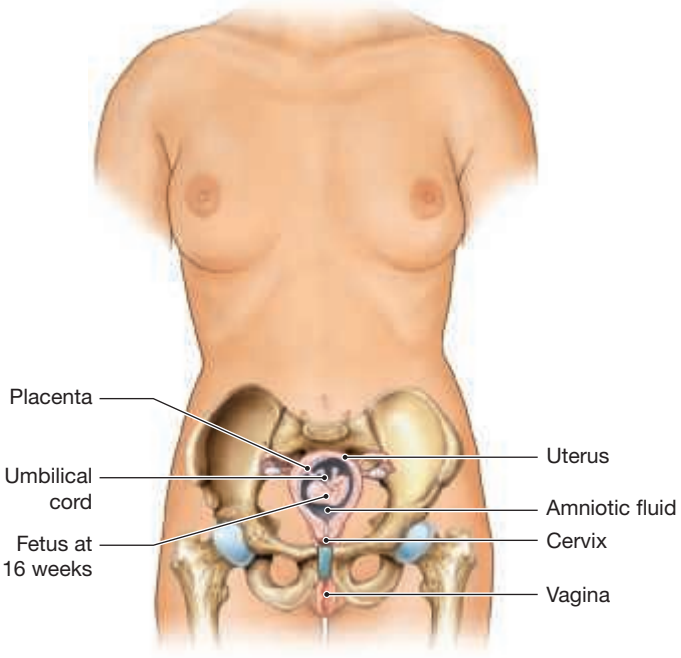
Changes in the Respiratory, Cardiovascular, Digestive, and Urinary Systems

The developing fetus is totally dependent on maternal organ systems for nourishment, respiration, and waste removal. Maternal systems perform these functions in addition to their normal operations. For example, the mother must absorb enough oxygen, nutrients, and vitamins for herself *and* for her fetus, and she must eliminate all the wastes that are generated. This is not a burden over the initial weeks of gestation, but the demands placed on the mother become significant as the fetus grows. For the mother to survive under these conditions, maternal systems must compensate for changes introduced by the fetus. In practical terms, the mother must breathe, eat, and excrete for two. The major changes in maternal systems include the following:

- *Maternal respiratory rate increases and tidal volume increases.* As a result, the mother's lungs deliver the extra oxygen required, and remove the excess carbon dioxide generated by the fetus.
- *Maternal blood volume increases.* This increase occurs because blood flowing into the placenta decreases the volume in the rest of the systemic circuit, and because fetal metabolic activity both decreases blood P_{O_2} and increases P_{CO_2}. The latter combination stimulates the production of renin and erythropoietin, leading to an increase in maternal blood volume through mechanisms detailed in Chapter 21 (see **Figure 21–15**, ↩ p. 797). By the end of gestation, maternal blood volume has increased by almost 50 percent.
- *Maternal requirements for nutrients increase 10–30 percent.* Pregnant women tend to have increased appetites because they must nourish both themselves and their fetus.
- *Maternal glomerular filtration rate increases by approximately 50 percent.* This increase corresponds to the increase in blood volume and accelerates the excretion of metabolic wastes generated by the fetus. Pregnant women need to urinate frequently because the volume of urine produced increases and the weight of the uterus presses down on the urinary bladder.

Changes in the Reproductive System

At the end of gestation, a typical uterus has undergone a tremendous increase in size, from 7.5 cm (3 in.) in length and 30–40 g (1–1.4 oz) in weight to 30 cm (12 in.) in length and 1100 g (2.4 lb) in weight. This remarkable expansion occurs through the enlargement (hypertrophy) of existing cells, especially smooth muscle fibers, rather than by an increase in the total number of cells. **Figure 29–9a,b,d** shows the positions of the uterus, fetus, and placenta from 16 weeks to *full term* (9 months). The uterus may then contain 2 liters of fluid, plus fetus and placenta, for a total weight of about 6–7 kg (13–15.4 lb). When the pregnancy is at full term, the uterus and fetus push many of the maternal abdominal organs out of their normal positions (compare **Figure 29–9c** and **Figure 29–9d**).



In addition, the mammary glands increase in size, and secretory activity begins. Mammary gland development requires a combination of hormones, including human placental lactogen and placental prolactin from the placenta, and prolactin (PRL), estrogens, progesterone, GH, and thyroxine from maternal endocrine organs. By the end of the sixth month of pregnancy, the mammary glands are fully developed and begin to produce clear secretions that are stored in the duct system and may be expressed from the nipple.

+ Clinical Note Abortion

Abortion is the termination of a pregnancy. Most references distinguish among spontaneous, therapeutic, and induced abortions. Most **spontaneous abortions**, or *miscarriages*, result from developmental problems (such as chromosomal defects in the embryo) or from hormonal problems, including abnormally low LH production by the maternal pituitary gland, reduced LH sensitivity at the corpus luteum, insufficient progesterone sensitivity in the endometrium, or insufficient placental production of hCG. Spontaneous abortions occur in at least 15 percent of recognized pregnancies. **Therapeutic abortions** are performed when continued pregnancy poses a threat to the life of the mother. **Induced abortions**, or *elective abortions*, are performed at the woman's request. Induced abortions remain the focus of considerable controversy.

29-7 Childbirth occurs through the process of labor, which consists of the dilation, expulsion, and placental stages

Learning Outcome List and discuss the events that occur during labor and delivery.

Parturition (par-tū-RISH-un), or *childbirth*, is the forcible expulsion of the fetus from the uterus through the cervix and vagina. This occurs by a series of strong, rhythmic uterine contractions called **labor**. This section looks at how labor starts, the three stages of the process, and difficulties that may occur during this process.

Initiation of Labor

The tremendous stretching of the uterus that occurs during pregnancy is associated with a gradual increase in the rate of spontaneous smooth muscle contractions in the myometrium. In the early stages of pregnancy, the contractions are weak, painless, and brief. Evidence indicates that progesterone released by the placenta has an inhibitory effect on uterine smooth muscle, preventing more extensive and more powerful contractions. Late in pregnancy, some women experience occasional spasms in the uterine musculature, but these contractions are not regular or persistent. Such contractions are called **Braxton Hicks contractions** (*false labor*).

Placental and fetal factors are involved in the initiation of **true labor** and delivery (Figure 29–10). When labor begins, the fetal pituitary gland secretes oxytocin, which is released into the maternal bloodstream at the placenta. This may be the actual trigger for the onset of true labor, as it increases myometrial contractions and prostaglandin production, on top of the priming effects of estrogens and maternal oxytocin.

The Stages of Labor

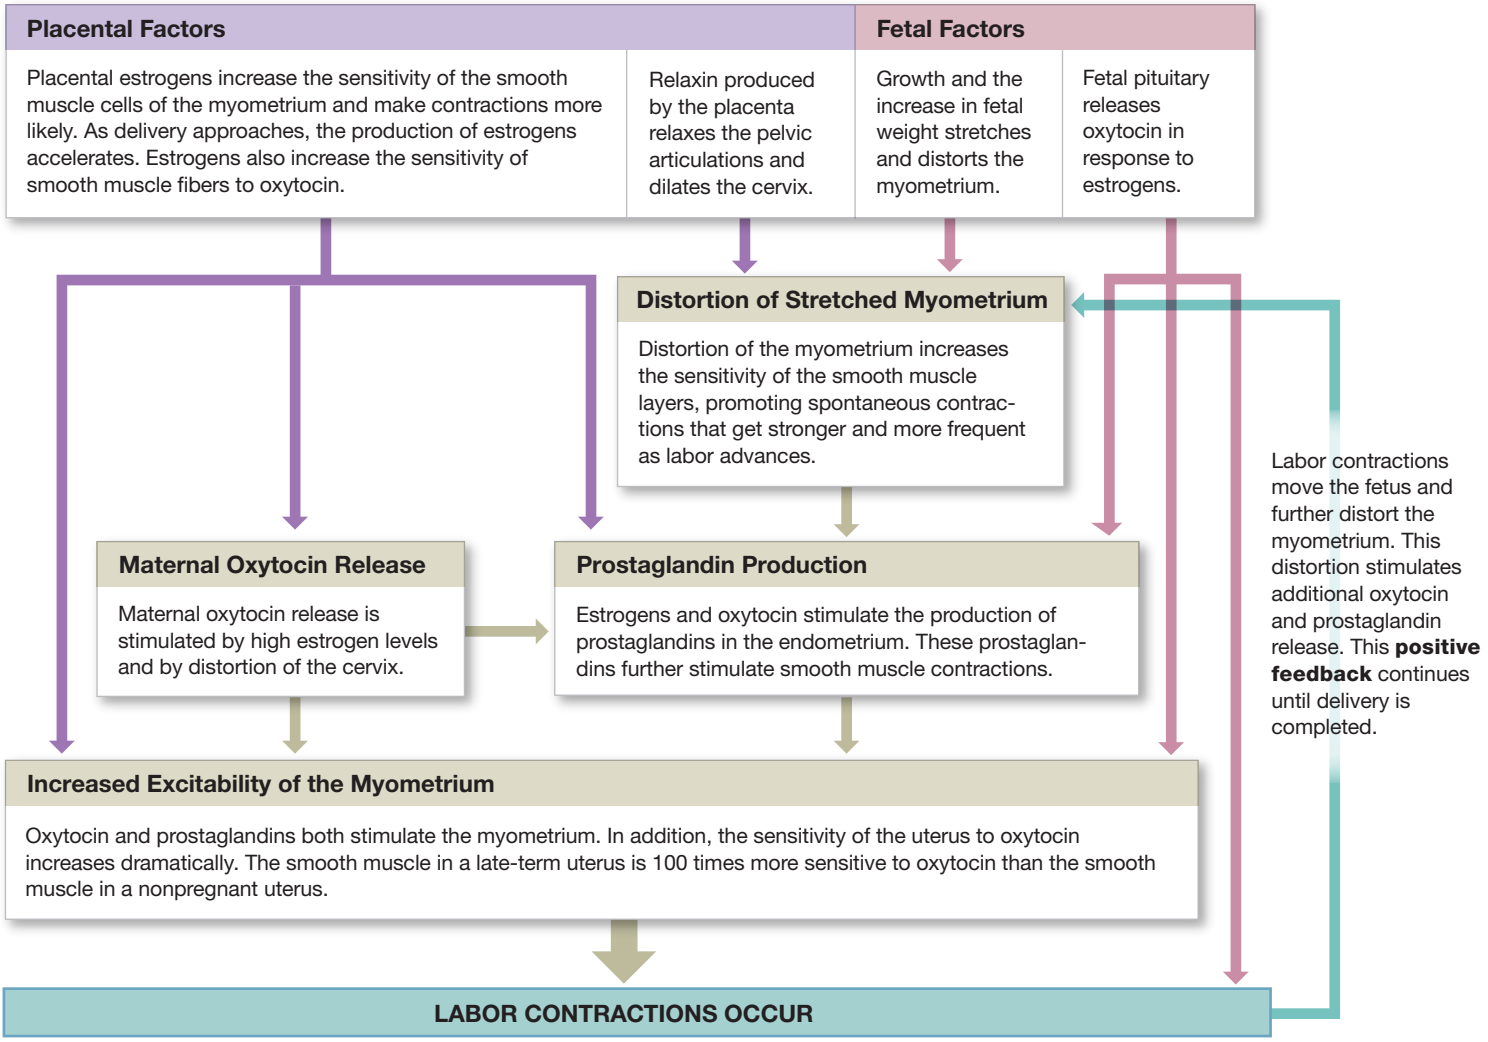
Once labor contractions have begun in the myometrium, positive feedback ensures that they will continue until delivery has been completed. During labor, each contraction begins near the superior portion of the uterus and sweeps in a wave toward the cervix. The contractions are strong and occur at regular intervals. As parturition approaches, the contractions increase in force and frequency, changing the position of the fetus and moving it toward the cervical canal. Labor has traditionally been divided into three stages: the *dilation stage*, the *expulsion stage*, and the *placental stage* (Figure 29–11).

The Dilation Stage

The **dilation stage** begins with the onset of true labor, as the cervix dilates and the fetus begins to shift toward the cervical canal, moved by gravity and uterine contractions (stage 1 in Figure 29–11). This stage is highly variable in length but typically lasts 8 or more hours. At the start of the dilation stage, labor contractions last up to half a minute and occur once every 10–30 minutes. Their frequency increases steadily. Late in this stage, the amniochorionic membrane ruptures, an event sometimes referred to as the woman having her "water break." If this event occurs before other events of the dilation stage, the life of the fetus may be at risk from infection. If the risk is sufficiently great, labor can be induced.

The Expulsion Stage

The **expulsion stage** begins as the cervix, pushed open by the approaching fetus, completes its dilation to about 10 cm (4 in.) (stage 2 in Figure 29–11). In this stage, contractions reach maximum intensity. They occur at perhaps 2- or 3-minute intervals and last a full minute. Expulsion continues until the fetus has emerged from the vagina. In most cases, the expulsion stage lasts less than 2 hours. The arrival of the newborn infant into the outside world is **delivery**, or birth.



If the vaginal canal is too small to permit the passage of the fetus, posing acute danger of perineal tearing, a clinician may temporarily enlarge the passageway by performing an **episiotomy** (eh-piz-ē-OT-ō-mē), an incision through the perineal musculature. After delivery, this surgical cut is repaired with sutures, a much simpler procedure than suturing the jagged edges associated with an extensive perineal tear.

Immediately after birth, clinicians assess the newborn's health in five areas: heart rate, breathing, skin color, muscle tone, and reflex response. This assessment is called an **Apgar score**. Each criterion is scored from 0 to 2, with 8–10 indicating a healthy baby.

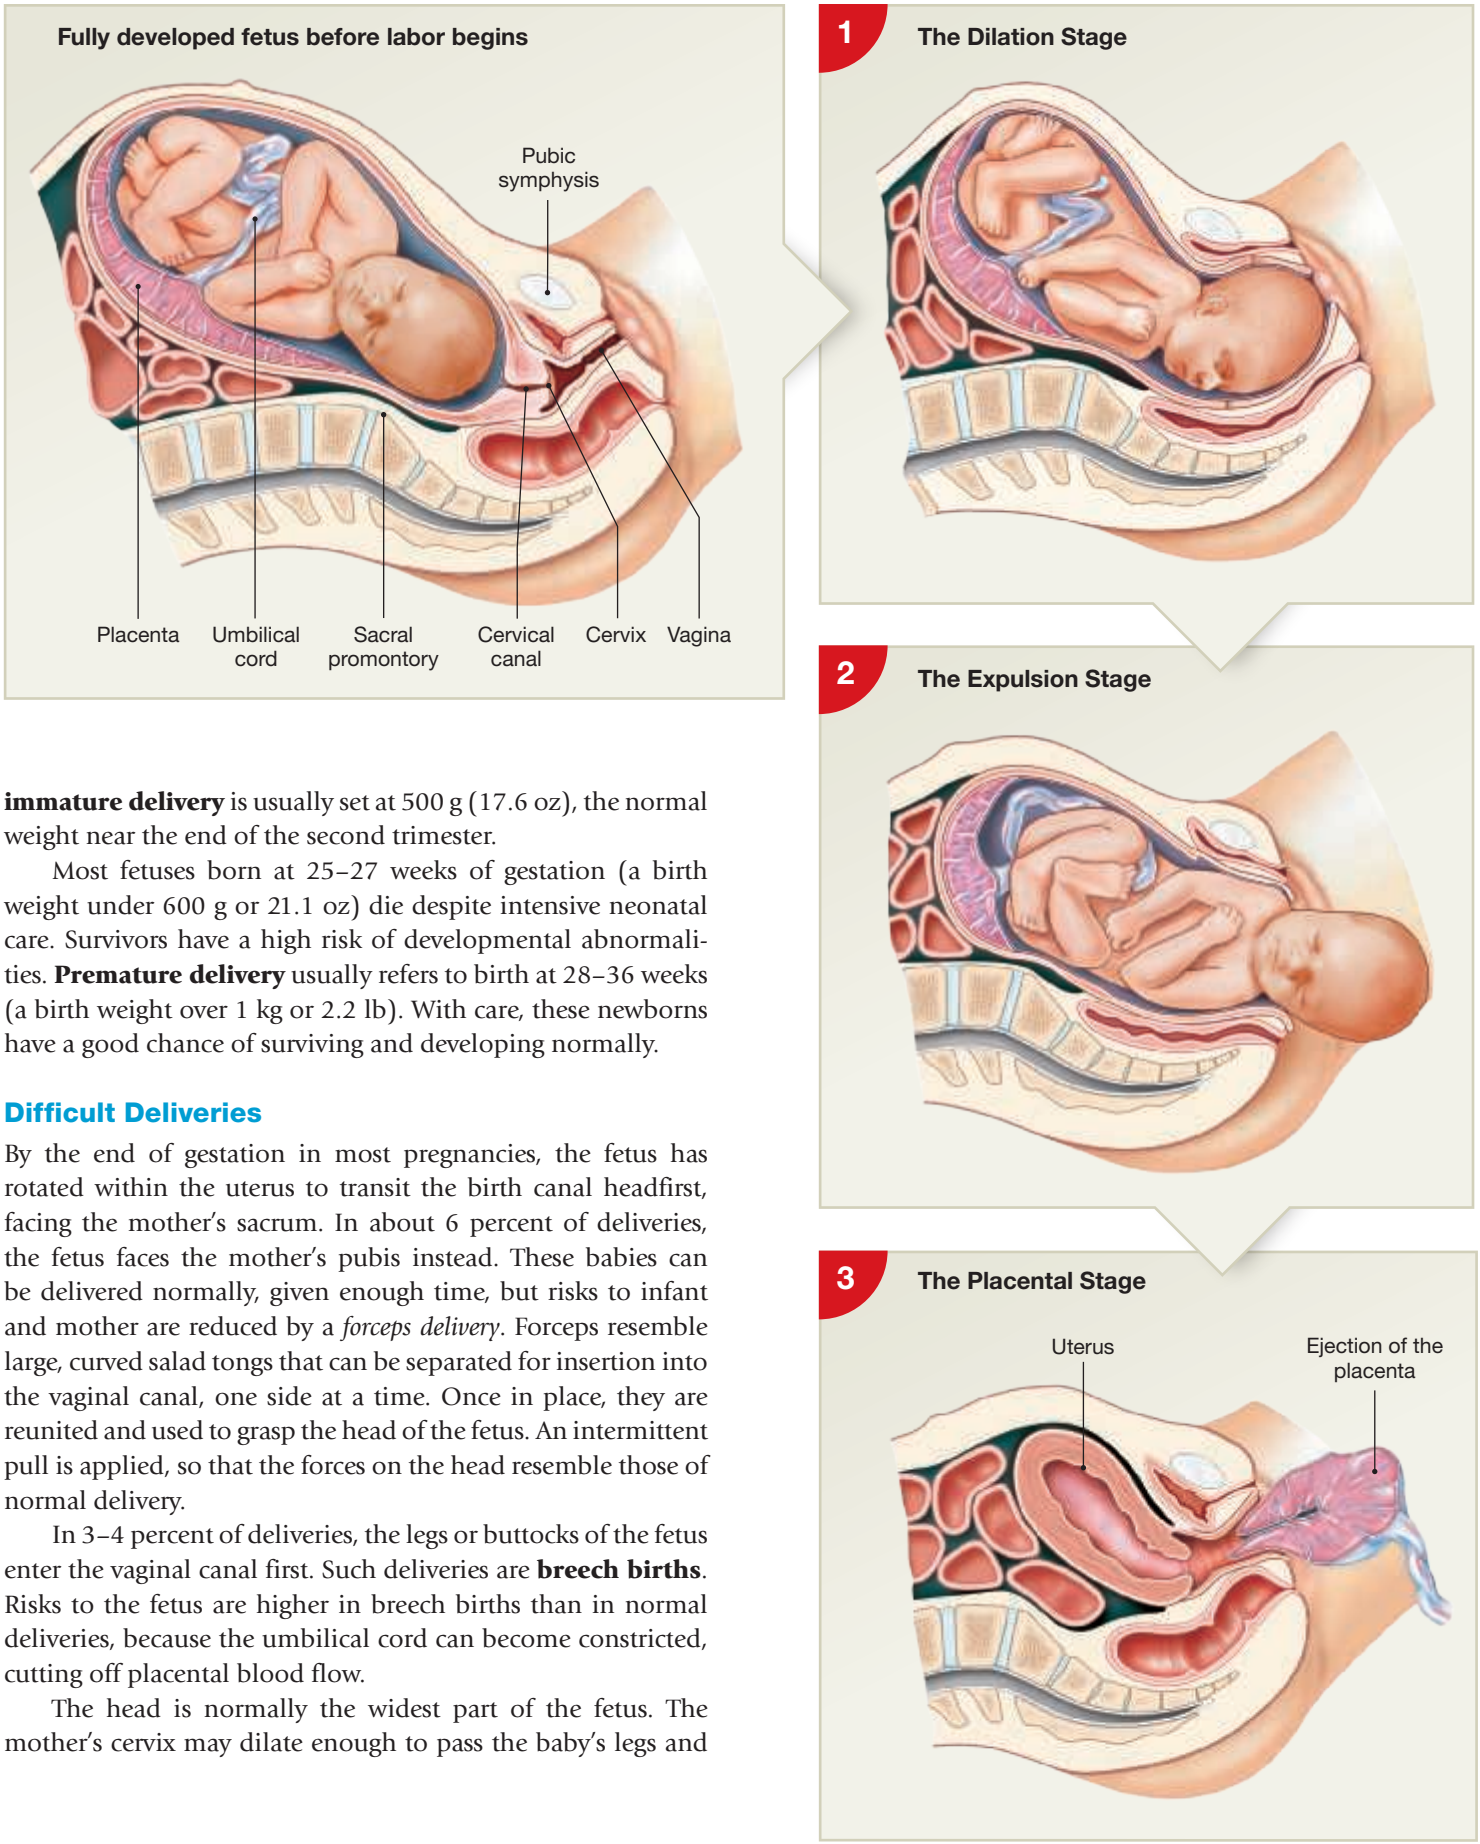
The Placental Stage

During the **placental stage** of labor, muscle tension builds in the walls of the partially empty uterus, which gradually

Figure 29–10 Factors Involved in the Initiation of Labor and Delivery.

? What hormones stimulate and increase the excitability of the myometrium?

decreases in size (stage 3 in Figure 29–11). This uterine contraction tears the connections between the endometrium and the placenta. In general, within an hour of delivery, the placental stage ends with the ejection of the placenta, or *afterbirth*. The disruption of the placenta is accompanied by a loss of blood, but associated uterine contraction compresses the uterine vessels and usually restricts this flow. Because maternal blood volume has increased greatly during pregnancy, the blood loss can normally be tolerated without difficulty.



Difficulties of Labor and Delivery and Multiple Births

Common complications of labor include issues with the umbilical cord looping around the baby's neck, an abnormal fetal heart rate (normal is 110–160 beats per minute), and stalled labor. Others include premature ("preterm") labor, a condition in which uterine contractions cause the cervix to open too soon, or difficult deliveries, which can stress the mother and/or the baby and sometimes cause severe complications.

Premature Labor

Premature labor occurs when true labor begins before the fetus has completed normal development. The newborn's chances of surviving are directly related to its body weight at delivery. Even with massive supportive efforts, newborns weighing less than 400 g (14 oz) at birth will not survive, primarily because their respiratory, cardiovascular, and urinary systems are unable to support life without aid from maternal systems. As a result, the dividing line between spontaneous abortion and

Figure 29–11 The Stages of Labor.

immature delivery is usually set at 500 g (17.6 oz), the normal weight near the end of the second trimester.

Most fetuses born at 25–27 weeks of gestation (a birth weight under 600 g or 21.1 oz) die despite intensive neonatal care. Survivors have a high risk of developmental abnormalities. **Premature delivery** usually refers to birth at 28–36 weeks (a birth weight over 1 kg or 2.2 lb). With care, these newborns have a good chance of surviving and developing normally.

Difficult Deliveries

By the end of gestation in most pregnancies, the fetus has rotated within the uterus to transit the birth canal headfirst, facing the mother's sacrum. In about 6 percent of deliveries, the fetus faces the mother's pubis instead. These babies can be delivered normally, given enough time, but risks to infant and mother are reduced by a *forceps delivery*. Forceps resemble large, curved salad tongs that can be separated for insertion into the vaginal canal, one side at a time. Once in place, they are reunited and used to grasp the head of the fetus. An intermittent pull is applied, so that the forces on the head resemble those of normal delivery.

In 3–4 percent of deliveries, the legs or buttocks of the fetus enter the vaginal canal first. Such deliveries are **breech births**. Risks to the fetus are higher in breech births than in normal deliveries, because the umbilical cord can become constricted, cutting off placental blood flow.

The head is normally the widest part of the fetus. The mother's cervix may dilate enough to pass the baby's legs and

+ Clinical Note C-Section

According to the CDC, about one in three pregnant women give birth by **cesarean section**, or **C-section**, in the United States. This high rate appears to accompany new risk factors for birth such as older mothers, mothers with diabetes or obesity, or the occurrence of multiple births (twins or triplets).

During this procedure, which typically lasts 1 to 2 hours, the mother first receives regional anesthesia to the pelvis (an "epidural"). The surgeon makes a low horizontal incision in the abdominal wall at the "bikini line." (When healing is complete the scar is easily covered by her underwear.) Another horizontal cut is then made to open the uterus, the amniochorionic membrane is ruptured, and the baby is taken out. The baby's umbilical cord is cut and the placenta is removed. The uterus is then carefully repaired with dissolvable sutures, and the abdomen is often closed with removable staples. Afterward, the mother and baby will stay in the hospital for a few days to recover.

body, but not the head. This entrapment compresses the umbilical cord, prolongs delivery, and subjects the fetus to severe distress and potential injury. If attempts to reposition the fetus or promote further dilation are unsuccessful over the short term, delivery by *cesarean section*, or *C-section* (see Clinical Note: C-Section) may be required.

Multiple Births

Multiple births (twins, triplets, quadruplets, and so forth) can take place for several reasons, including the growing use of fertility drugs and assisted reproductive technology. Another reason is the rise in the average age of women give birth (older women are more likely to release more than one oocyte in a cycle). According to the CDC, the rate of twin births in the United States is 33.7 twin births out of every 1,000 deliveries. "Fraternal twins," or **dizygotic** (dī-zī-GOT-ik) **twins**, develop when two separate oocytes are ovulated and fertilized. Because chromosomes are shuffled during meiosis, the odds against any two zygotes from the same parents having identical genes exceed 1 in 8.4 million.

"Identical twins" or **monozygotic twins**, result either from the separation of blastomeres early in cleavage or from the splitting of the inner cell mass before gastrulation. In either event, the genetic makeup of the twins is identical because both formed from the same pair of gametes.

Triplets, quadruplets, and larger multiples can result from multiple ovulations, blastomere splitting, or some combination of the two. For unknown reasons, the rates of naturally occurring multiple births fall into a pattern: Twins occur in 1 of every 89 births, triplets in 1 of every 89^2 (or 7921) births, quadruplets in 1 of every 89^3 (704,969) births, and so forth. Taking fertility drugs that stimulate the maturation of abnormally high numbers of follicles can increase the incidence of multiple births.

Pregnancies with multiple fetuses pose special problems because the strains on the mother are multiplied. The chances of premature labor are increased, and the risks to the mother are higher than for single births. Increased risks also extend to the fetuses during gestation, and to the newborns, because even at full term such newborns have lower-than-average birth weights. They are also more likely to have problems during delivery. For example, in more than half of twin deliveries, one or both fetuses enter the vaginal canal in an abnormal position.

If the splitting of the blastomeres or of the embryonic disc is not complete, **conjoined twins** may develop. These genetically identical twins typically share some skin, a portion of the liver, and perhaps other internal organs as well. Some infants can be surgically separated with some success.

29-8 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence and death

Learning Outcome Identify the features and physiological changes of the postnatal stages of life.

Developmental processes do not stop at delivery. Newborns have few of the anatomical, functional, or physiological characteristics of mature adults. The course of postnatal development typically includes five **life stages**: (1) the *neonatal period*, (2) *infancy*, (3) *childhood*, (4) *adolescence*, and (5) *maturity*. Each stage is typified by a distinctive combination of characteristics and abilities. These stages are familiar parts of human experience. Each stage has distinctive features, but the transitions between them are gradual, and the boundaries indistinct. At maturity, development ends and the process of aging, or *senescence*, begins, leading ultimately to death.

The Neonatal Period, Infancy, and Childhood

The **neonatal period** extends from birth to 1 month of age. **Infancy**, or babyhood, then continues through the first year of life. **Childhood** lasts from infancy until **adolescence** (puberty), the period of sexual and physical maturation. Two major events are under way during these developmental stages:

1. The organ systems (except those associated with reproduction) become fully operational and gradually acquire the functional characteristics of adult structures.
2. The individual grows rapidly, and body proportions change significantly.

Pediatrics is the medical specialty that focuses on postnatal development from infancy through adolescence. Infants and young children cannot clearly describe the problems they are experiencing, so pediatricians and parents must be skilled observers. Standardized tests are used to assess developmental progress relative to average values.

The Neonatal Period

The neonatal period is the 4-week period immediately after birth. During this time, the newborn adjusts to life outside the womb as extensive and ongoing system transitions occur.

Adjustments of the Neonate. Physiological and anatomical changes take place as the fetus completes the transition to the status of newborn, or **neonate**. The neonatal period is the time from birth through 28 days. Before delivery, dissolved gases, nutrients, wastes, hormones, and antibodies were transferred across the placenta. At birth, the neonate must become relatively self-sufficient, performing respiration, digestion, and excretion using its own specialized organs and organ systems. The transition from fetus to neonate can be summarized as follows:

- At birth, the lungs are collapsed and filled with fluid. Filling them with air requires a massive and powerful inhalation.
- When the lungs expand, the pattern of cardiovascular circulation changes due to alterations in blood pressure and flow rates. The ductus arteriosus closes, isolating the pulmonary and systemic trunks. Closure of the foramen ovale separates the atria of the heart, completing the separation of the pulmonary and systemic circuits.
- Typical neonatal heart rates (120–140 beats per minute) are lower than fetal heart rates (averaging 150 beats per minute). Both the neonatal heart rate and respiratory rate (30 breaths per minute) are considerably higher than in adults.
- Before birth, the digestive system is relatively inactive, although it does accumulate a mixture of bile secretions, mucus, and epithelial cells. This collection of debris, called *meconium*, is excreted during the first few days of life. During that period, the newborn begins to nurse.
- As wastes build up in the arterial blood, the kidneys excrete them. Glomerular filtration is normal, but the neonate's kidneys cannot concentrate urine to any significant degree. As a result, urinary water losses are high, and neonatal fluid requirements are proportionally much greater than those of adults.
- The neonate has little ability to control its body temperature, particularly in the first few days after delivery. As the infant grows larger and its insulating subcutaneous adipose "blanket" gets thicker, its metabolic rate also increases. Daily and even hourly shifts in body temperature continue throughout childhood. ↩ p. 1016
- During embryonic and fetal development, the mother's body is at normal body temperature. At birth, the neonate has little ability to control its body temperature. Neonates also lose heat very quickly, because they have a high surface-area-to-volume ratio. To maintain a constant body temperature, their cellular metabolic rates must be high. In fact, the metabolic rate per unit of body weight in neonates is approximately twice that of adults.

Over the entire neonatal period, the newborn is dependent on nutrients contained in milk, typically breast milk secreted by the mother's mammary glands.

Maternal Adjustments, Including Lactation. By the end of the sixth month of pregnancy, the mammary glands are fully developed, and the gland cells begin to secrete **colostrum** (kō-LOS-trum). Ingested by the infant during the first 2 or 3 days of life, colostrum contains more proteins and far less fat than breast milk. Many of the proteins are antibodies that may help the infant ward off infections until its own immune system becomes functional. In addition, the mucins present in both colostrum and milk can inhibit the replication of a family of viruses *(rotaviruses)* that can cause dangerous forms of gastroenteritis and diarrhea in infants.

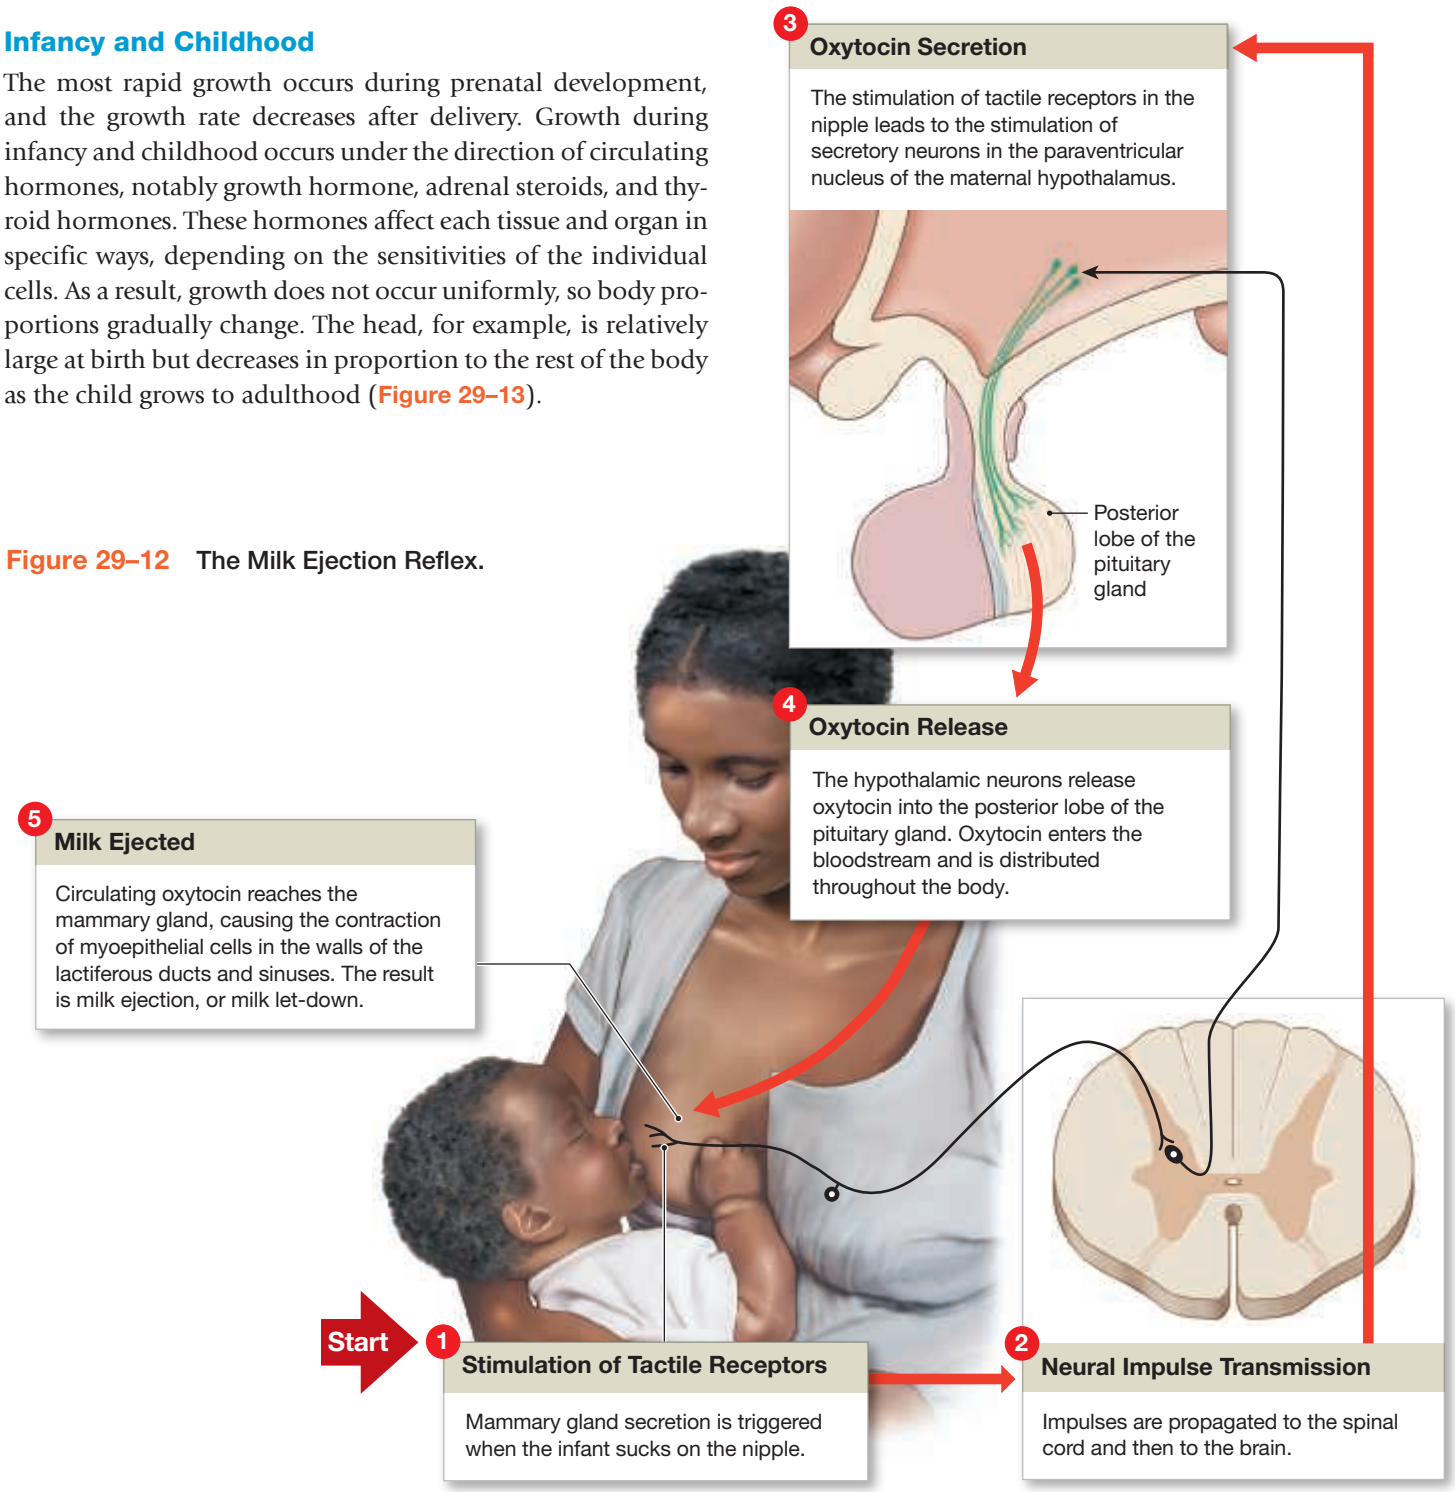
As colostrum production drops, the mammary glands convert to milk production. Breast milk consists of water, proteins, amino acids, lipids, sugars, and salts. It also contains large quantities of *lysozyme*, an enzyme with antibiotic properties. In terms of energy, human milk provides about 750 kilocalories per liter. The secretory rate varies with the demand, but a 5–6-kg (11–13-lb) infant usually requires about 850 mL (3.6 cups) of milk per day. (Maternal milk production throughout this period is maintained through the combined actions of several hormones, as detailed in Chapter 18. ↩ p. 670)

Milk becomes available to infants through the **milk ejection (milk let-down) reflex** (Figure 29–12). This reflex continues to function until *weaning*, the withdrawal of mother's milk, typically 1 to 2 years after birth. Milk production stops soon after, and the mammary glands gradually return to a resting state. Earlier weaning is a common practice in the United

States, where women take advantage of commercially prepared milk- or soy-based infant formulas that closely approximate the composition of natural breast milk. The major difference between such substitutes and natural milk is that the substitutes lack antibodies and lysozyme, which play important roles in maintaining the health of the infant. Consequently, early weaning is associated with an increased risk of infections and allergies in the infant.

Infancy and Childhood

The most rapid growth occurs during prenatal development, and the growth rate decreases after delivery. Growth during infancy and childhood occurs under the direction of circulating hormones, notably growth hormone, adrenal steroids, and thyroid hormones. These hormones affect each tissue and organ in specific ways, depending on the sensitivities of the individual cells. As a result, growth does not occur uniformly, so body proportions gradually change. The head, for example, is relatively large at birth but decreases in proportion to the rest of the body as the child grows to adulthood (Figure 29–13).



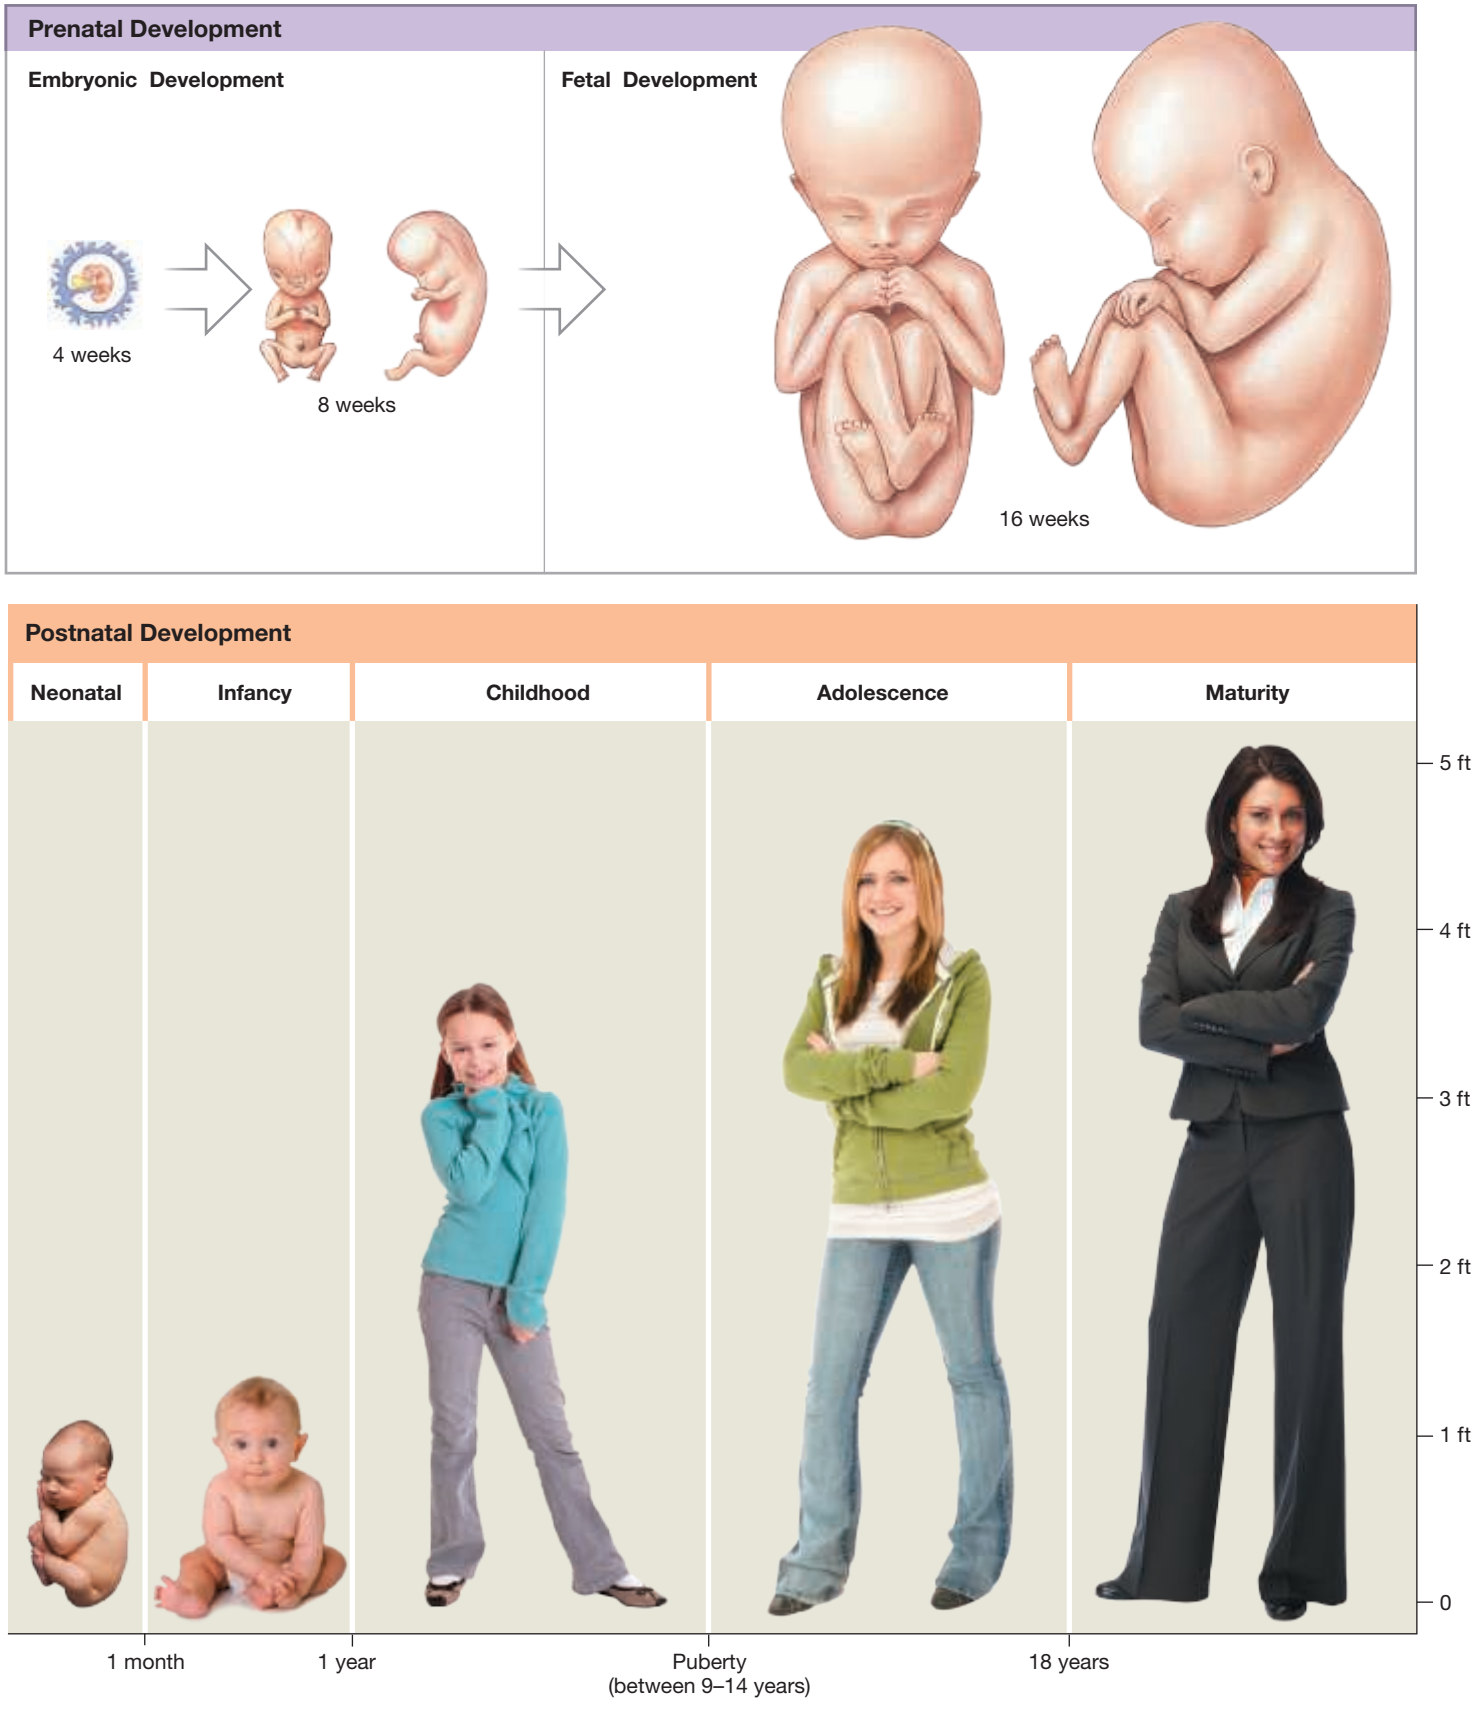


Figure 29–12 The Milk Ejection Reflex.

Figure 29–13 Prenatal and Postnatal Growth and Changes in Body Form and Proportion. The views at 4, 8, and 16 weeks of gestation are presented at actual size. Notice the changes in body form and proportions as development proceeds. For example, the head, which contains the brain and sense organs, is proportionately large at birth.

Adolescence and Maturity

Adolescence begins at **puberty**, the period of sexual maturation, and ends when growth is completed. Three major hormonal events interact at the onset of puberty:

1. The hypothalamic production of gonadotropin-releasing hormone (GnRH) increases. Evidence indicates that this increase is dependent on adequate levels of *leptin*, a hormone released by adipose tissues. ↩ p. 692
2. Endocrine cells in the anterior lobe of the pituitary gland become more sensitive to the presence of GnRH, so circulating levels of FSH and LH increase rapidly.
3. Ovarian or testicular cells become more sensitive to FSH and LH. These cells initiate (1) gamete production; (2) the secretion of sex hormones that stimulate the appearance of secondary sex characteristics and behaviors; and (3) a sudden acceleration in the growth rate, ending with closure of the epiphyseal cartilages.

The age at which puberty begins varies. In the United States today, puberty generally starts at about age 12 in boys and 11 in girls, but the normal ranges are broad (10–15 in boys, 9–14 in girls). Sex-specific differences in structure and function develop as many body systems alter their activities in response to circulating sex hormones and to the presence of growth hormone, thyroid hormones, prolactin, and adrenocortical hormones.

At puberty, endocrine system changes induce characteristic changes in various body systems:

- *Integumentary System*. Testosterone stimulates the development of terminal hairs on the face and chest of males. Under estrogen stimulation those follicles continue to produce fine hairs in females. The hairline recedes under testosterone stimulation. Both testosterone and estrogen stimulate terminal hair growth in the axillae and in the genital area. Androgens, which are present in both sexes, also stimulate sebaceous gland secretion and may cause acne. Adipose tissues respond differently to testosterone than to estrogens, and this difference produces changes in the distribution of subcutaneous body fat. In women, the combination of estrogens, prolactin, growth hormone, and thyroid hormones promotes the initial development of the mammary glands. The duct system becomes more elaborate, but true secretory alveoli do not yet develop. Much of the growth of the breasts during this period reflects increased deposition of fat rather than glandular tissue.
- *Skeletal System*. Both testosterone and estrogen accelerate bone deposition and skeletal growth. In the process, they promote closure of the epiphyseal cartilages and thus place a limit on growth in height. Girls generally do not grow as tall as boys because estrogens cause more rapid epiphyseal cartilage closure than does testosterone, and the period of skeletal growth ends at an earlier age in girls than in boys. Girls grow most rapidly between ages 10 and 13, whereas boys grow most rapidly between ages 12 and 15.
- *Muscular System*. Sex hormones stimulate the growth of skeletal muscle fibers, increasing strength and endurance. The effects of testosterone greatly exceed those of the estrogens, and the increased muscle mass accounts for significant sex differences in body mass, even for males and females of the same height. The stimulatory effects of testosterone on muscle mass have led to the use of anabolic steroids among competitive athletes of both sexes.
- *Nervous System*. Sex hormones affect central nervous system centers concerned with sexual drive and sexual behaviors. These centers differentiated in sex-specific ways during the second and third trimesters, when the fetal gonads secrete either testosterone (in males) or estrogens (in females). The surge in sex hormone secretion at puberty activates the CNS centers.
- *Cardiovascular System*. Testosterone stimulates erythropoiesis, increasing blood volume and the hematocrit. In females whose uterine cycles have begun, the iron loss associated with menstruation increases the risk of developing iron-deficiency anemia. Late in each uterine cycle, estrogens and progesterone promote the movement of water from plasma into interstitial fluid, leading to an increase in tissue water content. Estrogens decrease plasma cholesterol levels and slow the formation of plaque. As a result, premenopausal women have a lower risk of atherosclerosis ("hardening of the arteries") than do adult men.
- *Respiratory System*. Testosterone stimulates growth of the larynx and a thickening and lengthening of the vocal cords. These changes cause a gradual deepening of the voice of males compared with those of females.
- *Reproductive System*. In males, testosterone stimulates the functional development of the accessory reproductive glands, such as the prostate and seminal glands, and helps promote spermatogenesis. In females, estrogens target the uterus, promoting a thickening of the myometrium, increasing blood flow to the endometrium, and stimulating cervical mucus production. Estrogens also promote the functional development of accessory reproductive organs in females. The first few uterine cycles may or may not be accompanied by ovulation. After the initial stage, the woman will be fertile, even though her growth and physical maturation will continue for several years.

After puberty, the continued background secretion of estrogens or androgens maintains sex-specific differences. In both sexes, growth continues at a slower pace until age 18–21. By that time most of the epiphyseal cartilages have closed. The boundary between adolescence and maturity is indistinct, because it has physical, emotional, and behavioral components. Adolescence is often said to be over when growth stops, in the late teens or early twenties. The individual is then considered physically mature.

Senescence and Death

Physical growth may stop at maturity, but physiological changes continue. The sex-specific differences produced at puberty remain, but further changes take place when sex hormone levels decline at menopause or the male climacteric (andropause). ↩ p. 1140 All these changes are part of the process of **senescence** (*senesco*, to grow old), or aging, which reduces the functional capabilities of the person. Even without disease or injury, senescence-related changes at the molecular level ultimately lead to **death**.

Table 29–3 summarizes the age-related changes in organ systems discussed in earlier chapters. Taken together, these changes both decrease the functional abilities of the individual and affect homeostatic mechanisms. As a result, elderly people are less able to make homeostatic adjustments in response to internal or environmental stresses. The risks of contracting a variety of infectious diseases are proportionately increased as immune function deteriorates. Age-induced changes in vital systems cause problems such as infections, cancers, heart disease, strokes, arthritis, senile dementia, and anemia.

Physicians can attempt to adjust homeostatic mechanisms, and treat cancers and infections. **Geriatrics** (*geras*, old age) is the medical specialty that deals with the problems associated with aging. Physicians trained in geriatrics are known as **geriatricians**.

Eventually, however, this deterioration leads to drastic physiological changes that affect all internal systems. Death ultimately occurs when the body's existing homeostatic mechanisms cannot counter some combination of stresses.

Checkpoint

19. **Name the postnatal stages of development.**
20. **Describe the time frame for each of the following stages: neonatal period, infancy, and adolescence.**
21. **What is the difference between colostrum and breast milk?**
22. **Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of which stage of development?**

See the blue Answers tab at the back of the book.

Table 29–3 Effects of Aging on Organ Systems

The characteristic physical and functional changes that are part of the aging process affect all organ systems. Examples discussed in previous chapters include the following:

- A loss of elasticity in the skin that produces sagging and wrinkling. ↩ p. 221
- A decline in the rate of bone deposition, leading to weak bones, and degenerative changes in joints that make them less mobile. ↩ pp. 250, 331–332
- Reductions in muscular strength and ability. ↩ p. 371
- Impairment of coordination, memory, and intellectual function. ↩ pp. 604–605
- Reductions in the production of, and sensitivity to, circulating hormones. ↩ p. 693
- Appearance of cardiovascular problems and a reduction in peripheral blood flow that can affect a variety of vital organs. ↩ p. 824
- Reduced sensitivity and responsiveness of the immune system, leading to infection, cancer, or both. ↩ p. 873
- Reduced elasticity in the lungs, leading to decreased respiratory function. ↩ pp. 922–923
- Decreased peristalsis and muscle tone along the digestive tract. ↩ p. 977
- Decreased peristalsis and muscle tone in the urinary system, coupled with a reduction in the glomerular filtration rate. ↩ p. 1059
- Functional impairment of the reproductive system, which eventually becomes inactive when menopause or the male climacteric occurs. ↩ p. 1140

29-9 Genes and chromosomes determine patterns of inheritance

Learning Outcome Relate basic principles of genetics to the inheritance of human traits.

Recall that **chromosomes** contain **DNA** and proteins, and **genes** are functional segments of DNA. Each gene carries the information needed to direct the synthesis of a specific polypeptide. We introduced chromosome structure and the functions of genes in Chapter 3. ↩ pp. 129–136 We begin our discussion of genetics with the basic patterns of inheritance and their implications. We then examine the mechanisms responsible for regulating the activities of the genes during prenatal development.

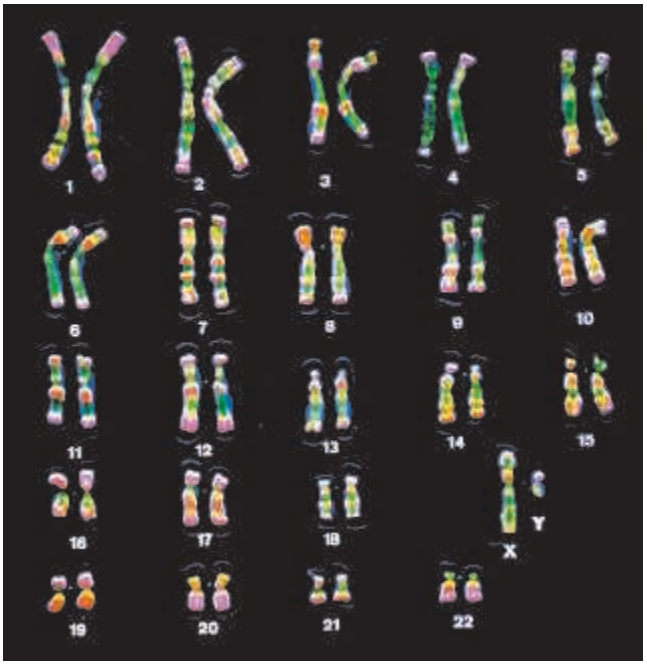
Genotype and Phenotype

Every nucleated somatic cell in your body carries copies of the original 46 chromosomes present when you were a zygote. Those chromosomes and their genes make up your **genotype** (JĒN-ō-tīp; *geno-*, gene).

Through development and differentiation, the instructions contained in the genotype are **expressed**, or carried out, in many ways. No single cell or tissue uses all the information and instructions contained in the genotype. For example, in

muscle fibers, the genes involved in the formation of excitable membranes and contractile proteins are active, but in cells of the pancreatic islets, a different set of genes is at work. Collectively, however, the instructions in your genotype determine the anatomical and physiological characteristics that make you a unique person. Those anatomical and physiological characteristics are your **phenotype** (FĒ-nō-tīp; *phaino*, to display). The phenotype results from the interaction between the person's genotype and the environment. In architectural terms, the genotype is a set of plans, and the phenotype is the finished building. Observable features, such as hair or eye color, are called phenotypic *characters*. Specific character variants, such as brown hair or eyes, are called phenotypic *traits*.

Your genotype is derived from the genotypes of your parents. Yet you are not an exact copy of either parent. Nor are you an easily identifiable mixture of their characteristics.



Homologous Chromosomes and Alleles

The 46 chromosomes carried by each human somatic cell occur in pairs. Every somatic cell contains 23 pairs of chromosomes. At amphimixis, the sperm supplies the paternal member of each pair, and the ovum supplies the maternal member. Recall that the two members of each of the 22 pairs are known as **homologous chromosomes**. ↩ p. 1111 Those 22 chromosome pairs are called **autosomes.** Most of the genes of autosomes affect somatic, or body, characteristics, such as hair color and skin pigmentation. The chromosomes of the 23rd pair are not truly homologous and are known as the **sex chromosomes**. One of their functions is to determine whether the individual is genetically male or female. Figure 29–14 shows the **karyotype** (*karyon*, nucleus + *typos*, mark), or entire set of chromosomes, of a normal male. In the discussion that follows, we deal with the inheritance of traits carried on the autosomal chromosomes. We will examine the patterns of inheritance by the sex chromosomes later in this section.

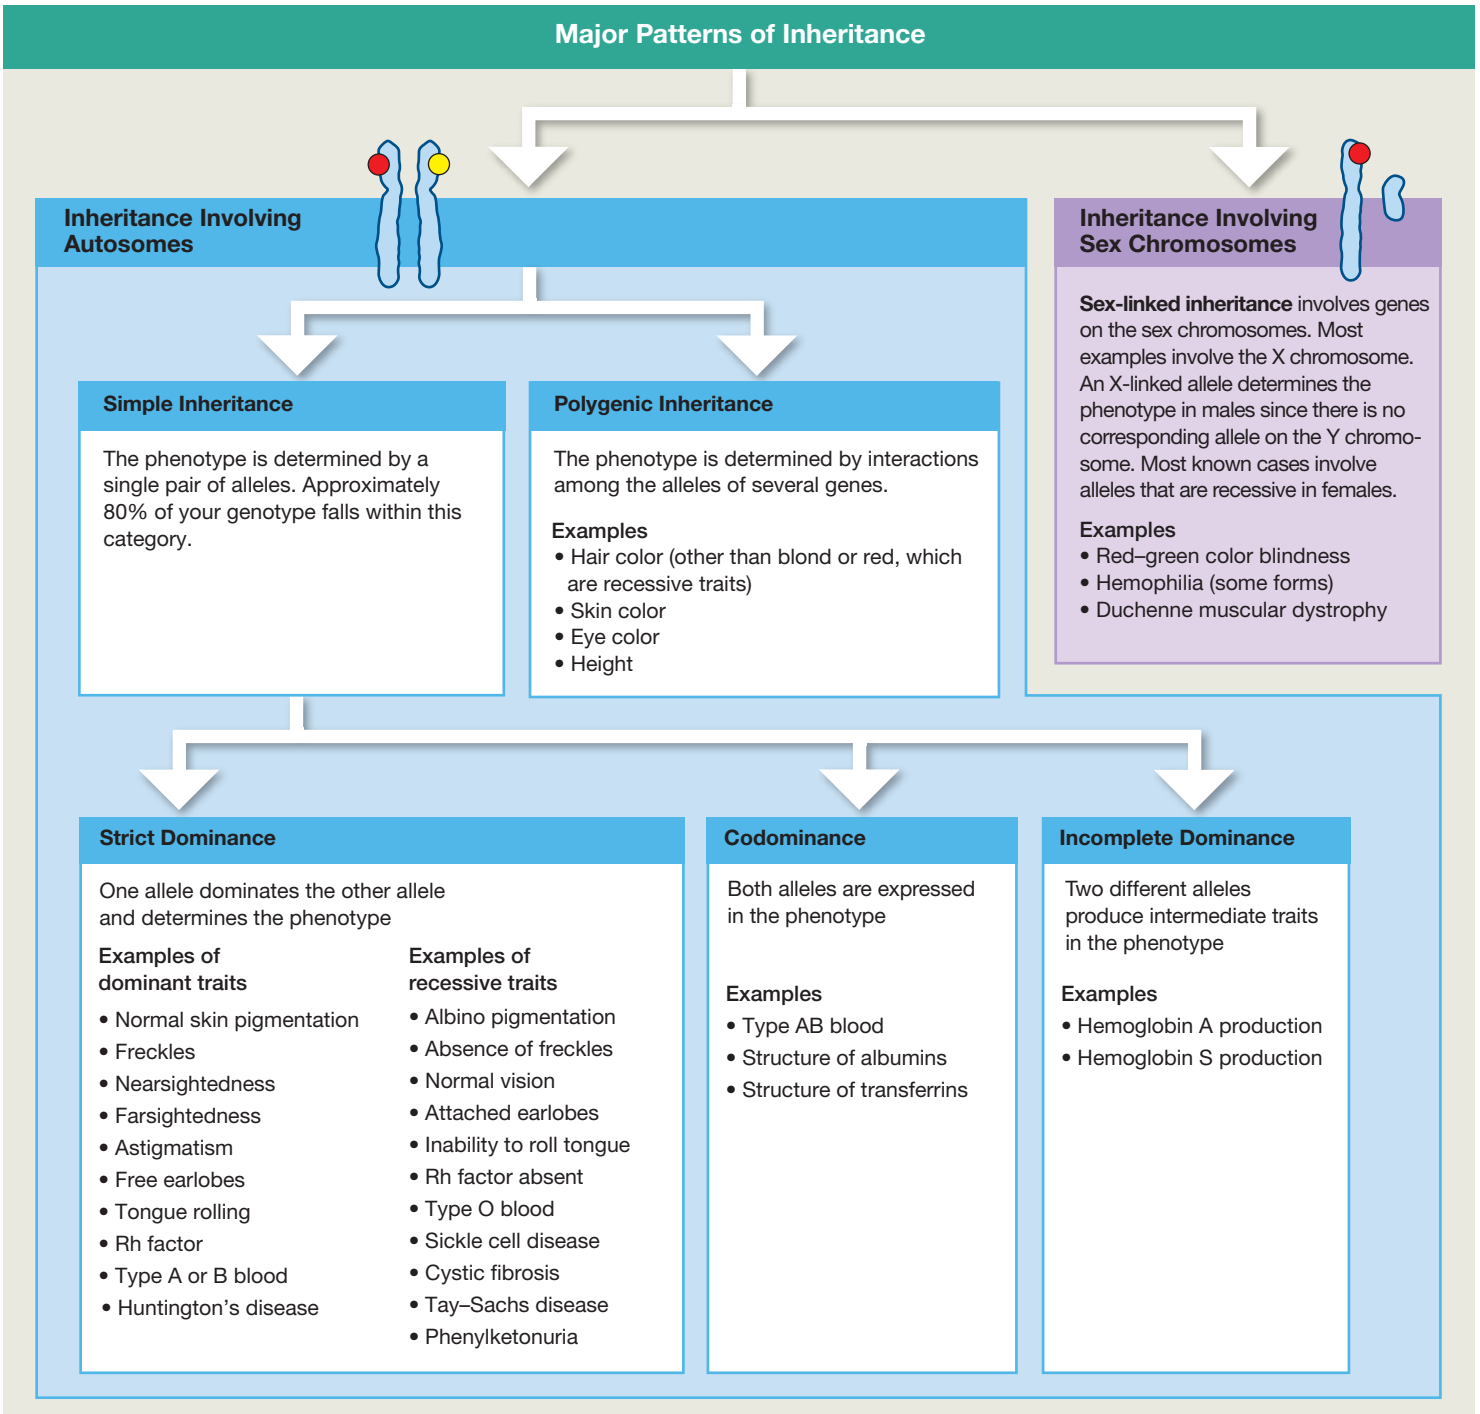
The two chromosomes in an autosomal homologous pair have the same structure and carry genes that affect the same traits. For example, suppose that one member of the pair contains three genes in a row, with the first gene determining hair color, the second eye color, and the third skin pigmentation. The other chromosome, or *homolog*, carries genes that affect the same traits, and the genes are in the same sequence. The genes are also located at equivalent positions on their respective chromosomes. A gene's position on a chromosome is called a **locus** (LŌ-kus; plural, *loci* [LŌ-sī]).

Because the two chromosomes of a homologous pair have different origins, one paternal and the other maternal, they may not carry the same *form*, or version, of each gene, however. The various forms of a given gene are called **alleles** (uh-LĒLZ). These *alternative forms* determine the precise effect of the gene on your phenotype. If the two chromosomes of a homologous pair carry the same allele of a particular gene, you are **homozygous** (hō-mō-ZĪ-gus; *homos*, the same) for the trait affected by that gene. If you have two different alleles for the same gene, you are **heterozygous** (het-er-ō-ZĪ-gus; *heteros*, other) for the trait determined by that gene.

Figure 29–14 A Human Male Karyotype.

? Explain why this is a karyotype of a male and not a female.

Autosomal Patterns of Inheritance



In **simple inheritance**, the phenotype is determined by interactions between a single pair of alleles. Some phenotypic traits are determined by interactions among several genes. Such interactions constitute **polygenic inheritance**. The potential interactions, which include examples of normal and abnormal phenotypic traits, are diagrammed in Figure 29–15.

Simple Inheritance

If you are homozygous for a particular trait, that allele will then indeed be expressed in your phenotype. For example, if you receive a gene for freckles from your father and a gene for freckles from your mother, you will be homozygous for freckles—and you will have freckles. About 80 percent of an individual's genome consists of homozygous alleles.

The phenotype that results from a heterozygous genotype depends on the nature of the interaction between the corresponding alleles. For example, if you received a gene for curly hair from your father, but a gene for straight hair from your

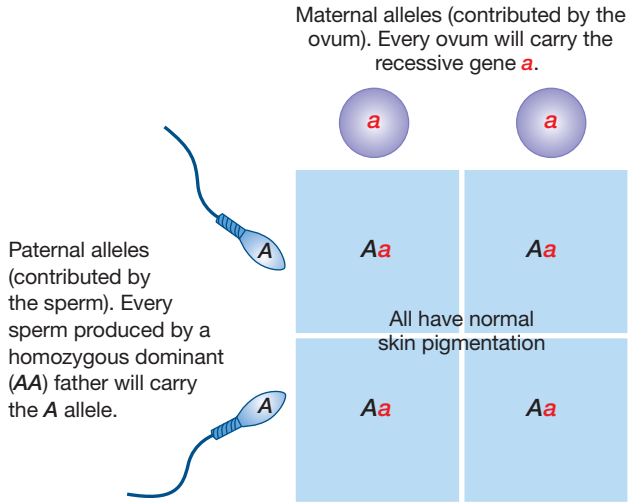
Figure 29–15 Major Patterns of Inheritance.

? What types of inheritance are involved in the following phenotypes-nearsightedness, normal vision, and red-green color blindness?

mother, whether *you* will have curly hair, straight hair, or even wavy hair depends on the relationship between the alleles for those traits. The relationship can be one of *strict dominance*, *codominance*, or *incomplete dominance*, as follows:

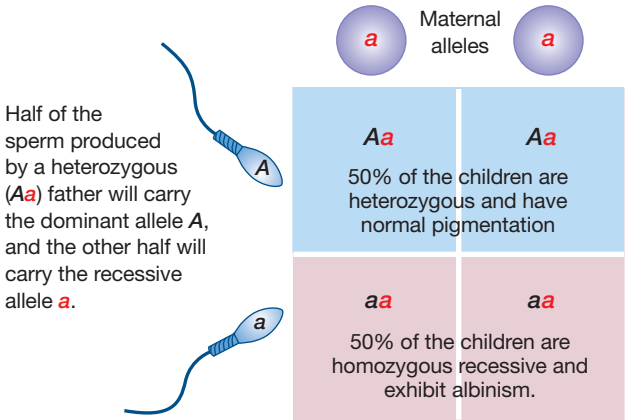
- In **strict dominance**, an allele that is **dominant** will be expressed in the phenotype, *regardless of any conflicting instructions carried by the other allele.* For instance, an individual with only one allele for freckles will have freckles, because that allele is dominant over the "nonfreckle" allele. An allele that is **recessive** will be expressed in the phenotype only if that same allele is present on *both chromosomes* of a homologous pair. For example, in Chapter 5 you learned that people with albinism cannot synthesize the yellow-brown pigment *melanin*. ↩ p. 207 The presence of one allele that directs melanin production will result in normal color. Two recessive alleles must be present to produce an individual with albinism. A single gene can have many different alleles *in a population*, some dominant and others recessive. An individual can have a maximum of only two alleles—one from the mother and the other one from the father. If both parents have the same alleles, then an individual has only one kind of allele, but two copies of it, and is thus, homozygous.
- In **codominance**, an individual who is heterozygous (has different alleles) for a given trait exhibits both phenotypes for that trait. Blood type in humans is determined by codominance. The alleles for type A and type B blood are dominant over the allele for type O blood, but a person with one type A allele and one type B allele has type AB blood, not A or B. The red blood cells that make up type AB blood express *both* type A antigens and type B antigens. ↩ p. 714
- In **incomplete dominance**, heterozygous alleles produce a phenotype that is intermediate (not completely dominant) to the phenotypes of individuals who are homozygous for one allele or the other. A good example is the sickling gene that affects the shape of red blood cells. Individuals with homozygous alleles that carry instructions for normal adult hemoglobin A have red blood cells of normal shape. Individuals with homozygous alleles for hemoglobin S, an abnormal form, have red blood cells that become sickle shaped in peripheral capillaries when the P_{O_2} decreases. These individuals develop *sickle cell disease.* ↩ p. 732 Individuals who are heterozygous for this trait do not develop anemia but their red blood cells may sickle when tissue oxygen levels are extremely low. The distinction between incomplete dominance and codominance is not always clear-cut. For example, a person who has alleles for hemoglobin A and hemoglobin S shows incomplete dominance for RBC shape, but codominance for hemoglobin. Each red blood cell contains a mixture of hemoglobin A and hemoglobin S. Incomplete dominance is relatively rare in humans.

Predicting Simple Inheritance: The Punnett Square When an allele can be neatly characterized as dominant or recessive, you can predict the characteristics of individuals on the basis of their parents' alleles.



In such calculations, dominant alleles are traditionally indicated by capitalized abbreviations, and recessive alleles by lowercase abbreviations. Thus, for a given trait, the possible genotypes are indicated by *AA* (homozygous dominant), *Aa* (heterozygous), or *aa* (homozygous recessive). Each gamete involved in fertilization contributes a single allele for a given trait. That allele must be one of the two alleles contained by all cells in the parent's body. For example, let's consider the possible offspring of a mother with albinism (no skin pigmentation) and a father with normal skin pigmentation. The alleles of the maternal genotype are abbreviated *aa* because albinism is a homozygous recessive trait. No matter which of her oocytes is fertilized, it will carry the recessive *a* allele. The father has normal pigmentation, a dominant trait. His genotype therefore is either homozygous dominant *or* heterozygous for this trait, because both *AA* and *Aa* will produce the same phenotype: normal skin pigmentation. Every sperm produced by a homozygous dominant father will carry the *A* allele. In contrast, half the sperm produced by a heterozygous father will carry the dominant allele *A*, and the other half will carry the recessive allele *a*.

A simple box diagram known as a **Punnett square** helps us to predict the probabilities that children will have particular phenotypic traits by showing the various combinations of parental alleles they can inherit. In the Punnett squares shown in **Figure 29–16**, the maternal alleles for skin pigmentation are listed along the horizontal axis, and the paternal ones along the vertical axis. The combinations of alleles appear in the small boxes. **Figure 29–16a** shows the possible offspring of an *aa* mother and an *AA* father. All the children will have the genotype *Aa*, so all will have normal skin pigmentation. Compare these results with those of **Figure 29–16b**, for a heterozygous father (*Aa*) and an *aa* mother. The heterozygous father produces two types of gametes, *A* and *a*. The mother's secondary oocyte, carrying an *a* allele, may be fertilized by either one. As a result, the probability is 50 percent that a child of such a father will inherit the genotype *Aa* and so have normal skin pigmentation. The probability of inheriting the genotype *aa*, and thus having the albinism phenotype, is also 50 percent.



A Punnett square can also be used to draw conclusions about the identity and genotype of a parent. For example, in our scenario, a man with the genotype *AA* cannot be the father of an albino child (genotype *aa*).

We can also predict the frequency of appearance of any inherited disorder that results from simple inheritance by using a Punnett square. Although they are rare in terms of overall

Figure 29–16 Predicting Phenotypic Traits by Using Punnett Squares.

a If the father is homozygous for normal pigmentation, all of the children will have the genotype Aa, and all will have normal skin pigmentation.

b If the father is heterozygous for normal skin pigmentation, the probability that a child will have normal pigmentation is reduced to 50%.

numbers, more than 1200 inherited disorders have been identified that reflect the presence of one or two abnormal alleles for a single gene.

Polygenic Inheritance

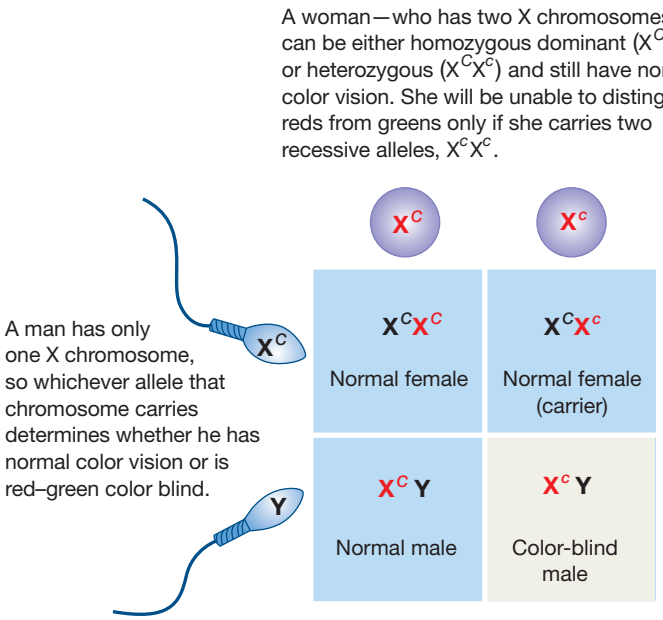
We cannot predict the presence or absence of phenotypic traits inherited in a polygenic manner using a simple Punnett square, because the resulting phenotype depends not only on the nature of the alleles but also on how those alleles interact. In *suppression*, one gene suppresses the other. As a result, the second gene has no effect on the phenotype. In *complementary gene action*, dominant alleles on two genes interact to produce a phenotype different from that seen when one gene contains recessive alleles. The risks of developing several important adult disorders, including hypertension and coronary artery disease, are linked to polygenic inheritance.

Many of the developmental disorders responsible for fetal deaths and congenital malformations result from polygenic inheritance. In these cases, an individual's genetic composition does not by itself determine the onset of the disease. Instead, the conditions regulated by these genes establish a susceptibility to particular environmental influences. As a result, not every individual with the genetic tendency for a certain condition will develop that condition. For this reason, it is difficult to track polygenic conditions through successive generations. However, steps can be taken to prevent a crisis because many inherited polygenic conditions are *likely* (but not *guaranteed*) to occur. For example, you can reduce hypertension by controlling your diet and fluid volume, and you can prevent coronary artery disease by lowering your blood serum cholesterol levels.

Sex-Linked Patterns of Inheritance

Sex-linked inheritance involves genes on the sex chromosomes (see Figure 29–15). Unlike the other 22 chromosomal pairs, the sex chromosomes are not identical in appearance and gene content. There are two types of sex chromosomes: an **X chromosome** and a **Y chromosome**. X chromosomes are considerably larger and have more genes than do Y chromosomes. The smaller Y chromosome carries the *SRY gene* not found on the X chromosome. It specifies that an individual with that chromosome will be male. The normal pair of sex chromosomes in males is XY. Females do not have a Y chromosome. Their sex chromosome pair is XX.

All oocytes carry an X chromosome, because the only sex chromosomes females have are X chromosomes. But each sperm carries either an X or a Y chromosome, because males have one of each and can pass along either one during meiosis. As a Punnett square shows, the ratio of males to females in offspring should be 1:1. The worldwide birth statistics differ slightly from that prediction, with 107 males born for every 100 females. It has been suggested that more males are born because a sperm that carries the Y chromosome can reach the oocyte first, because that sperm does not have to carry the extra weight of the larger X chromosome.



The X chromosome also carries genes that affect somatic structures. Genes that are found on the X chromosome but not on the Y chromosome are called **X linked**. The inheritance of

characteristics, or traits, regulated by these X-linked genes does not follow the pattern of alleles on autosomal chromosomes. (The SRY gene that determines "maleness" is an example of a Y-linked gene.)

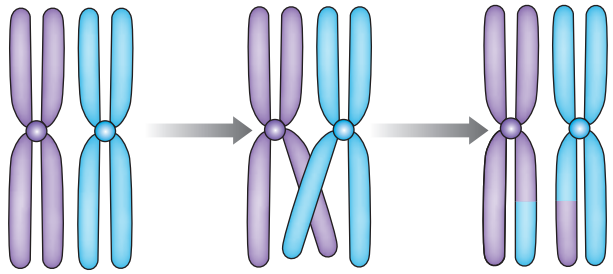
The inheritance of color blindness shows the differences between sex-linked inheritance and autosomal inheritance. The presence of a dominant allele, *C*, on the X chromosome (X^C) results in normal color vision. A recessive allele, *c*, on the X chromosome (X^c) results in red–green color blindness. A woman, with her two X chromosomes, can be either homozygous dominant (X^CX^C) or heterozygous (X^CX^c) and still have normal color vision. She will be unable to distinguish reds from greens only if she carries two recessive alleles, X^cX^c. But a male has only one X chromosome, so whichever allele that X chromosome carries determines whether he has normal color vision or has red–green color blindness. The Punnett square in Figure 29–17 reveals that the sons produced by a father with normal vision and a heterozygous (carrier) mother have a 50 percent chance of being red–green color blind. Any daughters have normal color vision. Recessive alleles on X chromosomes produce genetic disorders in males at a higher frequency than in females.

A number of other clinical disorders noted earlier in the text are X-linked traits, including certain forms of hemophilia, diabetes insipidus, and muscular dystrophy. In several instances, advances in molecular genetics techniques have enabled geneticists to locate the specific genes on the X chromosome. These techniques provide a reasonably direct method of screening for the presence of a particular condition before any signs or symptoms appear, and even before birth.

Figure 29–17 Inheritance of an X-Linked Trait.

Sources of Individual Variation

Just as you are not a copy of either of your parents, you also are not a 50–50 mixture of their characteristics. We noted one reason for this in Chapter 28: During meiosis, maternal and paternal chromosomes are randomly distributed, so each gamete has a unique combination of maternal and paternal chromosomes. For this reason, you may have an allele for freckles from your father and an allele for nonfreckles from your mother, even though your sister received an allele for nonfreckles from each of your parents.



Only in very rare cases does an individual receive both alleles from one parent. The few documented cases appear to have resulted when duplicate maternal chromatids failed to separate during meiosis II and the corresponding chromosome provided by the sperm did not participate in amphimixis. This condition, called *uniparental disomy*, generally remains undetected, because the individuals are phenotypically normal.

Genetic Recombination

During meiosis, various changes can occur in chromosome structure, producing gametes with chromosomes that differ from those of each parent. **Genetic recombination** greatly increases the genetic variation among gametes, and thus among the genotypes formed when those gametes combine in fertilization.

In one normal form of recombination, parts of homologous chromosomes become rearranged during synapsis of meiosis (Figure 29–18). When tetrads form, adjacent chromatids may overlap. The chromatids may then break, and the overlapping segments trade places, an event called **crossing over**. In contrast, genetic recombination between nonhomologous chromosomes it is called **translocation**. During recombination, portions of chromosomes may also break away and be lost, or *deleted*. This

Figure 29–18 Crossing Over and Recombination.

a Tetrad at synapsis Synapsis, with the formation of a tetrad during meiosis

b Crossing over Crossing over of portions of chromatids of two homologous chromosomes

c Recombination The exchange of corresponding segments and groups of genes increases genetic variation among the gametes produced.

event is abnormal, and it can have severe or even lethal effects on the zygote, depending on the nature of the lost genes.

Recombination that results in abnormal chromosome shapes or numbers is lethal for the zygote in almost all cases. Roughly 10 percent of zygotes have **chromosomal abnormalities**—that is, damaged, broken, missing, or extra copies of chromosomes—but only about 0.5 percent of newborns have such abnormalities. Few individuals with chromosomal abnormalities survive to full term. *Down syndrome (trisomy 21)*, which involves one of the smallest chromosomes in humans, is an exception.

In addition to contributing to prenatal mortality, chromosomal abnormalities produce a variety of serious clinical conditions. The high mortality rate and the severity of the problems reflect the fact that large numbers of genes have been added or deleted. Women who become pregnant later in life run a higher risk of birth defects and miscarriage due to chromosomal abnormalities in the oocyte. It seems that the longer the oocyte remains suspended in meiosis I, the more likely are recombination errors when meiosis is completed.

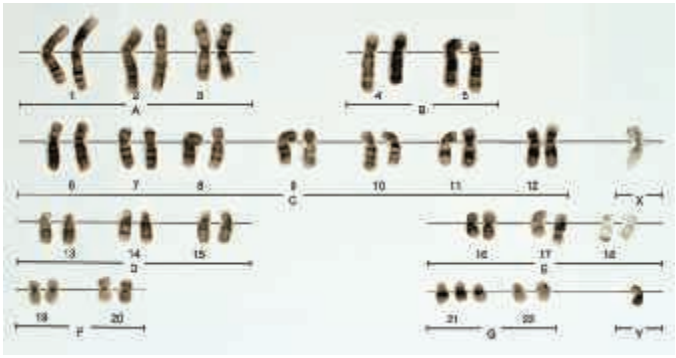
However, a lack of specific gene expression in a zygote is not necessarily due to chromosomal aberrations or deletions. Genes can be present, yet be prevented from being fully expressed. A genetic process called **genomic imprinting** is particularly important in the early embryo. Imprinting does not change the DNA itself. Instead, it results in specific (and usually reversible) chemical modifications, or markings, of DNA and its associated proteins. These changes then dictate whether the gene is expressed or not (silenced). As gametes mature,

+ Clinical Note Amniocentesis

Many genetic conditions can be detected before birth through the analysis of fetal cells. In **amniocentesis**, a sample of **amniotic fluid** is removed and the fetal cells it contains are analyzed. This procedure permits the identification of many congenital conditions, including Down syndrome, sickle cell disease, and neural tube defects. The needle inserted to obtain a fluid sample is guided into position during an ultrasound procedure. ↩ p. 63

Because the sampling procedure represents a potential threat to the health of both the fetus and the mother, amniocentesis is generally offered only to women who have a significant risk for genetic diseases.

Sampling cannot safely be performed until the volume of amniotic fluid is large enough that the fetus will not be injured during the process. The usual time for amniocentesis is between the 15th and 18th week of pregnancy. Results are usually available within 2–3 weeks.



+ Clinical Note Chromosomal Abnormalities

Embryos that have abnormal autosomal chromosomes (chromosomes 1–22) rarely survive. However, *translocation defects* and *trisomy* are two types of autosomal abnormalities that do not invariably result in prenatal death.

In a **translocation defect**, an exchange occurs between different (nonhomologous) chromosome pairs. For example, a piece of chromosome 8 may become attached to chromosome 14. The genes moved to their new position may function abnormally, becoming inactive or overactive. In a balanced translocation, where there is no net loss or gain of chromosomal material, embryos may survive.

In **trisomy**, a mistake occurs in meiosis. One of the gametes involved in fertilization carries an extra copy of one chromosome, so the zygote then has three copies of this chromosome rather than two. (The nature of the trisomy is indicated by the number of the chromosome involved. For example, individuals with trisomy 13 have three copies of chromosome 13.) Zygotes with extra copies of chromosomes seldom survive. The notable exception is trisomy 21.

Trisomy 21, or **Down syndrome**, is the most common viable chromosomal abnormality. According to the CDC, about 6000 babies, or about 1 in every 700 babies, are born with Down syndrome. The degree of developmental disability

ranges from moderate to severe. Anatomical problems affecting the cardiovascular system often prove fatal during childhood or early adulthood. Although some individuals survive to moderate old age, many develop Alzheimer's disease while still relatively young (before age 40).

For unknown reasons, there is a direct correlation between advancing maternal age and the risk of having a child with trisomy 21. This is becoming increasingly significant because many women are delaying childbearing until their mid-thirties or later.

a proportion of their genes develop characteristic, maternal and paternal specific, imprinting markings. These markings persist after fertilization and can regulate whether or not the maternally or the paternally derived gene is transcribed during embryonic development. Many of the genes known to be affected by genomic imprinting regulate many aspects of early development, including rates of prenatal and postnatal growth, behavior, and language development. Imprinting is a normal process that acts as a "volume control" for parental genes since it results in one active copy of an imprinted gene.

Incorrectly imprinted genes can have the same effect as deletion of the same gene. This is exemplified by two human genetic disorders linked to genes in a specific portion of chromosome 15 and their differential imprinting during sperm or oocyte formation. *Angelman syndrome*, which results in hyperactivity, severe developmental disability, and seizures, occurs when the maternal genes are inactive. *Prader–Willi syndrome*, which results in short stature, reduced muscle tone and skin pigmentation, underdeveloped gonads, and some degree of developmental disability, occurs when paternal genes are inactive.

Epigenetics is the study of inherited traits that are *not* due to changes in a person's genotype or DNA sequences. Similar to genomic imprinting, it acts at a level "above" the DNA by activating or inactivating specific genes. Such gene regulation occurs in a number of ways. One way is by chemically marking DNA and its histone proteins with methyl or acetyl groups, which permit or restrict transcription, respectively. Understanding the role of epigenetics in human clinical disorders, disease, and early development is an area of active study.

Mutations

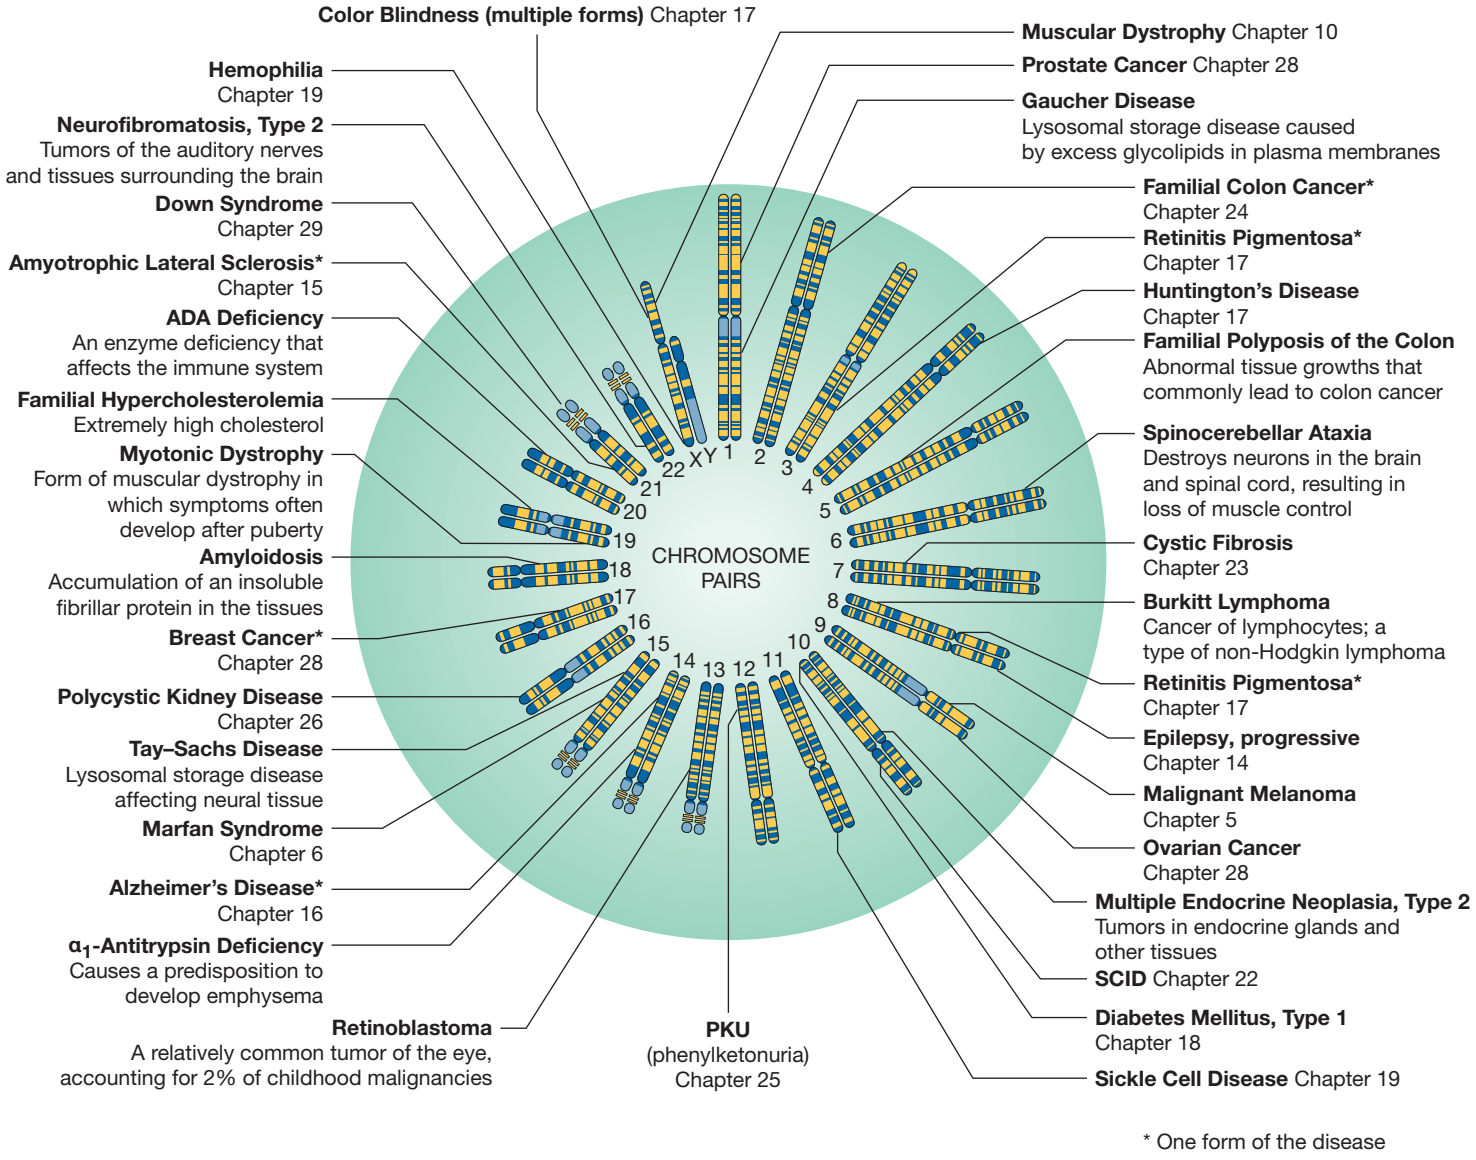
Variations at the level of the individual gene can result from *mutations*—changes in the nucleotide sequence of an allele. **Spontaneous mutations** result from random errors in DNA replication. Such errors are relatively common, but in most cases the error is detected and repaired by DNA repair enzymes in the nucleus. Those errors that go undetected and unrepaired have the potential to change the phenotype in some way.

Mutations occurring during meiosis can produce gametes that contain abnormal alleles. These alleles may be dominant or recessive, and they may occur on autosomal chromosomes or on sex chromosomes. The vast majority of mutations make the zygote incapable of completing normal development. Mutation, rather than chromosomal abnormalities, is probably the primary cause of the high mortality rate among pre-embryos and embryos. (Approximately 50 percent of all zygotes fail to complete cleavage, and another 10 percent fail to reach the fifth month of gestation.)

If the abnormal allele is dominant but does not affect gestational survival, the individual's phenotype will show the effects of the mutation. If the abnormal allele is recessive and is on an autosomal chromosome, it will not affect the individual's phenotype as long as the zygote contains a normal allele contributed by the other parent at fertilization. Over generations, a recessive autosomal allele can spread through the population, remaining undetected until a fertilization occurs in which the two gametes contribute identical recessive alleles. This individual, who will be homozygous for the abnormal allele, will be the first to show the phenotypic effects of the original mutation. Individuals who are heterozygous for an abnormal allele but do not show the effects of the mutation are called **carriers**. Available genetic tests can determine whether an individual is a carrier for any of several autosomal recessive disorders, including Tay–Sachs disease. The information obtained from these tests can be useful in counseling prospective parents. For example, if both parents are carriers of the same disorder, they have a 25 percent probability of producing a child with the disease. This information may affect their decision to conceive.

Effect of Environmental Factors: Penetrance and Expressivity

Differences in genotype lead to distinct variations in phenotype, but the relationships are not always predictable. The presence of a particular pair of alleles does not affect the phenotype in the same way in every individual. **Penetrance** is the percentage of individuals with a particular genotype that show the "expected" phenotype. In other individuals, the activity of other genes or environmental factors may override the effects of that genotype. For example, *emphysema*, a respiratory disorder discussed in Chapter 23, has been linked to a specific abnormal genotype. ↩ p. 923 However, about 20 percent of the individuals with this genotype do not develop emphysema, making the penetrance of this genotype approximately 80 percent. The effects of environmental factors are apparent: Most people who develop emphysema are cigarette smokers.



If a given genotype *does* affect the phenotype, it can do so to various degrees, again depending on the activity of other genes or environmental stimuli. For example, even though identical twins have the same genotype, they do not have exactly the same fingerprints. The extent to which a particular allele is expressed when it is present is termed its **expressivity**.

Environmental effects on genetic expression are particularly evident during embryonic and fetal development. Drugs, including certain antibiotics, alcohol, and nicotine in cigarette smoke, can disrupt fetal development. Factors that result in abnormal development are called **teratogens** (TER-ah-tō-jenz).

The Human Genome

The **human genome** is the full set of genetic material (DNA) in our chromosomes. We now know the nucleotide sequences of its total 3.2 billion base pairs spread among our 22 autosomes and X and Y sex chromosomes. This knowledge has revealed that our genome contains 20,000–25,000 protein-coding genes. It

Figure 29–19 A Map of Human Chromosomes. The banding patterns of typical chromosomes in a male, and the general locations of the mutated genes associated with specific inherited disorders. The chromosomes are not drawn to scale.

has also led to a description of roughly 10,000 different single-gene disorders. Most are very rare, but collectively they may affect 1 in every 200 births. Several examples are included in Figure 29–19. Genetic screening and diagnostic tests for abnormal genes are now performed for many of these disorders.

We have identified the normal genetic composition of a "typical" human and have begun to reveal how genes are regulated. *Gene therapy* is a rapidly growing field of medicine. **Gene therapy** involves inserting corrective genes made in a laboratory into a patient's cells to treat disorders or diseases caused by genetic defects.

We all are variations on a basic theme. How do we decide what set of genes to accept as "normal"? Moreover, as we improve our abilities to modify the expression of a gene or correct an abnormal gene, we will face many additional ethical and legal dilemmas. In the years to come, we will have to find answers to these dilemmas that are acceptable to us all.

Checkpoint

23. Describe the relationship between genotype and phenotype.
24. Define *heterozygous*.
25. Tongue rolling is an autosomal dominant trait. What would be the phenotype of a person who is heterozygous for this trait?
26. Why are children not identical copies of their parents?

See the blue Answers tab at the back of the book.

29 Chapter Review

Study Outline

An Introduction to Development and Inheritance p. 1150

1. Humans develop in the womb, grow to maturity, and live for most of a century.
2. An interplay between genes and the environment shapes physiological processes.

29-1 Directed by inherited genes, a fertilized ovum differentiates during prenatal development to form an individual; postnatal development brings that individual to maturity p. 1150

3. **Development** is the gradual modification of anatomical structures and physiological characteristics from conception to maturity. The formation of different types of cells is **differentiation**.
4. **Prenatal development** occurs before birth; **postnatal development** begins at birth and continues to **maturity**, when aging begins. **Inheritance** is the transfer of genetically determined characteristics from generation to generation. **Genetics** is the study of the mechanisms of inheritance.

29-2 Fertilization—the fusion of a secondary oocyte and a sperm—forms a zygote p. 1151

5. **Fertilization**, or *conception*, normally occurs in the uterine tube within a day after ovulation. Sperm cannot fertilize a secondary oocyte until they have undergone *capacitation*. *(Figure 29–1)*
6. The acrosomes of the sperm release **hyaluronidase** and **acrosin**, enzymes required for sperm to penetrate the corona radiata and zona pellucida of the oocyte. When a single sperm contacts the oocyte membrane, fertilization begins and **oocyte activation** follows. *(Figure 29–1)*
7. During activation, the oocyte completes meiosis II and thus becomes a functionally mature ovum. Membrane depolarization and the *cortical reaction* act as a **block to polyspermy**.
8. After activation, the **female pronucleus** and the **male pronucleus** replicate their DNA before fusing in a process called *amphimixis*. *(Figure 29–1)*

29-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters p. 1153

9. The 9-month **gestation** period can be divided into three **trimesters**.

29-4 The first trimester includes pre-embryonic and embryonic development, involving the processes of cleavage, implantation, placentation, and embryogenesis p. 1153

10. In the **first trimester**, **cleavage** subdivides the cytoplasm of the zygote in a series of mitotic divisions; the zygote becomes a **pre-embryo** and then a **blastocyst**. During **implantation**, the blastocyst becomes enclosed within the uterine endometrium. **Placentation** occurs as blood vessels form around the blastocyst and the **placenta** develops. **Embryogenesis** is the formation of a viable embryo.
11. The blastocyst consists of an outer **trophoblast** and an **inner cell mass**. *(Figure 29–2)*
12. Implantation occurs about 7 days after fertilization as the blastocyst adheres to the uterine lining. *(Figure 29–3)*
13. As the **syncytiotrophoblast** enlarges and spreads, maternal blood flows through open **lacunae**. After **gastrulation**, there is an **embryonic disc** composed of **endoderm**, **ectoderm**, and an intervening **mesoderm**. It is from these **germ layers** that the body systems differentiate. *(Figure 29–4; Table 29–1)*
14. During prenatal development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. The chemical interplay among developing cells is **induction**.
15. Germ layers are involved in forming four **extra-embryonic membranes**: the yolk sac, amnion, allantois, and chorion. *(Spotlight Figure 29–5)*
16. The **yolk sac** is an important site of blood cell formation. The **amnion** encloses fluid that surrounds and cushions the developing embryo. The base of the **allantois** later gives rise to the urinary bladder. Circulation within the vessels of the **chorion** provides a rapid-transit system that links the embryo with the trophoblast. *(Spotlight Figure 29–5; Figure 29–6)*
17. **Chorionic villi** extend outward into the maternal tissues, forming an intricate, branching network through which maternal blood flows. As development proceeds, the **umbilical cord** connects the fetus to the placenta. *(Figure 29–6)*
18. The first trimester is critical, because events in the first 12 weeks establish the basis for **organogenesis** (organ formation). *(Figure 29–7; Table 29–2)*

29-5 During the second and third trimesters, fetal development involves growth and organ function p. 1161

19. In the **second trimester**, the organ systems increase in complexity. During the **third trimester**, many of the organ systems become fully functional. *(Figure 29–8; Table 29–2)*
20. The fetus undergoes its largest weight gain in the third trimester. At the end of gestation, the fetus and the enlarged uterus displace many of the mother's abdominal organs. *(Figure 29–9)*

29-6 During gestation, maternal organ systems support the developing fetus; the reproductive system undergoes structural and functional changes p. 1163

21. The syncytiotrophoblast synthesizes **human chorionic gonadotropin (hCG)**, **human placental lactogen (hPL)**, **placental prolactin**, **relaxin**, **progesterone**, and **estrogens**.
22. The developing fetus is totally dependent on maternal organs for nourishment, respiration, and waste removal. Maternal adaptations include increases in respiratory rate, tidal volume, blood volume, nutrient and vitamin intake, and glomerular filtration rate, as well as changes in the size of the uterus and mammary glands.

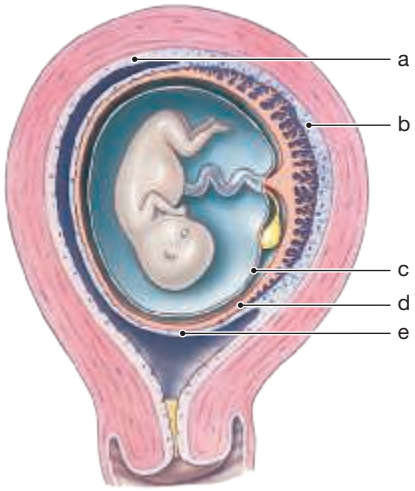
29-7 Childbirth occurs through the process of labor, which consists of the dilation, expulsion, and placental stages p. 1169

23. Progesterone produced by the placenta has an inhibitory effect on uterine muscles. Estrogens, oxytocin, and prostaglandins oppose its calming action. At some point, multiple factors interact to produce **labor contractions** in the uterine wall. *(Figure 29–10)*
24. The goal of **true labor** is **parturition**, the forcible expulsion of the fetus.
25. Labor can be divided into three stages: the **dilation stage**, the **expulsion stage**, and the **placental stage**. The Apgar score is used to assess the overall health of a newborn. *(Figure 29–11)*
26. **Premature labor** may result in **premature delivery**.
27. Difficult deliveries can include *forceps deliveries* and **breech births**—deliveries in which the legs or buttocks of the fetus, rather than the head, enter the vaginal canal first.
28. Twins are either **dizygotic** (fraternal) **twins** or **monozygotic** (identical) **twins**.

29-8 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence and death p. 1172

29. Postnatal development involves a series of five **life stages**: the neonatal period, infancy, childhood, adolescence, and maturity. *Senescence*, or aging, begins at maturity and ends in the death of the individual.
30. The **neonatal period** extends from birth to 1 month. In the transition from fetus to **neonate**, the respiratory, circulatory, digestive, and urinary systems of the infant begin functioning independently. The newborn must also begin thermoregulation.
31. Mammary gland cells produce protein-rich **colostrum** during the neonate's first few days of life and then convert to milk production. These secretions are released as a result of the **milk ejection (milk let-down) reflex**. *(Figure 29–12)*
32. Body proportions gradually change during **infancy** (from age 1 month to 2 years) and during **childhood** (from age 2 years to puberty). *(Figure 29–13)*
33. **Adolescence** begins at **puberty**, when (1) the hypothalamus increases its production of GnRH, (2) circulating levels of FSH and LH rise rapidly, and (3) ovarian or testicular cells become more sensitive to FSH and LH. These changes initiate gamete formation, the production of sex hormones, and a sudden increase in the growth rate. The hormonal changes at puberty, especially changes in sex hormone levels, produce sex-specific differences in the structure and function of many systems; these differences will be retained. Adolescence continues until growth is completed. Further changes occur when sex hormone levels decline at menopause or the male climacteric.
34. **Senescence** then begins, producing gradual reductions in the functional capabilities of all systems. *(Table 29–3)*

29-9 Genes and chromosomes determine patterns of inheritance p. 1177



35. Every somatic cell carries copies of the original 46 chromosomes in the zygote; these chromosomes and their genes make up the individual's **genotype**. The physical expression of the genotype is the individual's **phenotype**.
36. Every somatic human cell contains 23 pairs of chromosomes; 22 pairs consist of **homologous chromosomes**. These 22 pairs are called **autosomes**. The chromosomes of the 23rd pair are the **sex chromosomes**; they differ between the sexes. *(Figure 29–14)*
37. Chromosomes contain DNA, and genes are functional segments of DNA. The various forms of a given gene are called **alleles**. If both homologous chromosomes carry the same allele of a particular gene, the individual is **homozygous**; if they carry different alleles, the individual is **heterozygous**.
38. In **simple inheritance**, phenotypic traits are determined by interactions between a single pair of alleles. **Polygenic inheritance** involves interactions among alleles on several genes. *(Figure 29–15)*
39. Alleles are either **dominant** or **recessive**, depending on how their traits are expressed.
40. Combining maternal and paternal alleles in a **Punnett square** helps us predict the characteristics of offspring. *(Figure 29–16)*
41. The two types of sex chromosomes are an **X chromosome** and a **Y chromosome**. The normal sex chromosome complement of males is XY; that of females is XX. **Sex-linked inheritance** involves genes on the sex chromosomes. The X chromosome carries **X-linked genes**, which affect somatic structures but have no corresponding alleles on the Y chromosome. *(Figure 29–17)*
42. **Genetic recombination**, the gene reshuffling in **crossing over** and **translocation** during meiosis, increases the genetic variation of male and female gametes. *(Figure 29–18)*
43. **Spontaneous mutations** are the result of random errors in DNA replication. Such mutations can cause the production of abnormal alleles.
44. The **human genome** contains some 20,000–25,000 protein-coding genes. Thousands of single-gene disorders have been identified, including some of those responsible for inherited disorders. *(Figure 29–19)*
45. **Gene therapy** involves inserting corrective genes made in a laboratory into a patient's cells to treat disorders or diseases caused by genetic defects.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Fertilization typically takes place **(a)** in the ovaries, **(b)** in the endometrium of the uterus, **(c)** in the cavity of the uterus, **(d)** in the vaginal fornix, **(e)** near the junction between the ampulla and isthmus of the uterine tube.
2. Identify the two extra-embryonic membranes and the three different regions of the endometrium at week 10 of development in the following diagram.

(a)_____ **(b)**_____

(c)_____ **(d)**_____

(e)_____

3. An enzyme released from the acrosome of a sperm by the acrosome reaction is the **(a)** zonal inhibiting protein, **(b)** hyaluronidase, **(c)** progesterone, **(d)** DNA repair enzyme, **(e)** lysozyme.
4. Recessive X-linked traits **(a)** are passed from fathers to their sons, **(b)** are more likely to be expressed in males, **(c)** always affect some aspect of the reproductive system, **(d)** are never expressed in females, **(e)** cannot be passed from mothers to daughters.
5. The blastocyst consists of an inner cell mass and the **(a)** corona radiata, **(b)** zona pellucida, **(c)** amniotic cavity, **(d)** trophoblast.
6. In which week of gestation does the three-layered embryo appear? **(a)** week 1, **(b)** week 3, **(c)** week 4, **(d)** week 6.
7. The structure(s) that allow(s) active and passive exchange between the fetal and maternal bloodstreams is/are the **(a)** yolk stalk, **(b)** chorionic villi, **(c)** umbilical veins, **(d)** umbilical arteries.
8. If the presence of an allele on one of the parental chromosomes is sufficient to affect the phenotype, the allele is said to be **(a)** dominant, **(b)** recessive, **(c)** complementary, **(d)** heterozygous.
9. Describe the changes that occur in the oocyte immediately after fertilization.
10. **(a)** What are the four extra-embryonic membranes? **(b)** From which germ layers do these membranes form, and what are their functions?
11. Identify the three stages of labor, and describe the events that characterize each stage.
12. List the factors involved in initiating labor contractions.
13. Identify the three life stages that occur between birth and approximately age 10. Describe the timing and characteristics of each stage.
14. What hormonal events are responsible for puberty? Which life stage does puberty initiate?

LEVEL 2 Reviewing Concepts

15. A woman with normal vision, whose father was red–green color blind, marries a man with normal vision. What is the probability that they would have a color-blind child? **(a)** 100 percent, **(b)** 50 percent, **(c)** 25 percent, **(d)** 12.5 percent, **(e)** 6.25 percent.
16. One of the events that prevents polyspermy is **(a)** the completion of meiosis II, **(b)** an increase in the ovum's metabolic rate, **(c)** the formation of the female pronucleus, **(d)** membrane depolarization, **(e)** amphimixis.
17. The mesoderm contributes to the formation of **(a)** the lining of the pleural, pericardial, and peritoneal cavities, **(b)** pituitary gland and adrenal medullae, **(c)** epidermis, hair follicles, and hairs, **(d)** thymus, thyroid gland, and pancreas, **(e)** all neural tissue.
18. Why is colostrum important for neonates? Which hormone is involved in milk ejection?
19. Name the primary placental hormones and their functions.
20. Discuss the changes that occur in maternal systems during pregnancy. Why are these changes functionally significant?
21. What is the danger associated with breech births?
22. What physiological adjustments must an infant make during the neonatal period in order to survive?
23. Distinguish between the following paired terms: **(a)** genotype and phenotype, **(b)** heterozygous and homozygous, **(c)** simple inheritance and polygenic inheritance.
24. Indicate the type of inheritance involved in each of the following situations. **(a)** Children who exhibit the trait have at least one parent who also exhibits it. **(b)** Children exhibit the trait even though neither parent does. **(c)** The trait is expressed more commonly in sons than in daughters. **(d)** The trait is expressed equally in daughters and sons.

LEVEL 3 Critical Thinking and Clinical Applications

25. Hemophilia A, a condition in which blood does not clot properly, is a recessive trait located on the X chromosome (X^h). Suppose that a woman who is heterozygous for this trait (XX^h) has children with a normal male (XY). What is the probability that the couple will have daughters with hemophilia? What is the probability that the couple will have sons with hemophilia?
26. Joe and Jane desperately want to have children, and although they have tried for 2 years, they have not been successful. Finally, each of them consults a physician, and it turns out that Joe suffers from oligospermia (a low sperm count). He confides to you that he doesn't understand why this would interfere with his ability to have children since he remembers from biology class that it only takes one sperm to fertilize an egg. What would you tell him?
27. Alina has just given birth to a little girl. When the nurses take the infant back to the nursery, she becomes cyanotic, a condition characterized by bluish discoloration of the skin. The episode passes, but when the infant is bathed, she becomes cyanotic again. Blood gas levels indicate that arterial blood is only 60 percent saturated. Physical examination reveals no structural deformities involving the respiratory or digestive system. What might be causing the problem?
28. Jie is very happy to be pregnant, but she is experiencing heavy abdominal pain and there is also a small amount of vaginal bleeding. Blood tests and a pelvic ultrasound reveal an ectopic pregnancy. What could have led to this condition?

CLINICAL CASE Wrap-Up The Twins That Looked Nothing Alike

The winners of the "least-alike" twins prize are named Hans and Willem. These charming boys traveled all the way from the Netherlands to win this award in Twinsburg.

Hans and Willem's parents used the services of a prestigious fertility clinic in the Netherlands in the 1990s. Their mother's ovaries were hormonally stimulated, and the secondary oocytes that were released were harvested laparoscopically (by abdominal surgery through small holes). These oocytes were then fertilized with sperm in the laboratory. On the sixth post-fertilization day, coinciding with the time a normally fertilized blastocyst would be finishing its journey through the uterine tube into the uterus, two blastocysts were transferred to the mother's uterus. Both had a successful implantation, placentation, embryogenesis, fetal development, and birth.

Why, then, do Hans and Willem look so different? As it turned out, the technician performing the *in vitro* fertilization mistakenly used a previously used pipette to transfer the sperm. The couple that visited the clinic just before Hans and Willem's parents were of African descent, and the African man's sperm was still present in the pipette. As a result, one oocyte was fertilized by sperm from a Caucasian man, and the other was fertilized by sperm from an African man.

1. Why were the fertilized blastocysts implanted in Hans and Willem's mother on her sixth day after ovulation?
2. Are Hans and Willem monozygotic twins or dizygotic twins?

See the blue Answers tab at the back of the book.

Related Clinical Terms

eclampsia: A condition in which one or more convulsions occur in a pregnant woman suffering from high blood pressure, often followed by coma and posing a threat to the health of mother and baby.

gamete intrafallopian transfer (GIFT): An assisted reproductive procedure in which a woman's eggs are removed, mixed with sperm, and replaced into the woman's uterine tube where the fertilization takes place, rather than in the laboratory.

in vitro fertilization: Fertilization outside the body, generally in a Petri dish.

infertility: The inability to achieve pregnancy after engaging in 1 year of appropriately timed intercourse.

neural tube defects (NTDs): Major birth defects caused by an abnormal development of the neural tube—the structure present during the embryonic stage that later becomes the central nervous system. These are very common birth defects that cause infant mortality and disability and include anencephaly and spina bifida.

placenta abruptio: Condition in which there is separation of the placenta from the uterine site of implantation before delivery of the baby.

placenta previa: Condition during pregnancy in which the placenta is abnormally placed so as to totally or partially cover the cervix.

pre-eclampsia: A condition in pregnancy characterized by sudden hypertension, albuminuria, and edema of the hands, feet, and face. It is the most common complication of pregnancy, affecting about 5 percent of pregnancies.

therapeutic cloning: A procedure that usually takes skin cells from a patient, and inserts a skin cell nucleus into a fertilized egg whose nucleus has been removed to create a new cell. That new cell divides repeatedly to form a blastocyst from which stem cells can be extracted to grow new tissue that is genetically matched to the patient.

Answers to Checkpoints, Review Questions, Clinical Case Wrap-Ups, and Figure-Based Questions

Chapter 1

Answers to Checkpoints

PAGE 49 **1.** A learning outcome is an educational objective that uses key verbs to target specific skills, goals, aims, and achievements. In essence, learning outcomes describe what the reader should be able to do after completing a particular section. **2.** To enhance learning, the text and the art should be read together. That is, after reading the text, the reader should look at and study the accompanying art. Research has shown that reading the text and viewing the art together enhances learning. **PAGE 51** **3.** Anatomy is the study of internal and external body structures. **4.** Physiology is the study of how living organisms perform functions. **5.** Anatomy and physiology are closely related because all specific functions are performed by specific structures. **6.** Gross anatomy (often referred to as macroscopic anatomy) involves studying body structures that can be seen with the unaided eye. Microscopic anatomy is the study of body structures using a microscope to magnify the objects. **7.** Several specialties of physiology are cell physiology, organ physiology, systemic physiology, and pathological physiology. **8.** It is difficult to separate anatomy from physiology because the structures of body parts are so closely related to their functions; put another way, function follows form. **PAGE 52** **9.** The major levels of organization of the human body from the simplest to the most complex are as follows: chemical level → cellular level → tissue level → organ level → organ system level → organism level. **10.** Major organ systems (and some structures of each) are the integumentary system (skin, hair, sweat glands, and nails), skeletal system (bones, cartilages, associated ligaments, and bone marrow), muscular system (skeletal muscles and associated tendons), nervous system (brain, spinal cord, peripheral nerves, and sense organs), endocrine system (pituitary gland, thyroid gland, pancreas, adrenal glands, gonads, and other endocrine tissues), cardiovascular system (heart, blood, and blood vessels), lymphatic system (spleen, thymus, lymphatic vessels, lymph nodes, and tonsils), respiratory system (nasal cavities, sinuses, larynx, trachea, bronchi, lungs, and alveoli), digestive system (teeth, tongue, pharynx, esophagus, stomach, small intestine, large intestine, liver, gallbladder, and pancreas), urinary system (kidneys, ureters, urinary bladder, and urethra), male reproductive system (testes, epididymides, ductus deferentia, seminal glands, prostate gland, penis, and scrotum), and female reproductive system (ovaries, uterine tubes, uterus, vagina, labia, clitoris, and mammary glands). **11.** A histologist investigates structures and properties at the tissue level of organization. **PAGE 53** **12.** Medical terminology is the use of word roots, prefixes, suffixes, and combining forms to construct anatomical, physiological, or medical terms. **13.** An eponym is a commemorative name for a structure or clinical condition that was originally named for a real or mythical person. **14.** The book used as the international standard for anatomical vocabulary is *Terminologia Anatomica*. **PAGE 59** **15.** The purpose of anatomical terms is to provide a standardized frame of reference for describing the human body. **16.** In the anatomical position, an anterior view is seen from the front and a posterior view is from the back. **PAGE 64** **17.** Body cavities protect internal organs and cushion them from thumps and bumps that occur while walking, running, or jumping. Body cavities also permit the organs that they surround to change in size and shape without disrupting the activities of nearby organs. **18.** The thoracic cavity includes the pleural and pericardial cavities, which enclose the lungs and heart, respectively. The diaphragm forms the boundary between the superior thoracic cavity and the inferior abdominopelvic cavity. The abdominopelvic cavity contains the peritoneal cavity, which contains the superior abdominal cavity and the inferior pelvic cavity. **PAGE 65** **19.** Homeostasis refers to the existence of a stable internal environment. **20.** Extrinsic regulation is a type of homeostatic regulation resulting from activities of the nervous system or endocrine system. **21.** Physiological systems can function normally only under carefully controlled conditions. Homeostatic regulation prevents potentially disruptive changes in the body's internal environment. **PAGE 70** **22.** Negative feedback systems provide long-term control over the body's internal conditions—that is, they maintain homeostasis—by counteracting the effects of a stimulus or environmental change. **23.** When homeostasis fails, organ systems function less efficiently or even malfunction. The result is the state that we call disease. If the situation is not corrected, death can result. **24.** A positive feedback system amplifies or enhances the effects of a stimulus. **25.** Positive feedback is useful in processes that must be completed quickly, such as blood clotting. In contrast, it is harmful in situations in which a stable condition must be maintained, because it tends to increase any departure from the desired condition. Positive feedback in the regulation of body temperature, for example, would cause a slight fever to spiral out of control, with fatal results. For this reason, physiological systems are typically regulated by negative feedback, which tends to oppose any departure from the norm. **26.** Equilibrium is a dynamic (constantly changing) state in which two opposing forces or processes are in balance. **27.** When the body continuously adapts by using homeostatic mechanisms, it is said to be in a state of dynamic equilibrium.

Level 2 Reviewing Concepts

25. (a) Anatomy is the study of internal and external body structures and their physical relationships among other body parts. **(b)** Physiology is the study of how living organisms perform their vital functions. **26.** d **27.** Autoregulation occurs when the activities of a cell, tissue, organ, or organ system change automatically (that is, without neural or endocrine input) when faced with some environmental change. Extrinsic regulation results from the activities of the nervous or endocrine systems. It causes more extensive and

potentially more effective adjustments in activities. **28.** The body is erect, and the hands are at the sides with the palms facing forward. **29.** b **30.** c

Level 3 Critical Thinking and Clinical Applications

31. Insulin is released when blood glucose levels are increased. This hormone should bring about a decrease in blood glucose levels, thus decreasing the stimulus for its own release. **32.** A lack of blood flow to the hypothalamus of the brain would cause brain cells there to die. Since this is where the body's thermoregulatory center lies, then control of body temperature would be affected.

Answers to Clinical Case Wrap-Up

PAGE 72 **1.** In addition to the liver and most of the large intestine, the abdominal cavity contains the stomach, spleen, and small intestine. **2.** A deep knife wound superior to the diaphragm would have entered the thoracic cavity, which contains the lungs and heart; associated organs of the respiratory, cardiovascular, and lymphatic systems; the inferior portions of the esophagus; and the thymus.

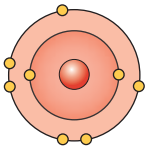
Chapter 2

Answers to Checkpoints

PAGE 78 **1.** An atom is the smallest stable unit of matter. **2.** Atoms of the same element that have the same atomic number but different numbers of neutrons are called isotopes. **3.** Hydrogen has three isotopes: hydrogen-1, with a mass number of 1; deuterium, with a mass number of 2; and tritium, with a mass number of 3. The heavier sample must contain a higher proportion of one or both of the heavier isotopes. **PAGE 83** **4.** A chemical bond is an attractive force acting between two atoms that may be strong enough to hold them together in a molecule or compound. The strongest attractive forces result from the gain, loss, or sharing of electrons. Examples of such chemical bonds are ionic bonds and covalent bonds. In contrast, the weaker hydrogen bonds occur between molecules or compounds. **5.** The atoms in a water molecule are held together by polar covalent bonds. Water molecules are attracted to one another by hydrogen bonds. **6.** Atoms combine with each other to gain a complete set of electrons in their outer energy level or valence shell. Oxygen atoms do not have a full outer energy level, so they readily react with many other elements to attain this stable arrangement. Neon already has a full outer energy level so it cannot combine with other elements. **PAGE 85** **7.** Using chemical notation, an ion is represented by a superscript plus or minus sign following the symbol of an element. If more than one electron has been lost or gained, the electric charge on the ion is represented by a number preceding the plus or minus sign. **8.** The molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms, is $C_6H_{12}O_6$. **9.** Three types of chemical reactions important to the study of human physiology include decomposition reactions, synthesis reactions, and exchange reactions. In a decomposition reaction, a chemical reaction breaks a molecule into smaller fragments. A synthesis reaction assembles smaller molecules into larger ones. In an exchange reaction, parts of the reacting molecules are shuffled around to produce new products. **10.** This reaction involves a large molecule being broken down into two smaller ones, so it is a decomposition reaction. **PAGE 86** **11.** An enzyme is a protein that lowers the activation energy of a chemical reaction, which is the amount of energy required to start the reaction. **12.** Without enzymes, chemical reactions would proceed only under conditions that the cells could not tolerate (e.g., high temperatures). By lowering the activation energy, enzymes make it possible for chemical reactions to rapidly proceed under conditions compatible with life. **13.** Organic compounds always contain carbon and hydrogen. Inorganic compounds do not contain carbon and hydrogen atoms as structural components. **PAGE 89** **14.** Specific chemical properties of water that make life possible include its strong polarity (enables it to be an excellent solvent), its reactivity (it participates in many chemical reactions), its high heat capacity (it absorbs and releases heat slowly), and its ability to serve as a lubricant. **PAGE 90** **15.** The pH is a measure of the concentration of hydrogen ions in fluids. Acid and base concentrations are measured in pH, which is the negative logarithm of hydrogen ion concentration, expressed in moles per liter. On the pH scale, 7 represents a neutral solution; values below 7 indicate acidic solutions, and values above 7 indicate basic (alkaline) solutions. **16.** If the body is to maintain homeostasis and thus health, the pH of different body fluids must remain within a fairly narrow range. **17.** An acid is a compound whose dissociation in solution releases a hydrogen ion and an anion; a base is a compound whose dissociation releases a hydroxide ion (OH^-) or removes a hydrogen ion (H^+) from the solution; a salt is an inorganic compound consisting of a cation other than H^+ and an anion other than OH^-. **18.** Stomach discomfort is commonly the result of excessive stomach acidity ("acid indigestion"). Antacids contain a weak base that neutralizes the excess acid. **PAGE 91** **19.** The macromolecules important to life are carbohydrates, lipids, proteins, and nucleic acids. **20.** The functional group that acts as an acid is the carboxyl group —COOH. **PAGE 93** **21.** The monomer common to both plant starch and glycogen is glucose. **PAGE 97** **22.** Lipids are a diverse group of compounds that include fatty acids, eicosanoids, glycerides, steroids, phospholipids, and glycolipids. They are organic compounds that contain carbon, hydrogen, and oxygen in a ratio that does not approximate 1:2:1. **23.** Human plasma membranes contain mainly phospholipids, plus small amounts of cholesterol and glycolipids. **PAGE 103** **24.** Proteins are organic compounds formed from amino acids that contain a central carbon atom, a hydrogen atom, an amino group ($-NH_2$), a carboxyl group (–COOH), and an R group or variable side chain. Proteins function in support, movement, transport, buffering, metabolic regulation, coordination and control, and defense. **25.** The heat of boiling breaks bonds that maintain the protein's tertiary structure, quaternary structure, or both. The resulting structural change, known as denaturation, affects the ability of the protein molecule to perform its normal biological functions. **PAGE 105** **26.** A nucleic acid is a large organic molecule made of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids regulate protein synthesis and make up the genetic material in cells. **27.** Both DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) contain nitrogenous bases and phosphate groups, but the nucleic acid described is RNA because it contains the sugar ribose. **PAGE 106** **28.** Adenosine triphosphate



(ATP) is a high-energy compound consisting of adenosine to which three phosphate groups are attached. The second and third phosphate groups are each attached by a high-energy bond. **29.** Phosphorylation of an ADP molecule yields a molecule of ATP.

Answers to Review Questions

PAGE 109

Level 1 Reviewing Facts and Terms

1. (a)

Oxygen atom

(b) Two more electrons can fit into the outermost energy level of an oxygen atom. **2.** condensation **3.** d **4.** b **5.** d **6.** c **7.** b **8.** b **9.** d **10.** d **11.** b **12.** d **13.** e **14.** d **15.** a **16.** protons, neutrons, and electrons **17.** carbohydrates, lipids, proteins, and nucleic acids **18.** Triglycerides (1) provide a significant energy reserve, (2) serve as insulation and thus act in heat conservation, and (3) protect organs by cushioning them. **19.** (1) support (structural proteins); (2) movement (contractile proteins); (3) transport (transport proteins); (4) buffering; (5) metabolic regulation; (6) coordination and control (hormones and neurotransmitters); and (7) defense (antibodies) **20. (a)** DNA: deoxyribose, phosphate, and nitrogenous bases (A, T, C, G); **(b)** RNA: ribose, phosphate, and nitrogenous bases (A, U, C, G) **21.** storing: conversion of ADP to ATP; releasing: breakdown of ATP to ADP

Level 2 Reviewing Concepts

22. c **23.** d **24.** Enzymes are specialized protein catalysts that lower the activation energy for chemical reactions. Enzymes speed up chemical reactions but are not used up or changed in the process. **25.** A buffer is a compound that stabilizes the pH of a solution by removing or replacing hydrogen ions. Buffers and buffer systems help maintain the pH of body fluids within normal limits, which is important for biochemical reactions to take place. **26.** Potential energy is stored energy that has the potential to do work, whereas kinetic energy is the energy that can be transferred to another object and do work. **27.** d **28.** c **29.** The molecule is a nucleic acid. Carbohydrates and lipids do not contain nitrogen. Although both proteins and nucleic acids contain nitrogen, only nucleic acids normally contain phosphorus.

Level 3 Critical Thinking and Clinical Applications

30. (a) number of electrons = 12; **(b)** atomic number = 12; **(c)** atomic weight = 24; **(d)** 2 electrons in first energy level, 8 in second energy level, 2 in third energy level (valence shell). **31.** Decreasing the amount of enzyme at the second step would slow down the remaining steps of the pathway because less substrate would be available for the next two steps. The net result would be a decrease in the amount of product. **32.** If a person exhales large amounts of CO_2, the level of H^+ in the blood will decrease. A decrease in the level of H^+ will cause the pH to increase.

Answers to Clinical Case Wrap-Up

PAGE 110 **1.** Baby Sean's stools contained undigested lipids and carbohydrates, which gave them a fatty or greasy appearance. **2.** Digestive enzymes aid in the decomposition reactions that break down lipids and carbohydrates in food, so they can be absorbed from the digestive tract. If these large molecules cannot be broken down, they cannot be used as energy sources or chemical building blocks.

Answers to Figure-Based Questions

FIGURE 2–3 The second energy level can hold 8 electrons when completely filled.

FIGURE 2–8 Hydrogen bonds act between adjacent molecules and between atoms of the same molecule. Hydrogen bonds form between a slight positive charge on the hydrogen atom of a polar covalent bond and a slight negative charge on an oxygen atom of another polar covalent bond.

FIGURE 2–24 Adenine and guanine are purines, which means they are double-ringed molecules. Cytosine, thymine, and uracil are pyrimidines, which means they are single-ringed molecules.

FIGURE 2–26 AMP undergoes two phosphorylations, which adds two phosphate groups (for a total of three phosphates) to form ATP.

Chapter 3

Answers to Checkpoints

PAGE 117 **1.** The general functions of the plasma membrane include physical isolation, regulation of exchange with the environment, sensitivity to the environment, and structural support. **2.** The components of the plasma membrane that allow it to perform its characteristic functions are membrane lipids, membrane proteins, and membrane carbohydrates. **3.** The phospholipid bilayer of the plasma membrane forms a physical barrier between the cell's internal and external environments. **4.** Channel proteins are integral proteins that allow water, ions, and small water-soluble solutes to pass through the plasma membrane. **PAGE 128** **5.** Cytoplasm is the material between the plasma membrane and the nuclear membrane. Cytosol is the fluid portion of the cytoplasm; cytosol is also called intracellular fluid. It is a mixture of water and various dissolved and insoluble materials, in which the organelles and inclusions are suspended. **6.** Cytosol has a higher concentration of potassium ions and suspended proteins, and a lower concentration of sodium ions, than does extracellular fluid. Cytosol also includes small quantities of carbohydrates and large reserves of amino acids and lipids. **7.** The nonmembranous organelles and their functions include (1) centriole = essential for movement of chromosomes during cell division; organization of microtubules in cytoskeleton; (2) cilia = movement of materials over cell surface (motile cilia), environmental sensor (primary cilium); flagella = propel sperm (3) cytoskeleton = strength and support; movement of cellular structures and materials; cell movement; (4) microvilli = increase surface area to facilitate absorption of extracellular materials; (5) proteasomes = breakdown and recycling of intracellular proteins; (6) ribosomes = protein synthesis. **PAGE 129** **8.** The membranous organelles and their functions include (1) endoplasmic reticulum = synthesis of secretory products; intracellular storage and transport; (2) smooth ER = lipid and carbohydrate synthesis; (3) rough ER =

modification and packaging of newly synthesized proteins; (4) Golgi apparatus = storage, modification, and packaging of secretory products and lysosomal enzymes; (5) lysosomes = intracellular removal of damaged organelles or pathogens; (6) peroxisomes = neutralization of toxic compounds; (7) mitochondria = production of 95 percent of the ATP required by the cell. **9.** The SER synthesizes lipids, such as steroids. Ovaries and testes produce large amounts of steroid hormones, which are lipids, and thus need large amounts of SER. **10.** Mitochondria produce energy, in the form of ATP molecules, for the cell. A large number of mitochondria in a cell indicates a high demand for energy. **PAGE 131** **11.** The nucleus is a cellular organelle that contains DNA, RNA, enzymes, and proteins. The nuclear envelope is a double membrane that surrounds the nucleus; the perinuclear space is the region between this double membrane. Nuclear pores enable chemical communication between the nucleus and the cytosol. **12.** A gene is a portion of a DNA strand that functions as a hereditary unit. Each gene is located at a particular site on a specific chromosome and codes for a specific protein. **PAGE 136** **13.** Gene activation is the process of uncoiling the segment of DNA containing the nucleotide sequence of that gene, and temporarily removing histones, so that the gene can affect the cell. **14.** Transcription is the synthesis of RNA from a DNA template. Translation uses the information from an mRNA strand to form a linear chain of amino acids, or protein. **15.** A cell that lacked the enzyme RNA polymerase would not be able to transcribe RNA from DNA. **PAGE 140** **16.** A selectively permeable membrane allows the passage of some substances and restricts the passage of others. It lies between two extremes: impermeable, which allows no substances to pass, and freely permeable, which permits the passage of any substance. **17.** Diffusion is the passive movement of a substance from an area of higher concentration to an area of lower concentration. Diffusion proceeds until the concentration gradient is eliminated (equilibrium is reached). **18.** Five factors that influence the diffusion of substances in the body are (1) distance, (2) ion or molecule size, (3) temperature, (4) concentration gradient, and (5) electrical forces. **19.** Diffusion is driven by a concentration gradient. The steeper the concentration gradient, the faster the rate of diffusion, and the less steep the concentration gradient, the slower the rate of diffusion. If the concentration of oxygen in the lungs were to decrease, the concentration gradient between oxygen in the lungs and oxygen in the blood would decrease (as long as the oxygen level of the blood remained constant). Thus, oxygen would diffuse more slowly into the blood. **20.** Osmosis is the diffusion of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. **21.** The 10 percent salt solution is hypertonic with respect to the cells lining the nasal cavity, because it contains a higher salt (solute) concentration than do the cells. The hypertonic solution would draw water out of the cells, causing the cells to shrink and adding water to the mucus, thereby diluting it and relieving congestion. **PAGE 145** **22.** In carrier-mediated transport, integral proteins bind specific ions or organic substrates and carry them across the plasma membrane. All forms of carrier-mediated transport are specific, have saturation limits, and are regulated (usually by hormones). **23.** An active transport process must be involved because it takes an expenditure of energy to move the hydrogen ions against their concentration gradient—that is, from a region where they are less concentrated (the cells lining the stomach) to a region where they are more concentrated (the interior of the stomach). **24.** Endocytosis is the movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface. Types of endocytosis are receptor-mediated endocytosis, the clathrin-coated vesicle-mediated movement into the cytoplasm of specific target molecules (ligands); pinocytosis, the vesicle-mediated movement into the cytoplasm of extracellular fluid and its contents; and phagocytosis, the vesicle-mediated movement into the cytoplasm of extracellular solids, especially bacteria and debris. **25.** Exocytosis is the ejection of cytoplasmic materials by the fusion of a membranous vesicle with the plasma membrane. **26.** The process by which certain white blood cells engulf bacteria is called phagocytosis. **PAGE 148** **27.** The membrane potential of a cell is the difference in electrical potential that results from the uneven distribution of positive and negative charges across the plasma membrane. It is expressed in millivolts (mV). **28.** If the plasma membrane of a cell were freely permeable to sodium ions, more of these positively charged ions would move into the cell, and the membrane potential would become less negative (move closer to zero). **PAGE 149** **29.** The biological term for cellular reproduction is cell division, and the term for cell death is apoptosis. **30.** Important enzymes for DNA replication include helicases, DNA polymerase, and ligases. **31.** Interphase is a stage in a cell's life when it performs all its normal functions and, if necessary, prepares for cell division. The stages of interphase include G_1, S, G_2, and G_0. A cell in G_0 is not preparing for cell division. **32.** This cell is likely in the G_1 phase of its life cycle. **33.** Mitosis is the essential step in cell division in which a single cell nucleus divides to produce two identical daughter cell nuclei. The four stages of mitosis are prophase, metaphase, anaphase, and telophase. **34.** If spindle fibers failed to form during mitosis, the cell would not be able to separate the chromosomes into two sets. If cytokinesis occurred, the result would be one cell with two sets of chromosomes and one cell with none. **PAGE 153** **35.** A growth factor is a natural substance, such as a peptide or hormone, that can stimulate the division of specific cell types. Representative growth factors include M-phase promoting factor (maturation-promoting factor), growth hormone, prolactin, fibroblast growth factor (FGF), nerve growth factor (NGF), epidermal growth factor (EGF), erythropoietin, thymosins and related compounds, and chalones. **PAGE 155** **36.** An illness characterized by mutations that disrupt normal controls and produce potentially malignant cells is termed cancer. **37.** Metastasis is the spread of cancer cells to distant tissues and organs, leading to the establishment of secondary tumors. **38.** Cellular differentiation is the development of specific cellular characteristics and functions that are different from those of the original cell. It results from genes in the cell being switched off, restricting the cell's potential functions.

Answers to Review Questions

PAGE 158

Level 1 Reviewing Facts and Terms

1. a. isotonic b. hypotonic c. hypertonic **2.** b **3.** e **4.** d **5.** a **6.** d **7.** b **8.** d **9.** a **10.** b **11.** (1) Cells are the building blocks of all plants and animals. (2) Cells are produced by the division of preexisting cells. (3) Cells are the smallest units that perform all vital physiological functions. (4) Each cell maintains homeostasis at the cellular level. **12.** Four general functions of the plasma membrane are (1) physical isolation, (2) regulation of exchange with the environment, (3) sensitivity, and (4) structural support. **13.** Membrane proteins function as receptors, channels, carriers, enzymes, anchors, and identifiers. **14.** The major transport mechanisms are (1) diffusion, (2) carrier-mediated transport, and (3) vesicular transport. **15.** Factors that affect diffusion rate are (1) distance, (2) steepness of the concentration gradient, (3) molecule size, (4) temperature, and

(5) electrical forces. **16.** Major functions of the ER are (1) synthesis of proteins, carbohydrates, and lipids; (2) storage of absorbed or synthesized molecules; (3) transport of materials; and (4) detoxification of drugs or toxins.

Level 2 Reviewing Concepts

17. a **18.** c **19.** c **20.** c **21.** c **22.** d **23.** d **24.** G_0: normal cell functions, nondividing state; G_1: cell growth, duplication of organelles, and protein synthesis; S: DNA replication and synthesis of histones; G_2: protein synthesis **25.** Prophase: chromatin condenses and chromosomes become visible; centrioles migrate to opposite poles of the cell and spindle fibers develop; and the nuclear membrane disintegrates. Metaphase: chromatids attach to spindle fibers and line up along the metaphase plate. Anaphase: chromatids separate and migrate toward opposite poles of the cell. Telophase: the nuclear membrane forms; chromosomes disappear as they uncoil back to chromatin; and nucleoli appear. **26. (a)** Cytokinesis is the cytoplasmic movement that separates two daughter cells. **(b)** Cytokinesis completes the process of cell division.

Level 3 Critical Thinking and Clinical Applications

27. This process is facilitated diffusion, which requires a carrier molecule but not cellular energy. The energy for this process is provided by the concentration gradient of the substance being transported. When all the carriers are actively involved in transport, the rate of transport reaches a saturation point. **28.** Since solution A has a higher solute concentration, the fluid level in it will increase through osmosis. This can be prevented by applying hydrostatic pressure on solution A equal to the osmotic pressure of the solution. **29.** c **30.** The isolation of the internal contents of membrane-bound organelles allows them to manufacture or store secretions, enzymes, or toxins that could adversely affect the cytoplasm in general. Another benefit is the increased efficiency of having specialized enzyme systems concentrated in one place. For example, the concentration of enzymes necessary for energy production in the mitochondrion increases the efficiency of cellular respiration.

Answers to Clinical Case Wrap-Up

PAGE 159 **1.** The other cell that might also be affected is the sperm cell, the only human cell with a tail-like flagellum, which has the same microtubule structure as motile cilia. **2.** Because Jackson's sperm cells will be affected, he is likely to experience difficulties in fathering children. Also, normal ciliary action is necessary to move sperm from the testes into the male reproductive tract.

Answers to Figure-Based Questions

FIGURE 3–3 The three components that make up the cytoskeleton in all body cells are microfilaments, intermediate filaments, and microtubules.

FIGURE 3–9 The two reactants needed are oxygen and short carbon chains (such as the pyruvate molecule shown). The products from this reaction are carbon dioxide (CO_2), water (H_2O), and ATP.

FIGURE 3–11 In a dividing cell, DNA is tightly coiled and organized as chromosomes. In a nondividing cell, DNA is loosely coiled and organized as chromatin.

FIGURE 3–15 Small water-soluble molecules and ions diffuse through membrane channels. Lipid-soluble molecules diffuse directly through the plasma membrane.

FIGURE 3–17 In part b, the intracellular fluid is hypertonic to the extracellular fluid. In part c, the intracellular fluid is hypotonic to the extracellular fluid.

FIGURE 3–18 The concentration gradient determines the direction in which glucose molecules will be transported. Facilitated diffusion is a passive process, so glucose molecules will travel from high to low concentration.

FIGURE 3–19 Breaking the high-energy bond of ATP provides the energy for the sodium–potassium exchange pump.

Chapter 4

Answers to Checkpoints

PAGE 161 **1.** Histology is the study of tissues. **2.** The four major types of tissues that form all body structures are epithelial, connective, muscle, and nervous tissue. **PAGE 166** **3.** Epithelial tissue provides physical protection, controls permeability, provides sensation, and produces specialized secretions. **4.** Epithelial tissue is characterized by polarity, cellularity, attachment, avascularity, and regeneration. **5.** An epithelium whose cells have microvilli is probably involved in absorption or secretion. The microvilli greatly increase the cellular surface area available for these processes. **6.** Epithelial cell junctions include tight junctions, gap junctions, spot desmosomes, and hemidesmosomes. **7.** Gap junctions allow small molecules and ions to pass from cell to cell. When connecting epithelial cells, they help coordinate such functions as the beating of cilia. In cardiac and smooth muscle tissues, they are essential for coordinating muscle cell contractions. **PAGE 172** **8.** The three cell shapes that are characteristic of epithelial cells are squamous (thin and flat), cuboidal (box shaped), and columnar (tall and slender). **9.** When classifying epithelial tissue, one with a single layer of cells is called simple, whereas one with multiple layers of cells is called stratified. **10.** No, this is not a sample from the skin surface. A simple squamous epithelium does not provide enough protection against infection, abrasion, or dehydration. The skin surface has a stratified squamous epithelium. **11.** All these regions are subject to mechanical trauma and abrasion—by food (pharynx and esophagus), by feces (anus), and by intercourse or childbirth (vagina). **12.** The two primary types of glandular epithelia are endocrine glands and exocrine glands. **13.** Sebaceous glands exhibit holocrine secretion. **14.** An endocrine gland releases its secretions directly into the interstitial fluid. **PAGE 174** **15.** Functions of connective tissues include (1) establishing a structural framework for the body; (2) transporting fluids and dissolved materials; (3) protecting delicate organs; (4) supporting, surrounding, and interconnecting other types of tissue; (5) storing energy reserves; and (6) defending the body from invading microorganisms. **16.** The three categories of connective tissues are connective tissue proper, fluid connective tissues, and supporting connective tissues. **PAGE 181** **17.** Cells found in connective tissue proper are adipocytes, fibroblasts, fibrocytes, lymphocytes, macrophages, mast cells, melanocytes, mesenchymal cells, and microphages. **18.** The reduced collagen production resulting from a lack of vitamin C in the diet would cause connective tissue to be weak and prone to damage. **19.** Mast cells and basophils produce the histamine, which antihistamines block. **20.** The type of connective tissue that contains triglycerides is adipose (fat) tissue. **21.** The three layers of fascia are superficial fascia (areolar and adipose tissue), deep fascia (dense regular connective tissue), and subserous fascia (areolar tissue). **PAGE 182** **22.** Blood and lymph each have a fluid matrix and are fluid connective tissues. **23.** The recirculation of fluid in the body is a continuous process from the cardiovascular system, through the interstitial fluid, to the lymph, and then back to the

cardiovascular system. **PAGE 186** **24.** The two types of supporting connective tissue are cartilage and bone. **25.** Bone heals faster than cartilage because, unlike cartilage, bone has a direct blood supply, which is necessary for proper and rapid healing to occur. **26.** The type of cartilage damaged in a herniated intervertebral disc is fibrocartilage. **PAGE 188** **27.** The four types of tissue membranes found in the body are the cutaneous membrane, mucous membranes, serous membranes, and synovial membranes. **28.** The pleural, peritoneal, and pericardial cavities are all lined by serous membranes. **29.** Mucous membranes typically line body passageways that open to the exterior. **PAGE 190** **30.** The three types of muscle tissue in the body are skeletal muscle, cardiac muscle, and smooth muscle. **31.** Muscle tissue that lacks striations is smooth muscle. Both cardiac and skeletal muscles are striated. **32.** Skeletal muscle is repaired by the division of myosatellite cells, which are stem cells that persist in adult skeletal muscle tissue. **PAGE 191** **33.** The cells are most likely neurons. **PAGE 192** **34.** The two phases in the response to tissue injury are inflammation and regeneration. **35.** The four common signs of inflammation are redness, heat (warmth), swelling, and pain. **36.** With advancing age, the speed and effectiveness of tissue repair decrease, the rate of energy consumption in general decreases, hormonal activity is altered, and other factors contribute to changes in structure and chemical composition. **37.** Longer life is associated with a longer period of potential exposure to chemicals and other environmental factors.

Answers to Review Questions

PAGE 196

Level 1 Reviewing Facts and Terms

1. (a) simple squamous epithelium, **(b)** simple cuboidal epithelium, **(c)** simple columnar epithelium, **(d)** stratified squamous epithelium, **(e)** stratified cuboidal epithelium, **(f)** stratified columnar epithelium. **2.** b **3.** c **4.** c **5.** b **6.** a **7.** c **8.** a **9.** b **10.** d **11.** d **12.** a **13.** b **14.** e **15.** b **16.** b **17.** Epithelial tissue (1) provides physical protection, (2) controls permeability, (3) provides sensations, and (4) produces specialized secretions. **18.** Endocrine glands secrete hormones onto the surface of the gland or directly into the surrounding fluid; exocrine glands secrete through ducts. **19.** Exocrine glandular epithelial cells release their secretions by (1) merocrine secretion, (2) apocrine secretion, or (3) holocrine secretion. **20.** Connective tissues contain (1) specialized cells, (2) extracellular protein fibers, and (3) a fluid ground substance. **21.** The four membranes in the body are (1) mucous membranes, (2) serous membranes, (3) the cutaneous membrane (skin), and (4) synovial membranes. **22.** Nervous tissue contains (1) neurons, which propagate electrical impulses in the form of reversible changes in the membrane potential, and (2) neuroglia, which include several kinds of supporting cells and play a role in providing nutrients to neurons.

Level 2 Reviewing Concepts

23. The secretions of the salivary glands are merocrine secretions. Milk production in the mammary glands involves a combination of merocrine and apocrine secretions. **24.** Tight junctions block the passage of water or solutes between cells. In the digestive system, these junctions keep enzymes, acids, and wastes from damaging delicate underlying tissues. **25.** Fluid connective tissues have a watery matrix. They differ from supporting connective tissues in that they have many soluble proteins in the matrix, and they do not include insoluble fibers. **26.** In the superficial layers of the skin, epithelial cells are strongly connected to each other due to the abundance of desmosomes. Therefore, when sunburn damages the skin, cells are usually lost in sheets rather than as a powder of individual cells. **27.** b **28.** c **29.** Similarities: actin and myosin interactions produce contractions. Differences: skeletal muscle tissue cells are relatively large, multinucleate, striated, and contract only under neural stimulation; cardiac muscle tissue cells have one to five nuclei, are interconnected in a branching network, and contract in response to pacemaker cell activity; smooth muscle tissue cells are small, spindle shaped, nonstriated, with only one nucleus, and are not under voluntary control.

Level 3 Critical Thinking and Clinical Applications

30. Because apocrine secretions are released by pinching off a portion of the secreting cell, you could test for the presence of plasma membranes, specifically for the phospholipids in plasma membranes. Merocrine secretions do not contain a portion of the secreting cell, so they would lack plasma membrane components. **31.** Skeletal muscle tissue would be made up of densely packed fibers running in the same direction, but since muscle fibers are composed of cells, they would have many nuclei and mitochondria. Skeletal muscle tissue also has an obvious banding pattern, or striations, due to the arrangement of the actin and myosin filaments within the cell. The student is probably looking at a slide of tendon (dense connective tissue). The small nuclei would be those of fibroblasts. **32.** The Pap test involves exfoliative cytology. It is a procedure in which cells are scraped from the cervix, the portion of the uterus that projects into the vagina, and are screened for cancer.

Answers to Clinical Case Wrap-Up

PAGE 197 **1.** The collagen fibers within the matrix of connective tissue are defective in Ehlers-Danlos syndrome. **2.** Connective tissues throughout Anne Marie's body are affected by Ehlers-Danlos syndrome. This includes structures and organs composed of dense regular connective tissue (tendons, ligaments, aponeuroses), dense irregular connective tissue (skin, organ capsules of liver, kidneys, and spleen), and reticular tissue (spleen, liver, lymph nodes) as well.

Answers to Figure-Based Questions

FIGURE 4–3 Only gap junctions allow the diffusion of ions and molecules between cells. Tight junctions, hemidesmosomes, and spot desmosomes do not.

FIGURE 4–6 Columnar describes cell shape. Simple describes the number of cell layers; here, simple means one layer.

FIGURE 4–8 Holocrine secretion destroys superficial gland cells. Merocrine secretion uses exocytosis to release product from vesicles, and apocrine secretion sheds the apical cytoplasm to produce secretions.

FIGURE 4–11 Adipose tissue provides padding, cushions shock, reduces heat loss, and stores energy. It is most commonly found deep to the skin of the sides, buttocks, and breasts.

FIGURE 4–14 White blood cells contain a nucleus. Red bloods cells and platelets do not.

FIGURE 4–16 Chondrocytes (cartilage cells) are the only type of cell found in cartilage matrix. Chondrocytes are found within small chambers in the matrix called lacunae.

FIGURE 4–18 The epithelium that lines the peritoneal cavity is called the mesothelium.

FIGURE 4–19 Skeletal muscle tissue consists of multinucleate cells.

Chapter 5

Answers to Checkpoints

PAGE 204 **1.** The layers of the epidermis are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. **2.** Dandruff consists of cells from the stratum corneum. **3.** This splinter is lodged in the stratum granulosum. **4.** Wrinkles in the tips of the fingers (and toes) are due to the constriction of blood vessels in the underlying skin, which causes the skin to shrink. This effect is controlled by the autonomic nervous system, a division of the nervous system that acts outside our awareness. **5.** Sanding the tips of the fingers will not permanently remove fingerprints. The ridges of the fingerprints are formed in layers of the skin that are constantly regenerated, so these ridges will eventually reappear. The pattern of the ridges is determined by the arrangement of tissue in the dermis, which is not affected by sanding. **6.** Salivary glands and duodenal glands (glands of the duodenum) produce epidermal growth factor (EGF). **7.** Epidermal growth factor (EGF) promotes the divisions of basal cells in the stratum basale and stratum spinosum, accelerates the production of keratin in differentiating keratinocytes, stimulates epidermal development and epidermal repair after injury, and stimulates synthetic activity and secretion by epithelial glands. **PAGE 206** **8.** The dermis (a connective tissue layer) is located between the epidermis and the subcutaneous layer (hypodermis). **9.** The capillaries and sensory nerve fibers that supply the epidermis are located in the papillary layer of the dermis. **10.** The presence of elastic fibers and the flexibility and resilience of skin turgor allow the dermis to undergo repeated cycles of stretching and recoiling (returning to its original shape). **PAGE 207** **11.** The tissue that connects the dermis to underlying tissues is the subcutaneous layer or hypodermis. **12.** The subcutaneous layer is a layer of loose connective tissue (areolar tissue) and adipose tissue below (deep to) the dermis. The subcutaneous layer is not considered a part of the integument, but it is important in stabilizing the position of the skin in relation to underlying tissues. **13.** Subcutaneous fat provides insulation to help reduce heat loss, serves as an energy reserve, and acts as a shock absorber for the body. **PAGE 209** **14.** The two major pigments in the epidermis are melanin, which ranges in color from red-yellow (pheomelanin) to brown-black (eumelanin), and carotene, an orange-yellow pigment. **15.** When exposed to the ultraviolet (UV) radiation in sunlight, melanocytes in the epidermis and dermis synthesize the pigment melanin, darkening the skin. **16.** When skin gets warm, arriving oxygenated blood is diverted to the superficial dermis for the purpose of eliminating heat. The oxygenated blood gives a reddish coloration to the skin. **PAGE 211** **17.** In the presence of ultraviolet radiation in sunlight, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid compound into cholecalciferol, or vitamin D_3. **18.** Cholecalciferol (vitamin D_3) is needed to form strong bones and teeth. When the body surface is covered, UV light cannot penetrate to the stratum basale in the skin to begin vitamin D_3 production, resulting in fragile bones. **PAGE 214** **19.** A typical hair is a keratinous strand produced by epithelial cells of the hair follicle. **20.** The contraction of the arrector pili muscle pulls the hair follicle erect. The result is known as "goose bumps." **21.** Even though hair is a derivative of the epidermis, the hair follicles are in the dermis. Where the epidermis and deep dermis are destroyed, new hair will not grow. **PAGE 217** **22.** Two types of exocrine glands found in the skin are sebaceous (oil) glands and sweat glands. **23.** The functions of sebaceous secretions (called sebum) are to lubricate and protect the keratin of the hair shaft, lubricate and condition the surrounding skin, and inhibit the growth of bacteria. **24.** Deodorants are used to mask the odor of apocrine sweat gland secretions, which contain several kinds of organic compounds. Some of these compounds have an odor, and others produce an odor when metabolized by skin bacteria. **25.** Apocrine sweat glands enlarge and increase secretory activity in response to the increase in sex hormones that occurs at puberty. **26.** Keratin is the substance that makes fingernails hard. **27.** The area of thickened stratum corneum under the free edge of a nail is called the hyponychium. **28.** Nail growth occurs at the nail root, an epidermal fold that is not visible from the surface. **PAGE 219** **29.** The combination of fibrin clots, fibroblasts, and the extensive network of capillaries in tissue that is healing is called granulation tissue. **30.** Skin can regenerate effectively even after considerable damage because stem cells persist in both the epithelial and connective tissue components of skin. When injury occurs, cells of the stratum basale replace epithelial cells, and mesenchymal cells replace cells lost from the dermis. **PAGE 221** **31.** As a person ages, the blood supply to the dermis decreases and eccrine sweat glands become less active. These changes make it more difficult for older individuals to cool themselves in hot weather. **32.** With advancing age, melanocyte activity decreases, leading to gray or white hair.

Answers to Review Questions

PAGE 224

Level 1 Reviewing Facts and Terms

1. (a) epidermis **(b)** dermis **(c)** papillary layer **(d)** reticular layer **(e)** subcutaneous layer (hypodermis) **2.** a **3.** c **4.** b **5.** d **6.** d **7.** b **8.** d **9.** d **10.** b **11.** c **12.** a **13.** c **14.** a **15.** Epidermal cell division occurs in the stratum basale. **16.** These smooth muscles cause hairs to stand erect when stimulated. **17.** Epidermal growth factor promotes the divisions of basal cells in the stratum basale and stratum spinosum, accelerates the production of keratin in differentiating epidermal cells, stimulates both epidermal development and epidermal repair after injury, and stimulates secretory product synthesis and secretion by epithelial glands. **18.** The dermis is made up of (1) the papillary layer, which consists of areolar connective tissue and contains capillaries and sensory nerve fibers and receptors, and (2) the reticular layer, which consists of dense irregular connective tissue and bundles of collagen fibers. Both layers contain networks of blood vessels, lymphatic vessels, and nerve fibers. **19.** Regeneration of injured skin involves (1) bleeding and inflammation (inflammation phase), (2) scab and granulation tissue formation (migration phase), (3) loss of granulation and undermining of the scab (proliferation phase), and (4) scarring (scarring phase).

Level 2 Reviewing Concepts

20. Thin skin contains four layers of keratinocytes, whereas thick skin contains five layers. **21.** The integument is the first barrier to substances entering the body. This method of delivering drugs requires the substance to move across the epidermal plasma membranes. The lipid bilayer of the plasma membranes creates a barrier that prevents water from rapidly entering or leaving the cells. Fat-soluble (lipophilic) substances, such as oil containing a dissolved drug, can easily pass through this barrier to underlying connective

tissue and enter the circulation. Water-soluble drugs are lipophobic and thus do not readily penetrate the integument. **22.** In a first-degree burn, only the surface of the epidermis is damaged. The skin reddens and can be painful. In a second-degree burn, the entire epidermis and some of the dermis are damaged. Hair follicles and glands are usually not affected, but blistering, pain, and swelling occur. Third-degree burns destroy the epidermis and dermis, extending into the subcutaneous layer. Despite swelling, these burns are less painful than second-degree burns, because sensory nerves are destroyed. **23.** Incisions along tension lines—which represent the orientation of dermal collagen and elastin fibers—are more likely to remain closed, and thus heal more quickly, than incisions that cut across tension lines. **24.** c **25.** c **26.** d

Level 3 Critical Thinking and Clinical Applications

27. a **28.** Lisa has vitiligo. The white patches on her skin are the result of the loss of melanocytes in those areas. This condition develops when the body's immune defenses malfunction and antibodies attack normal melanocytes. **29. (a)** Ultraviolet radiation in sunlight converts a cholesterol-related steroid compound into vitamin D_3, or cholecalciferol. This compound is then converted to the hormone calcitriol, which is essential for absorbing the calcium and phosphate ions by the small intestine that is necessary for normal bone maintenance and growth. **(b)** The child can drink more milk. Milk is routinely fortified with cholecalciferol, normally identified as "vitamin D," which is easily absorbed by the intestines. **30.** Sweating from eccrine sweat glands is precisely regulated, and one influencing factor is emotional state. Presumably, a person who is lying is nervous and sweats profusely; the lie detector machine detects a change in electrical skin conductance caused by this sweating. **31.** The chemicals in hair dyes break the protective covering of the cortex, allowing the dyes to stain the medulla of the shaft. Dying is not permanent because the cortex remains damaged, allowing shampoo and UV rays from the sun to enter the medulla and affect the color. Also, the living portion of the hair remains unaffected, so that when the shaft is replaced the color will be lost.

Answers to Clinical Case Wrap-Up

PAGE 225 **1.** Ichthyosis affects keratinization, also called cornification. This disorder causes abnormal function of keratinocytes, the most numerous cells of the epidermis. Dysfunction begins in the stratum granulosum and continues through the stratum corneum. Keratinocytes in the granulosum layer make defective keratohyalin, which does a poor job of linking keratin fibers into the waterproof web desired for protection of the skin. As dying keratinocytes are pushed up, they bring this fragmented web to the surface, where it dries, peels, and scales. **2.** Sweat glands are connected to the epidermal surface through ducts. In ichthyosis, the thick scales block the sweat pores. Grandpa can't easily secrete sweat onto his body surface to cool his body temperature through evaporation. The thermoregulatory function of his integument is impaired, so he must guard against overheating.

Answers to Figure-Based Questions

FIGURE 5–1 Sebaceous glands and sweat glands are found in the skin.

FIGURE 5–6 The subpapillary plexus supplies blood to the capillary loops that follow the epidermis–dermis boundary.

FIGURE 5–8 Melanocytes are found in the stratum basale.

FIGURE 5–10 Sunlight and food are the body's sources of vitamin D_3.

FIGURE 5–13 A sebaceous gland discharges its secretion into a hair follicle. A sebaceous follicle discharges its secretion directly onto the epidermis.

Chapter 6

Answers to Checkpoints

PAGE 228 **1.** Major functions of the skeletal system are support, storage of minerals and lipids, blood cell production, protection, and leverage. **PAGE 229** **2.** The different broad categories for classifying bones according to shape are sutural bones, irregular bones, short bones, flat bones, long bones, and sesamoid bones. **3.** Bone markings (surface features) are characteristics of a bone's surface that have specific functions, such as joint formation, muscle attachment, or the passage of nerves and blood vessels. **PAGE 233** **4.** Mature bone cells are known as osteocytes, bone-building cells are called osteoblasts, and osteoclasts are bone-resorbing cells. **5.** If the ratio of collagen to hydroxyapatite in a bone increased, the bone would become less strong (as well as more flexible). **6.** Because osteoclasts break down or demineralize bone, the bone would have a decreased mineral content (less mass); as a result, it would also be weaker. **PAGE 236** **7.** Compact bone consists of osteons (Haversian systems) with little space between them. Compact bone lies over spongy bone and makes up most of the diaphysis. It functions to protect, support, and resist stress. Spongy bone consists of trabeculae with numerous red marrow–filled spaces. Spongy bone makes up most of the structure of short, flat, and irregular bones and is also found at the epiphyses of long bones. Spongy bone functions in storing marrow and providing some support. **8.** The presence of lamellae that are not arranged in osteons is indicative of spongy bone, which is located in an epiphysis. **PAGE 240** **9.** In endochondral ossification, cells of the inner layer of the perichondrium differentiate into osteoblasts, and a cartilage model is gradually replaced by bone. **10.** During intramembranous ossification, fibrous connective tissue is replaced by bone. **11.** Long bones of the body, such as the femur, have an epiphyseal cartilage, a plate of cartilage that separates the epiphysis from the diaphysis so long as the bone is still growing lengthwise. An x-ray would indicate whether the epiphyseal cartilage is still present. If it is, growth is still occurring. If it is not, the bone has reached its adult length and, thus, the person has reached full height. **PAGE 242** **12.** Bone remodeling refers to the process whereby old bone is continuously being destroyed by osteoclasts while new bone is being constructed by osteoblasts. **13.** The biochemistry of some heavy-metal ions, such as strontium, cobalt, uranium, and plutonium, is very similar to that of calcium. Osteoblasts cannot differentiate these heavy-metal ions from normal calcium ions, so the heavy-metal ions become incorporated into the bone matrix. Over time, these dangerous ions can be released into the bloodstream during normal bone remodeling. **PAGE 243** **14.** The larger arm muscles of the weight lifter would apply more mechanical stress to the bones of the upper limbs. In response to that stress, the bones would grow thicker. **15.** Growth continues throughout childhood. At puberty, a growth spurt takes place and is followed by the closure of the epiphyseal cartilages. The later puberty begins, the taller the child will be when the growth spurt begins, so the taller the person will be when growth is completed. **16.** Increased levels of growth hormone prior to puberty will result in excessive

bone growth, making the child taller. **PAGE 246** **17.** Parathyroid hormone (PTH) indirectly stimulates osteoclasts to release calcium ions from bone and enhances calcitriol's effect on the intestinal absorption of calcium. Increased PTH secretion would result in an increase in the level of calcium ions in the blood. **18.** The bones of children who have rickets are poorly mineralized and as a result are quite flexible. Under the weight of the body, the leg bones bend. The instability makes walking difficult and can lead to other problems of the legs and feet. **PAGE 247** **19.** Immediately following a fracture, extensive bleeding occurs at the injury site. After several hours, a large blood clot called a fracture hematoma develops. Next, an internal callus forms as a network of spongy bone unites the inner edges, and an external callus of cartilage and bone stabilizes the outer edges. The cartilaginous external callus is eventually replaced by bone, and the struts of new spongy bone now unite the broken ends. With time, the swelling that initially marks the location of the fracture is remodeled, new compact bone is formed, and there is little evidence that a break occurred. **20.** An external callus forms early in the healing process, when cells from the endosteum and periosteum migrate to the area of the fracture. These cells form an enlarged collar (external callus) that encircles the bone in the area of the fracture. **PAGE 250** **21.** Osteopenia is inadequate ossification and is common during the aging process. It results from decreasing osteoblast activity accompanied by normal osteoclast activity. **22.** In women, the sex hormone known as estrogen plays an important role in moving calcium into bones. After menopause, the level of estrogen decreases dramatically. As a result, older women have difficulty replacing the calcium in bones that is being lost due to normal aging. In men, the level of testosterone does not decrease until much later in life.

Answers to Review Questions

PAGE 252

Level 1 Reviewing Facts and Terms

1. b **2.** b **3.** a **4.** c **5.** d **6.** a **7. (a)** long bone **(b)** flat bone **(c)** sutural bone **(d)** irregular bone **(e)** short bones **(f)** sesamoid bone. **8.** a **9.** a **10.** c **11.** (1) support, (2) storage of minerals and lipids, (3) blood cell production, (4) protection, and (5) leverage **12.** Diploë is the layer of spongy bone between the layers of compact bone in the cranium. **13.** A sinus is a chamber within a bone and is normally filled with air. **14.** In endochondral ossification, bone replaces a cartilage model. In intramembranous ossification, bone replaces mesenchyme or fibrous connective tissue. **15.** organic = collagen; inorganic = hydroxyapatite crystals **16. (a)** calcium salts, phosphate salts, and vitamins A, C, and D_3; **(b)** calcitriol, growth hormone, thyroxine, estrogen (in females) or testosterone (in males), parathyroid hormone, and calcitonin. **17.** The three organs or tissues are the bones, the intestines of the digestive tract, and the kidneys. **18.** Parathyroid hormone stimulates osteoclast activity, increases the rate of intestinal absorption of calcium ions, and decreases the rate of excretion of calcium ions by the kidneys. These effects increase blood calcium levels.

Level 2 Reviewing Concepts

19. Blood is carried to and from an osteon by a capillary and a venule that run in the osteon's central canal. **20.** The osteons are aligned parallel to the long axis of the shaft, which does not bend when forces are applied to either end. Stresses or impacts to the side of the shaft can lead to a fracture. **21.** The lack of physical stress during inactivity leads to the removal of calcium salts from bones. Up to one-third of the bone mass can be lost in this manner, causing the bones to become thin and brittle. **22.** In pregnant women, the increase in calcitonin secretion is suspected to be responsible for transferring maternal calcium to the fetus and also for preserving and recovering bone mineral density in the mother. **23.** There are many long bones in the hand, each of which has an epiphyseal cartilage (plate). Measuring the width of these plates will provide clues to the hormonal control of growth in the child. **24.** In a greenstick fracture, only one side of the shaft of a long bone is broken, while the other side is bent. Such fractures occur commonly in children because their long bones have not yet fully ossified. **25.** b **26.** Bone markings give clues as to the size, age, sex, and general appearance of an individual.

Level 3 Critical Thinking and Clinical Applications

27. The fracture might have damaged the epiphyseal cartilage in Sally's right leg. Even though the bone healed properly, the damaged leg did not produce as much cartilage as did the undamaged leg. The result would be a shorter bone on the side of the injury. **28.** a **29.** a **30.** The matrix of bone will absorb traces of minerals from the diet. These minerals can be identified hundreds of years later. A diet rich in calcium and vitamin B will produce denser bones than will a diet deficient in them. Cultural practices such as the binding of appendages or the wrapping of infant heads will manifest in misshapen bones. Heavy muscular activity will result in larger bone markings, indicating an athletic or physically demanding lifestyle.

Answers to Clinical Case Wrap-Up

PAGE 253 **1.** The compact bone in Alex's tibia is composed of osteons that have plenty of calcified matrix (for hardness) but few "supporting beams" of collagen. The spongy bone of his epiphyses is likewise missing collagen reinforcement in the trabeculae. Therefore, the bony architecture of Alex's tibia is intrinsically weak. The bone won't be able to bend with forces placed on it during daily activities, especially in sports, and will be prone to snap. **2.** Alex should not continue playing soccer, and he should avoid contact sports. As this incident shows, Alex is at much higher risk for fractures than any other soccer player on the field. He should be encouraged to pursue swimming, music, writing, art, or other stimulating, yet less physical, activities.

Answers to Figure-Based Questions

FIGURE 6–3 In long bones, spongy bone is found in the epiphyses. In flat bones, spongy bone is found between two layers of compact bone.

FIGURE 6–5 An osteogenic cell divides to produce osteoblasts. Osteoblasts become osteocytes when they are completely surrounded by bone matrix.

FIGURE 6–7 Lamellae are organized concentrically around an osteon, interstitially between osteons, and circumferentially around the entire bone.

FIGURE 6–10 The periosteum covers the superficial layer of compact bone and is made up of the fibrous and cellular layers.

FIGURE 6–16a The parathyroid gland secretes parathyroid hormone when the blood calcium level is too low.

Chapter 7

Answers to Checkpoints

PAGE 255 **1.** The axial skeleton includes the skull (8 cranial bones and 14 facial bones), the bones associated with the skull (6 auditory ossicles and the hyoid bone), the thoracic cage (the sternum and 24 ribs), and the vertebral column (24 vertebrae, the sacrum, and the coccyx). **2.** The axial skeleton serves as a framework that supports and protects organs, provides an extensive surface area for muscle attachment, and stabilizes and positions parts of the appendicular skeleton that support the limbs.
PAGE 271 **3.** The foramen magnum is located in the base of the occipital bone. **4.** Tomás has fractured his right parietal bone. **5.** The sphenoid contains the sella turcica, which in turn contains the pituitary gland. **6.** The 14 facial bones include 2 inferior nasal conchae, 2 lacrimal bones, 1 mandible, 2 maxillae (maxillary bones), 2 nasal bones, 2 palatine bones, 1 vomer, and 2 zygomatic bones. **7.** The mental foramen is found in the mandible. Structures passing through this opening include the mental nerve, which carries sensory information to the brain, and mental vessels, which supply the chin and lips. **8.** The optic canal is found in the sphenoid. The optic nerve and ophthalmic artery pass through this structure. **9.** The foramina in the ethmoid are the olfactory foramina. **PAGE 272** **10.** The bones forming the orbital complex are the frontal, sphenoid, zygomatic, palatine, maxilla, lacrimal, and ethmoid. **11.** The bones forming the nasal complex are the frontal, ethmoid, nasal, maxilla, palatine, and sphenoid. **12.** The sphenoid, ethmoid, frontal, and paired palatine and maxillary bones contain the paranasal sinuses. **PAGE 273** **13.** A fontanelle is a relatively soft, flexible, fibrous region between two flat bones in the developing skull. The major fontanelles are the anterior fontanelle, posterior fontanelle, sphenoidal fontanelles, and mastoid fontanelles. **14.** Because they are not ossified at birth, fontanelles permit the skull to change shape during childbirth, and they allow for enlargement of the brain during infancy and early childhood. **PAGE 275** **15.** The secondary curves of the spine allow us to balance our body weight on our lower limbs with minimal muscular effort. Without the secondary curves, we would not be able to stand upright for extended periods. **16.** The adult vertebral column consists of 26 bones: the vertebrae (24), the sacrum (1), and the coccyx. **PAGE 283** **17.** The adult vertebral column has fewer vertebrae than a newborn because, in an adult, the five sacral vertebrae fuse to form a single sacrum, and the four coccygeal vertebrae fuse to form a single coccyx. **18.** The axis is fractured. The dens is a tooth-like process projecting upward from the body of the axis, or second cervical vertebra, which is located in the neck (cervical region). **19.** The presence of transverse foramina indicates that this vertebra is from the cervical region of the vertebral column. These foramina are passageways for important blood vessels that supply the brain. **20.** The bodies of the lumbar vertebrae are larger because they must support a great deal more weight than do vertebrae that are more superior in the spinal column. The larger vertebral bodies allow the weight to be distributed over a larger area. **PAGE 285** **21.** False ribs (ribs 8–12) are the five lower ribs on either side that do not articulate with the sternum directly. **22.** Improper compression of the chest during CPR can—and commonly does—result in a fracture of the xiphoid process of the sternum or the ribs. **23.** True ribs (ribs 1–7) attach directly to the sternum by separate costal cartilages; floating ribs (ribs 11–12) are the two lower ribs on either side that are not attached anteriorly to the sternum.

Answers to Review Questions

PAGE 287

Level 1 Reviewing Facts and Terms

1. (a) occipital bone **(b)** parietal bone **(c)** frontal bone **(d)** temporal bone **(e)** sphenoid **(f)** ethmoid **(g)** vomer **(h)** mandible **(i)** lacrimal bone **(j)** nasal bone **(k)** zygomatic bone **(l)** maxilla **2.** a **3.** b **4.** c **5.** b **6.** e **7. (a)** cervical **(b)** thoracic **(c)** lumbar **8.** a **9.** b **10.** d **11.** (1) occipital bone; (2) frontal bone; (3) sphenoid; (4) ethmoid; (5) paired parietal bones; and (6) paired temporal bones **12.** (1) sphenoid; (2) frontal bone; (3) ethmoid; (4) lacrimal bone; (5) maxilla; (6) palatine bone; (7) zygomatic bone **13.** The vomer forms the anterior, inferior portion of the bony nasal septum that separates the right and left nasal cavities. **14.** The fibrocartilage discs between adjacent vertebrae make the vertebral column more flexible.

Level 2 Reviewing Concepts

15. Together the lacrimal bones and the maxillae form the nasolacrimal canals. These canals open into the lower part of the nasal cavity. They provide protection for the lacrimal sacs and the lacrimal ducts, which carry tears from the orbits to the nasal cavity. **16.** The two superior nasal conchae and the two middle nasal conchae are projections that are part of the ethmoidal labyrinth. The two inferior nasal conchae articulate with the maxillae. **17.** The ribs raise and lower to increase and decrease the volume of the thoracic cage. When they rise, the thoracic cage expands and we breathe in. When the ribs are lowered to their original position, the volume of the thoracic cage decreases and we breathe out. **18.** Keeping your back straight keeps the weight aligned along the axis of your vertebral column, where it can be transferred to your lower limbs. Bending your back would strain the muscles and ligaments of the back, increasing the risk of injury. **19.** c **20.** Fontanelles are fibrous connections between cranial bones. They help ease birth by permitting the skull to change shape without damage during delivery. **21.** a **22.** b **23.** e

Level 3 Critical Thinking and Clinical Applications

24. d **25.** The large bones of a child's cranium are not yet fused; they are connected by fontanelles, areas of fibrous tissue. By examining the bones, the archaeologist could readily see if sutures had formed. By knowing approximately how long it takes for the various fontanelles to close and by determining their sizes, she could estimate the age of the person at death. **26.** Craniostenosis is the premature closure of cranial fontanelles. In trying to respond to the growth of the brain, the rest of the skull changes shape. This can lead to either a long and narrow or a very broad skull, depending on which suture closes early. When all cranial sutures close early, the brain cannot develop. Surgery is then inevitable to prevent brain damage.

Answers to Clinical Case Wrap-Up

PAGE 288 **1.** The seven bones that make up the orbital complex are the frontal bone (forming the roof), the zygomatic bone (forming the lateral wall), the maxilla (forming most of the floor), the lacrimal bone, the ethmoidal labyrinth, the sphenoid, and the palatine bone (forming the thin medial wall and floor). **2.** The four paranasal sinuses surrounding the orbital complex are the frontal, maxillary, and sphenoidal sinuses, and ethmoidal cells.

Answers to Figure-Based Questions

FIGURE 7–3 The skull contains four major sutures: the sagittal suture, the lambdoid suture, the squamous suture, and the coronal suture.

FIGURE 7–16 The infant skull has six fontanelles: sphenoidal (paired), mastoid (paired), anterior, and posterior. As the skull develops, bones ossify and fuse. In an adult skull, all of the bones are complete and fused, so there aren't any fontanelles on the adult skull.

FIGURE 7–17 The thoracic and the sacral regions of the spine form primary curves.

FIGURE 7–23 The last two pairs of ribs (11 and 12) are the floating ribs and do not attach to the sternum. The other false ribs are indirectly attached to the sternum by costal cartilage.

ANSWERS

Chapter 8

Answers to Checkpoints

PAGE 293 **1.** Each of the two pectoral girdles consists of a clavicle (collarbone) and a scapula (shoulder blade). Each arm articulates with the trunk at the pectoral girdle. **2.** The clavicle attaches the scapula to the sternum, and restricts the scapula's range of motion (mobility). When the clavicle is broken, the scapula has a greater than normal range of motion and is less stable. **3.** The head of the humerus articulates with the scapula at the glenoid cavity. **PAGE 298** **4.** The bones of an upper limb are the humerus, ulna, radius, carpal (wrist) bones (scaphoid, lunate, triquetrum, pisiform, trapezium, trapezoid, capitate, and hamate), 5 metacarpals (palm bones), and 14 phalanges (fingers). **5.** The two rounded projections on either side of the elbow are the lateral and medial epicondyles of the humerus. **6.** The radius is lateral to the ulna while in the anatomical position; or the ulna is medial to the radius while in the anatomical position. **7.** The first distal phalanx is located at the tip of the pollex (thumb), so Bill's thumb is broken. **PAGE 300** **8.** The pelvic girdle is composed of the paired hip bones, also known as the coxal bones or pelvic bones. **9.** The three bones that make up a hip bone are the ilium, ischium, and pubis. **10.** When you are seated, your body weight is supported by the ischial tuberosities. **PAGE 306** **11.** The bones of the lower limb are the femur (thigh), patella (kneecap), tibia and fibula (leg), tarsal (ankle) bones (talus, calcaneus, cuboid, navicular, medial cuneiform, intermediate cuneiform, and lateral cuneiform), 5 metatarsals, and 14 phalanges. **12.** The fibula is not part of the knee joint and does not bear weight, but it is an important point of attachment for many leg muscles. When the fibula is fractured, these muscles cannot function properly to move the leg, so walking is difficult and painful. The fibula also helps stabilize the ankle joint. **13.** Joey has most likely fractured the calcaneus (heel bone). **14.** The talus transfers the weight of the body from the tibia toward the toes. **15.** In general, the bones of males tend to be heavier than those of females, and bone markings are more prominent in males than in females. **16.** Bones can reveal information about a person's sex, age, muscular development, nutritional state, handedness, and occupation, plus other information relative to the medical history. **17.** The female pelvis is adapted for supporting the weight of the developing fetus and enabling its passage through the pelvic outlet during delivery. Compared to males, such adaptations of the female pelvis include an enlarged pelvic outlet, a sacrum and coccyx with less curvature, a pelvic inlet that is wider and more circular, a relatively broad shape, ilia that project farther laterally, and an inferior angle between the pubic bones that is greater than 100 degrees (as opposed to 90 degrees or less for males).

Answers to Review Questions

PAGE 309

Level 1 Reviewing Facts and Terms

1. (a) anterior view; **(b)** lateral view; **(c)** posterior view; **(d)** acromion; **(e)** coracoid process; **(f)** spine; **(g)** glenoid cavity **2.** d **3. (a)** sacrum; **(b)** coccyx; **(c)** ilium; **(d)** pubis; **(e)** ischium; **(f)** hip bone **4.** b **5.** b **6.** d **7.** b **8.** radial groove **9.** pubic bones and a pad of fibrocartilage **10.** (1) talus; (2) calcaneus; (3) cuboid; (4) navicular; and (5–7) three cuneiform bones

Level 2 Reviewing Concepts

11. d **12.** c **13.** e **14.** b **15.** d **16.** d **17.** b **18.** The true pelvis is the space enclosed by the bones of the pelvic girdle beneath the pelvic brim. The false pelvis is the space surrounded by the broad, bladelike portions of each ilium superior to the pelvic brim. **19.** The clavicles are small and fragile, so they are easy to break. Once this part of a pectoral girdle is broken, the attacker would no longer have efficient use of his arms. **20.** c **21.** e **22.** A shoulder girdle consists of a clavicle and a scapula. The clavicle articulates with the manubrium of the sternum, and this is the only direct connection between the shoulder girdle and the axial skeleton. The scapula is connected to the thoracic cage only by skeletal muscles. This arrangement makes the shoulders very mobile but not very strong. **23.** e

Level 3 Critical Thinking and Clinical Applications

24. In osteoporosis, a decrease in the calcium content of the bones leads to bones that are weak and brittle. Hip fractures involve the femur, not the hip bones. Because the hip joint must help support the body's weight, any weakening of the femoral bones may result in their breaking under the weight of the body. The shoulder, by contrast, is not a load-bearing joint and is not subject to the same great stresses or strong muscle contractions as the hip joint. As a result, it is less likely to become broken. **25.** The surgical neck lies between the round head and the narrow shaft of the humerus. It derives its name from the fact that fractures very frequently occur at this site. **26.** Several characteristics are important in determining a person's sex from the pelvis, including its general appearance, shape of the pelvic inlet, depth of the iliac fossa, characteristics of the ilium, angle inferior to the pubic symphysis, position of the acetabulum, shape of the obturator foramen, and characteristics of the ischium. The person's age can be estimated by the bone's size, degree of mineralization (mineral content), and various markings. The person's general appearance can be reconstructed from the markings where muscles attach to the bones, which can indicate the size and shape of the muscles and thus the person's general body contours.

Answers to Clinical Case Wrap-Up

PAGE 310 **1.** The clavicle makes up the anterior part of the pectoral, or shoulder, girdle. It anchors the upper extremity to the axial skeleton by articulating with the acromion of the scapula laterally and the manubrium of the sternum medially. **2.** When his clavicle was fractured, Ken's shoulder was destabilized, resulting in his upper extremity dangling uselessly on that side.

Answers to Figure-Based Questions

FIGURE 8–1 The appendicular skeleton is composed of the pectoral girdles (clavicles and scapulae), upper limbs (humeri, radii, ulnae, carpal bones, metacarpals, and phalanges), pelvic girdle

(hip bones), and lower limbs (femurs, patellae, tibias, fibulas, tarsal bones, metatarsals, and phalanges).

FIGURE 8–6 Metacarpal IV articulates with the hamate and capitate.

FIGURE 8–8 The opening formed by the pubis and the ischium is the obturator foramen.

FIGURE 8–12 The fibula does not articulate with the femur. The fibula does articulate with the tibia.

Chapter 9

Answers to Checkpoints

PAGE 314 **1.** The three types of joints as classified by range of motion are (1) an immovable joint or synarthrosis, (2) a slightly movable joint or amphiarthrosis, and (3) a freely movable joint or diarthrosis. A synarthrosis can be fibrous or cartilaginous, depending on the nature of the connection, or it can be a bony fusion, which develops over time. An amphiarthrosis is either fibrous or cartilaginous, depending on the nature of the connection. A diarthrosis is a synovial joint, which permits the greatest range of motion. **2.** Both synarthrotic joints (except synostoses) and amphiarthrotic joints consist of bony regions separated by fibrocartilage or cartilaginous connective tissue. **3.** These are fibrous joints known as sutures. **PAGE 316** **4.** Components of a synovial joint include a joint capsule (articular capsule), articular cartilages, synovial fluid, and various accessory structures (menisci, fat pads, ligaments, tendons, and bursae). Synovial joints are freely movable joints that have a joint (synovial) cavity, which is the space between the articulating surfaces of two bones in a joint. Articular cartilages resembling hyaline cartilage cover the articulating bone surfaces. The fibrous joint capsule surrounds the joint, and a synovial membrane, which secretes synovial fluid, lines the walls of the joint cavity. Within the cavity, synovial fluid lubricates, distributes nutrients, and absorbs shocks. Menisci are pads of fibrocartilage that allow for variation in the shapes of the articulating surfaces. Fat pads protect the cartilages. Ligaments are cords of fibrous tissue that support, strengthen, and reinforce the joint. Tendons passing across or around the joint limit the range of motion and provide mechanical support. Bursae are synovial fluid-filled pockets that reduce friction and absorb shocks. **5.** Because articular cartilages are avascular (lack a blood supply), they rely on synovial fluid to supply nutrients and eliminate wastes. Impairing the circulation of synovial fluid would have the same effect as impairing a tissue's blood supply: Nutrients would not be delivered to meet the tissue's needs, and wastes would accumulate. Tissue damage or death could ultimately result. **6.** A dislocation is a complete loss of contact between the articulating surfaces within a joint. **PAGE 322** **7.** Based on the shapes of the articulating surfaces, synovial joints are classified as plane (gliding), hinge, pivot, condylar (ellipsoid), saddle, and ball-and-socket joints. **8.** When doing jumping jacks, you move your lower limbs away from the body's midline; this movement is abduction. When you bring the lower limbs back together, the movement is adduction. **9.** Flexion and extension are the movements associated with hinge joints. **PAGE 323** **10.** The type of joint that only permits slight movements is an amphiarthrosis **11.** Intervertebral discs are not found between the first and second cervical vertebrae, between sacral vertebrae in the sacrum, or between coccygeal vertebrae in the coccyx. An intervertebral disc between the first and second cervical vertebrae would prohibit rotation. The vertebrae in the sacrum and coccyx are fused to provide a firm attachment for muscles and ligaments. **12.** The vertebral movement involved in (a) bending forward is flexion. The movement involved in (b) bending to the side is lateral flexion. The movement involved in (c) moving the head to signify "no" is rotation. **PAGE 327** **13.** Terry has most likely damaged his annular ligament. **14.** Damage to the menisci of the knee joint decreases the joint's stability, so the person would have a difficult time locking the knee in place while standing and would have to use muscle contractions to stabilize the joint. If the person had to stand for a long time, the muscles would fatigue and the knee would "give out." It is also likely that the person would feel pain. **15.** Like members of the clergy, carpet layers and roofers kneel a lot (and they also slide along on their knees), causing inflammation of the bursae in the knee joint. **16.** The bones involved with the knee joint are the femur, tibia, and patella. The fibula is not part of the knee joint. **PAGE 331** **17.** Ligaments and muscles provide most of the stability for the shoulder joint. **18.** The subscapular bursa is located in the shoulder joint, so the tennis player would be more likely to develop inflammation of this structure (bursitis). The condition is associated with repetitive motion that occurs at the shoulder, such as swinging a tennis racket. The jogger would be more at risk for injuries to the knee joint. **19.** A shoulder separation is an injury involving partial or complete dislocation of the acromioclavicular joint. **20.** The bones making up the shoulder joint are the humerus and scapula. **21.** The iliofemoral, pubofemoral, and ischiofemoral ligaments are at the hip joint. **PAGE 332** **22.** Rheumatism is a general term describing any painful condition of the bones, muscles, and joints (musculoskeletal system). One of several forms of rheumatism is arthritis. **23.** Arthritis applies to all the rheumatic diseases that affect synovial joints. Of the many different types of arthritis, osteoarthritis is the most common. **24.** Osteoblast activity must equal osteoclast activity or else the integrity of bone structure is compromised. For example, if osteoclast activity outpaces osteoblast activity, the result is thin, brittle bones. **25.** The skeletal system provides structural support for all body systems and stores energy, calcium, and phosphate. The integumentary system synthesizes vitamin D_3, which is essential for calcium and phosphorus absorption. Calcium and phosphorus are needed for bone growth and maintenance.

Answers to Review Questions

PAGE 335

Level 1 Reviewing Facts and Terms

1. (a) joint capsule; **(b)** synovial membrane; **(c)** articular cartilage; **(d)** joint cavity (contains synovial fluid) **2.** b **3.** b **4.** c **5.** d **6.** d **7.** c **8.** b **9.** c **10.** b **11.** b **12.** a **13.** c **14.** a **15.** a **16.** b **17.** a **18.** b **19.** b

Level 2 Reviewing Concepts

20. b **21.** c **22.** A meniscus subdivides a synovial cavity, channels the flow of synovial fluid, and allows variations in the shape of the articular surfaces. Menisci also act as cushions and shock absorbers. **23.** Twisting an extended weight-bearing knee frequently leads to the injury of the anterior cruciate ligament. **24.** In joints affected by gouty arthritis, crystals of uric acid form within the synovial fluid. This hampers movement. **25.** In a bulging disc, the nucleus pulposus does not extrude. In a herniated disc, the nucleus pulposus breaks through the annulus fibrosus. **26.** Height decreases during adulthood in part as a result of osteoporosis in the vertebrae, and in part as a result of the decrease in water content of the nucleus pulposus region of intervertebral discs. **27.** (1) plane (gliding): clavicle and sternum; (2) hinge: elbow; (3) condylar: radius and carpal bones; (4) saddle: thumb; (5) pivot: atlas and axis; (6) ball-and-socket: shoulder

Level 3 Critical Thinking and Clinical Applications

28. The upward, twisting pull on the elbow joint in pronation could have caused a partial dislocation of the radial head from the annular ligament known as nursemaid's elbow. **29.** Cartilage does not contain blood vessels, so the chondrocytes rely on diffusion to gain nutrients and eliminate wastes. The synovial fluid is very important in supplying nutrients to the articular cartilages that it bathes and in removing wastes. If the circulation of the synovial fluid is impaired or stopped, the cells will not get enough nutrients or be able to get rid of their waste products. This combination of factors can lead to the death of the chondrocytes and the breakdown of the cartilage. **30.** Shoulder dislocations would occur more frequently than hip dislocations because the shoulder is a more mobile joint. Because the shoulder joint is not bound tightly by ligaments or other structures, it is easier to dislocate when excessive forces are applied. By contrast, the hip joint, although mobile, is less easily dislocated because it is stabilized by four heavy ligaments, and the bones fit together snugly in the joint. Additionally, the synovial capsule of the hip joint is larger than that of the shoulder, and its range of motion is decreased.

ANSWERS

Answers to Clinical Case Wrap-Up

PAGE 336 **1.** Only diarthroses, or synovial joints, are affected by juvenile rheumatoid arthritis. This is a disease of the synovial lining, so it does not affect joints that have no synovial membrane. **2.** Normal synovial membranes are thin, delicate, and smooth. The inflamed synovial membrane in a joint affected by rheumatoid arthritis would look thickened, red, excessively fluid filled, swollen, and overgrown.

Answers to Figure-Based Questions

FIGURE 9–1 Articular cartilage covers the bony surfaces of a synovial joint. The articular cartilage on each bony surface is separated by a thin layer of synovial fluid.

FIGURE 9–3 Angular movements include flexion/extension/hyperextension, abduction/adduction, and circumduction.

FIGURE 9–6 The annulus fibrosus provides the tough outer layer of fibrocartilage and the nucleus pulposus provides the soft inner core for resiliency and shock absorption.

FIGURE 9–9 The acromioclavicular ligament connects the scapula (specifically, the acromion of the scapula) and the clavicle.

Chapter 10

Answers to Checkpoints

PAGE 339 **1.** The three types of muscle tissue are skeletal muscle, cardiac muscle, and smooth muscle. Skeletal muscle tissue moves the body by pulling on our bones, cardiac muscle tissue pumps blood through the cardiovascular system, and smooth muscle tissue pushes fluids and solids along the digestive tract and other internal organs, and regulates the diameters of small arteries. **2.** Muscle tissues share the common properties of excitability (the ability to receive and respond to a stimulus), contractility (the ability of a muscle cell to shorten when it is stimulated), extensibility (stretching movement of a muscle), and elasticity (the ability of a muscle to recoil to its resting length). **3.** Skeletal muscles produce skeletal movement, maintain posture and body position, support soft tissues, guard body entrances and exits, maintain body temperature, and store nutrients. **4.** The epimysium is a dense layer of collagen fibers that surrounds the entire muscle; the perimysium divides the skeletal muscle into a series of compartments, each containing a bundle of muscle fibers called a fascicle; and the endomysium surrounds individual skeletal muscle cells (muscle fibers). The collagen fibers of the epimysium, perimysium, and endomysium come together to form either bundles known as tendons, or broad sheets called aponeuroses. Tendons and aponeuroses generally attach skeletal muscles to bones. **5.** Because tendons attach muscles to bones, severing the tendon would disconnect the muscle from the bone, and so the muscle could not move a body part. **PAGE 348** **6.** Sarcomeres, the smallest contractile units of a striated muscle cell, are segments of myofibrils. Each sarcomere has a dark A band and light I bands. The A band contains the M line, the H band, and the zone of overlap. Each I band contains thin filaments, but not thick filaments. Z lines bisect the I bands and mark the boundaries between adjacent sarcomeres. **7.** Skeletal muscle fibers appear striated when viewed through a light microscope because the Z lines and thick filaments of the myofibrils within the muscle fibers are aligned. **8.** You would expect the greatest concentration of calcium ions in a resting skeletal muscle fiber to be in the terminal cisternae of the sarcoplasmic reticulum. **PAGE 357** **9.** The neuromuscular junction, is the synapse between a motor neuron and a skeletal muscle cell (fiber). This connection enables communication between the nervous system and a skeletal muscle fiber. **10.** Acetylcholine (ACh) release from the axon terminal is necessary for skeletal muscle contraction, because it serves as the first step in the process that leads to the formation of cross-bridges in the sarcomeres. A muscle's ability to contract depends on the formation of cross-bridges between the myosin heads and actin myofilaments. A drug that blocks ACh release would interfere with this cross-bridge formation and prevent muscle contraction. **11.** If the sarcolemma of a resting skeletal muscle suddenly became permeable to Ca^{2+}, the cytosolic concentration of Ca^{2+} would increase, and the muscle would contract. In addition, because the amount of calcium ions in the cytosol must decrease for relaxation to occur, the increased permeability of the sarcolemma to Ca^{2+} might prevent the muscle from relaxing completely. **12.** Without acetylcholinesterase (AChE), the motor end plate would be stimulated continuously by acetylcholine, locking the muscle in a state of contraction. **PAGE 360** **13.** A muscle's ability to contract depends on the formation of cross-bridges between the myosin and actin myofilaments in the muscle. In a muscle that is overstretched, the myofilaments would overlap very little, so very few cross-bridges between myosin and actin could form and, thus, the contraction would be weak. If the myofilaments did not overlap at all, then no cross-bridges would form and the muscle could not contract. **PAGE 365** **14.** Yes, a skeletal muscle can contract without shortening. The muscle can shorten (isotonic concentric contraction), elongate (isotonic eccentric contraction), or remain the same length (isometric contraction), depending on the relationship between the load (resistance) and the tension produced by actin–myosin interactions. **PAGE 369** **15.** Muscle fibers synthesize ATP continuously by utilizing creatine phosphate (CP) and metabolizing glycogen and fatty acids. Most cells generate ATP only through aerobic metabolism in the mitochondria and through glycolysis in the cytosol. **16.** Oxygen debt is the amount of oxygen required to restore normal, pre-exertion conditions in muscle tissue. **PAGE 373** **17.** The three types of skeletal muscle fibers are (1) fast fibers (also called white muscle fibers, fast-twitch glycolytic fibers, Type II-B fibers, and fast fatigue fibers); (2) slow fibers (also called red muscle fibers, slow-twitch oxidative fibers, Type I fibers, and slow oxidative fibers); and (3) intermediate fibers (also called fast-twitch oxidative fibers,

Type II-A fibers, and fast resistant fibers). **18.** Muscle fatigue is a muscle's reduced ability to contract due to low pH (hydrogen ion buildup), low ATP levels, or other problems. **19.** General age-related effects on skeletal muscles include decreased skeletal muscle fiber diameters, diminished muscle elasticity, decreased tolerance for exercise, and a decreased ability to recover from muscular injuries **20.** A sprinter requires large amounts of energy for a short burst of activity. To supply this energy, the sprinter's muscles rely on anaerobic metabolism. Anaerobic metabolism is less efficient in producing energy than aerobic metabolism, and the process also produces acidic wastes; this combination contributes to muscle fatigue. Conversely, marathon runners derive most of their energy from aerobic metabolism, which is more efficient and produces fewer wastes than anaerobic metabolism does. **21.** Activities that require short periods of strenuous activity produce a greater oxygen debt, because such activities rely heavily on energy production by anaerobic metabolism. Because lifting weights is more strenuous over the short term than swimming laps, which is an aerobic activity, weight lifting would likely produce a greater oxygen debt than would swimming laps. **22.** People who excel at endurance activities have a higher than normal percentage of slow fibers. Slow fibers are physiologically better adapted to this type of activity than are fast fibers, which are less vascular and fatigue faster. **PAGE 374** **23.** Compared to skeletal muscle tissue, cardiac muscle tissue (1) has relatively small cells; (2) has cells with a centrally located nucleus (some may contain two or more nuclei); (3) has T tubules that are short and broad and do not form triads; (4) has an SR that lacks terminal cisternae and has tubules that contact the plasma membrane as well as the T tubules; (5) has cells that are nearly totally dependent on aerobic metabolism as an energy source; and (6) contains intercalated discs that assist in stabilizing tissue structure and spreading action potentials. **24.** Cardiac muscle cells are joined by gap junctions, which allow ions and small molecules to flow directly between cells. As a result, action potentials generated in one cell spread rapidly to adjacent cells. Thus, all the cells contract simultaneously, as if they were a single unit (a syncytium). **PAGE 377** **25.** Smooth muscle cells lack sarcomeres, and thus smooth muscle tissue is nonstriated. Additionally, the thin filaments are anchored to dense bodies. **26.** Skeletal muscle contractions are least affected by changes in extracellular Ca^{2+} concentrations. In skeletal muscle, most of the calcium ions come from the sarcoplasmic reticulum. Most of the calcium ions that trigger a contraction in cardiac and smooth muscles come from the extracellular fluid. **27.** The looser organization of actin and myosin filaments in smooth muscle allows smooth muscle to contract over a wider range of resting lengths than skeletal muscle.

Answers to Review Questions

PAGE 380

Level 1 Reviewing Facts and Terms

1. (a) sarcolemma **(b)** sarcoplasm **(c)** mitochondria **(d)** myofibril **(e)** thin filament **(f)** thick filament **(g)** sarcoplasmic reticulum **(h)** T tubules **2.** d **3.** a **4.** c **5.** d **6.** a **7.** d **8.** c **9.** (1) skeletal muscle; (2) cardiac muscle; and (3) smooth muscle **10.** (1) epimysium: surrounds entire muscle; (2) perimysium: surrounds bundles of muscle fibers (fascicles); and (3) endomysium: surrounds individual skeletal muscle fibers (cells) **11.** b **12.** The transverse (T) tubules propagate action potentials into the interior of the cell. **13.** (1) exposure of active sites; (2) attachment of cross-bridges; (3) pivoting of myosin heads (power stroke); (4) detachment of cross-bridges; and (5) reactivation of myosin heads (recocking myosin head) **14.** Both the frequency of motor unit stimulation and the number of motor units involved affect the amount of tension produced when a skeletal muscle contracts. **15.** Resting skeletal muscle fibers contain ATP, creatine phosphate, and glycogen. **16.** Glycolysis and aerobic metabolism generate ATP from glucose in muscle cells. **17.** The calcium-binding protein in smooth muscle tissue is calmodulin.

Level 2 Reviewing Concepts

18. b **19.** a **20.** a **21.** e **22.** In an initial latent period (after the stimulus arrives and before tension begins to increase), an action potential generated in the muscle fiber triggers the release of calcium ions from the SR. In the contraction phase, calcium ions bind to troponin (cross-bridges form) and tension begins to increase. In the relaxation phase, tension decreases because cross-bridges have detached and because calcium ion levels have decreased; the active sites are once again covered by the troponin–tropomyosin complex. **23.** (1) O_2 for aerobic metabolism is consumed by liver cells, which must make a great deal of ATP to convert lactate to pyruvate, and pyruvate to glucose; (2) O_2 for aerobic metabolism is consumed by skeletal muscle fibers as they restore ATP, creatine phosphate, and glycogen concentrations to their former levels; and (3) the normal O_2 concentration in blood and peripheral tissues is replenished. **24.** Skeletal muscles fatigue much more rapidly than cardiac muscle. Cardiac muscle cells have a longer refractory period. Their contractions last about 10 times longer than those of skeletal muscle cells. **25.** If atracurium blocked the binding of ACh to ACh receptors at the motor end plates of neuromuscular junctions, the muscle's ability to contract would be inhibited. **26.** In rigor mortis, the membranes of the dead cells are no longer selectively permeable; the SR is no longer able to retain calcium ions. As calcium ions enter the cytosol, a sustained contraction develops, making the body extremely stiff. Contraction persists because the dead muscle cells can no longer make the ATP required for cross-bridge detachment from the active sites. Rigor mortis begins a few hours after death and ends after one to six days, or when decomposition begins. Decomposition begins when the lysosomal enzymes released by autolysis break down the myofilaments. **27.** b

Level 3 Critical Thinking and Clinical Applications

28. Because organophosphates block the action of acetylcholinesterase (AChE), ACh released into the synaptic cleft would not be removed. It would continue to stimulate the motor end plate, causing a state of persistent contraction (spastic paralysis). If the muscles of respiration were affected (which is likely), Ivan would die of suffocation. Prior to death, the most obvious sign would be uncontrolled tetanic contractions of skeletal muscles. **29.** CK is the enzyme creatine kinase. It functions in the anaerobic reaction that transfers phosphate from creatine phosphate to ADP in muscle cells. The presence of cardiac troponin, a form found only in cardiac muscle cells, provides direct evidence that cardiac muscle cells have been severely damaged. **30.** A good warm-up is important to stimulate blood circulation in the muscles and to increase muscle temperature. Glucose is the preferred energy source, so she should consume a lot of carbohydrates before the event and glucose-rich sports drinks during the event.

Answers to Clinical Case Wrap-Up

PAGE 381 **1.** A drug that inhibits acetylcholinesterase (AChE) is inhibiting the enzyme that breaks down the neurotransmitter acetylcholine (ACh). As a result, ACh is present longer in the

neuromuscular junction (NMJ). Because a patient with myasthenia gravis does not have enough functioning ACh receptors, a greater amount of ACh is better for strength of muscular response. In short, by inhibiting the breakdown of ACh, the drug strengthens the patient's muscular response. **2.** Myasthenia gravis affects voluntary, skeletal muscle at the neuromuscular junction (NMJ). Cardiac muscle tissue contracts without neural stimulation, a property known as automaticity. There is no neural stimulation, no NMJ, no ACh neurotransmitter or receptor required for cardiac muscle contraction. For these reasons, myasthenia gravis would not affect cardiac muscle.

Answers to Figure-Based Questions

FIGURE 10–3 The terminal cisternae are part of the sarcoplasmic reticulum.

FIGURE 10–6 A skeletal muscle is surrounded by epimysium. A muscle fascicle is surrounded by perimysium. A muscle fiber is surrounded by endomysium. A myofibril is surrounded by sarcoplasmic reticulum.

FIGURE 10–14 If the zone of overlap is decreased, the sarcomere length is increased.

FIGURE 10–21 Slow fibers contain more mitochondria than fast fibers.

Chapter 11

Answers to Checkpoints

PAGE 385 **1.** Based on the patterns of fascicle arrangement, the four types of skeletal muscles are parallel muscles, convergent muscles, pennate muscles, and circular muscles. **2.** Contraction of a pennate muscle generates more tension than would contraction of a parallel muscle of the same size because a pennate muscle contains more muscle fibers, and thus more myofibrils and sarcomeres, than does a parallel muscle of the same size. **3.** The anal opening between the large intestine and the exterior would be guarded by a circular muscle, or sphincter. The concentric circles of muscle fibers found in sphincters are ideally suited for opening and closing passageways and for acting as valves in the body. **4.** A lever is a rigid structure—such as a board, a pry bar, or a bone—that moves on a fixed joint called a fulcrum. There are three classes of levers: In a first-class lever, the fulcrum lies between the applied force and load; in a second-class lever, the load lies between the applied force and fulcrum; and in a third-class lever, the applied force or pull exerted is between the fulcrum and the load. Third-class levers are the most common type in the body. **5.** The joint between the occipital bone and the first cervical vertebra is part of a first-class lever system. The joint between the two bones (the fulcrum) lies between the skull (which provides the load) and the neck muscles (which provide the applied force). **PAGE 387** **6.** The origin of a muscle is the end that is less movable. Because the gracilis moves the tibia, the origin of this muscle must be on the pelvis (pubis and ischium). **7.** Muscles A and B are antagonists to each other, because they perform opposite actions. **8.** A synergist is a muscle that helps a larger prime mover (or agonist—a muscle that is responsible for a specific movement) perform its actions more efficiently. **PAGE 392** **9.** Names of skeletal muscles are based on several factors, including region of the body; position, direction, or fascicle arrangement; origin and insertion; shape and size; and action. **10.** The name *flexor carpi radialis longus* tells you that this muscle is a long muscle (longus) that lies next to the radius (radialis) and flexes (flexor) the wrist (carpi). **PAGE 393** **11.** Axial muscles arise on the axial skeleton. They position the head and vertebral column, move the rib cage, and form the pelvic floor. **12.** Appendicular muscles stabilize or move structures of the appendicular skeleton. These muscles move and support the pectoral (shoulder) girdles and the upper and lower limbs. **PAGE 408** **13.** Contracting the masseter elevates the mandible, and relaxing this muscle depresses the mandible. You would probably be chewing something. **14.** The buccinator, which positions the mouth for blowing, is well developed in a trumpet player. **15.** Swallowing involves contractions of the palatal muscles, which elevate the soft palate as well as portions of the superior pharyngeal wall. Elevation of the superior portion of the pharynx enlarges the opening to the auditory tube, permitting airflow to the middle ear and the inside of the eardrum. Making this opening larger by swallowing facilitates airflow into or out of the middle ear cavity. **16.** Damage to the intercostal muscles would interfere with breathing. **17.** A hit in the rectus abdominis would cause that muscle to contract forcefully, resulting in flexion of the vertebral column. In other words, you would "double over." **18.** The sore muscles in Joe's back are most likely the erector spinae, especially the longissimus and the iliocostalis of the lumbar region. These muscles would have to contract with more tension than normal to counterbalance the increased anterior weight when carrying heavy boxes. **PAGE 429** **19.** When you shrug your shoulders, you are contracting your levator scapulae. **20.** The muscles involved in a rotator cuff injury are the supraspinatus, infraspinatus, teres minor, and subscapularis (SITS). **21.** Injury to the flexor carpi ulnaris would impair your ability to flex and adduct the wrist. **22.** Injury to the obturator would impair your ability to laterally rotate the hip. **23.** A "pulled hamstring" refers to a strain affecting one or more of the three muscles that collectively flex the knee: the biceps femoris, semitendinosus, and semimembranosus. **24.** A torn calcaneal tendon would make plantar flexion difficult because this tendon attaches the soleus and gastrocnemius to the calcaneus (heel bone). **25.** The muscular system generates heat that maintains normal body temperature. **26.** Exercise affects the cardiovascular system by increasing heart rate and dilating blood vessels. With exercise, the rate and depth of breathing increases, and sweat gland secretion increases. The physiological effects that result from exercise are directed and coordinated by the nervous and endocrine systems.

Answers to Review Questions

PAGE 432

Level 1 Reviewing Facts and Terms

1. (a) deltoid (multipennate); **(b)** extensor digitorum (unipennate); **(c)** rectus femoris (bipennate) **2. (a)** supraspinatus; **(b)** infraspinatus; **(c)** teres minor **3.** c **4.** a **5.** d **6.** b **7.** a **8.** c **9.** a **10.** c **11.** b **12.** d **13.** a **14.** The possible actions are flexion, extension, adduction, abduction, medial rotation, and lateral rotation. **15.** An aponeurosis is a collagenous sheet connecting two muscles. The epicranial aponeurosis and the linea alba are examples. **16.** The axial musculature includes (1) muscles of the head and neck, (2) muscles of the vertebral column, (3) oblique and rectus muscles, and (4) muscles of the pelvic floor. **17.** The muscles of the pelvic floor (1) support the organs of the pelvic cavity, (2) flex joints of the sacrum and coccyx, and (3) control movement of materials through the urethra and anus. **18.** The supraspinatus, infraspinatus, and teres minor originate on the posterior body of the scapula, and the subscapularis originates on the anterior body of the scapula. All four muscles insert on the humerus. **19.** The functional muscle groups in the lower limbs are (1) muscles that move the thigh, (2) muscles that move the leg, and (3) muscles that move the foot and toes.

Level 2 Reviewing Concepts

20. c **21.** a **22.** retinaculum **23.** pitcher's arm **24.** The vertebral column does not have a massive series of anterior flexors because many of the large trunk muscles flex the vertebral column when they contract. In addition, most of the body weight lies anterior to the vertebral column, and gravity tends to flex the intervertebral joints. **25.** In a convergent muscle, the direction of pull can be changed by stimulating only one group of muscle cells at any one time. When all the fibers contract at once, they do not pull as hard on the tendon as would a parallel muscle of the same size, because the muscle fibers on opposite sides of the tendon are pulling in different directions rather than working together. **26.** A pennate muscle contains more muscle fibers, and thus more myofibrils and sarcomeres, than does a parallel muscle of the same size, resulting in a contraction that generates more tension. **27.** Lifting heavy objects becomes easier as the elbow approaches a 90° angle. As you increase the angle at or near full extension, tension production decreases, so movement becomes more difficult. **28.** Trapezius and rhomboid act as fixators when biceps brachii produces flexion at the elbow.

Level 3 Critical Thinking and Clinical Applications

29. Mary is not happy to see Jill. Contraction of the frontalis would wrinkle Mary's brow, contraction of the procerus would flare her nostrils, and contraction of the levator labii on the right side would raise the right side of her lip, as in sneering. **30.** c **31.** Although the pectoralis is located across the chest, it inserts on the greater tubercle of the humerus, the bone of the arm. When this muscle contracts, it contributes to flexion, adduction, and medial rotation of the humerus at the shoulder joint. All of these arm movements would be impaired if the muscle were damaged.

Answers to Clinical Case Wrap-Up

PAGE 433 **1.** Downward-Facing Dog engages muscles throughout the body: extensors of the neck and vertebral column (erector spinae group), hip flexors (iliopsoas group and tensor fasciae latae), extensors of the knee (quadriceps femoris group), ankle flexors (tibialis anterior), extensors of the shoulder (latissimus dorsi and teres major), extensors of the elbow (triceps brachii) and wrist (extensor carpi group), and abductors of the fingers (abductor pollicis brevis and interossei). **2.** The muscles of the "core" support good posture. These include the abdominal muscles (rectus abdominis, external and internal obliques, transversus abdominis); muscles of the pelvic floor; the erector spinae group, especially the longissimus thoracis; and the diaphragm, a muscle that is often overlooked when considering skeletal muscles.

Answers to Figure-Based Questions

FIGURE 11–5 The term *levator anguli oris* means "to raise the mouth." This is one of the muscles that contributes to a smile.

FIGURE 11–6 From the lateral or the medial surface you can see five of the six eye muscles. From the lateral surface, you cannot see the medial rectus and from the medial surface you cannot see the lateral rectus.

FIGURE 11–10 The digastric, geniohyoid, omohyoid, sternohyoid, stylohyoid, and thyrohyoid all insert on the hyoid bone. The mylohyoid inserts on the hyoid bone by a band of connective tissue.

FIGURE 11–17 The triceps brachii has three heads, and each head has a different origin. The lateral head's origin is on the superior lateral surface of the humerus. The long head's origin is on the scapula. The medial head's origin is on the posterior surface of the humerus.

FIGURE 11–19 The adductor pollicis and abductor pollicis brevis are an agonist-antagonist pair.

FIGURE 11–21 The vastus intermedius is not visible from the superficial anterior view of the thigh. This muscle and the vastus lateralis, vastus medialis, and rectus femoris make up the quadriceps femoris.

Chapter 12

Answers to Checkpoints

PAGE 438 **1.** The three anatomical divisions of the nervous system are the central nervous system (CNS), consisting of the brain and spinal cord, the peripheral nervous system (PNS), consisting of all nervous tissue outside the CNS and ENS, and the enteric nervous system (ENS), consisting of the network of neurons and nerve networks in the walls of the digestive tract. **2.** The two functional divisions of the peripheral nervous system are the afferent division, which brings sensory information to the CNS from receptors in peripheral tissues and organs, and the efferent division, which carries motor commands from the CNS to muscles, glands, and adipose tissue. **3.** The two components of the efferent division of the PNS and their effectors are the somatic nervous system (SNS) and the autonomic nervous system (ANS). The SNS effectors are skeletal muscles and the ANS effectors include smooth and cardiac muscle, glands, and adipose tissue. **4.** Damage to the afferent division of the PNS, which is composed of nerves that carry sensory information to the brain and spinal cord, would interfere with a person's ability to experience a variety of sensory stimuli. **PAGE 441** **5.** The structural components of a typical neuron include a cell body or soma (which contains the nucleus and perikaryon), dendrites (some with dendritic spines), an axon, telodendria, Nissl bodies, neurofilaments, intermediate neurotubules, neurofibrils, axoplasm, axolemma, initial segment, axon hillock, and collaterals. **6.** According to structure, neurons are classified as anaxonic, bipolar, unipolar, or multipolar. **7.** According to function, neurons are classified as sensory neurons, motor neurons, or interneurons. **8.** Because most sensory neurons of the PNS are unipolar, these neurons most likely function as sensory neurons. **PAGE 447** **9.** Central nervous system neuroglia include astrocytes, ependymal cells, oligodendrocytes, and microglia. **10.** Peripheral nervous system neuroglia include satellite cells and Schwann cells (neurolemmocytes). **11.** The small phagocytic cells called microglia occur in increased numbers in infected (and damaged) areas of the CNS **PAGE 455** **12.** The resting membrane potential is the membrane potential of a normal, unstimulated cell. **13.** If the voltage-gated sodium ion channels in the plasma membrane of a neuron could not open, sodium ions could not flood into the neuron and it would not be able to depolarize. **14.** If the extracellular concentration of potassium ions decreased, more potassium would leave the cell, and the membrane potential would become more negative. This condition is called hyperpolarization. **PAGE 462** **15.** An action potential is a propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions. **16.** The four steps involved in the generation of action potentials are (1) depolarization to threshold; (2) activation of voltage-gated sodium ion channels and rapid depolarization; (3) inactivation of voltage-gated sodium ion channels and activation

of voltage-gated potassium ion channels; and (4) closing of voltage-gated potassium ion channels and return to normal permeability. **17.** The presence of myelin greatly increases the propagation speed of action potentials. **18.** Action potentials travel along myelinated axons (by saltatory propagation) at much higher speeds than along unmyelinated axons. The axon with a propagation speed of 50 meters per second must be the myelinated axon. Typical propagation speeds for unmyelinated axons are about 1 m/sec. **PAGE 466** **19.** The general structural components of a synapse, the site where a neuron communicates with another cell, are a presynaptic cell and a postsynaptic cell, whose plasma membranes are separated by a narrow synaptic cleft. **20.** If a synapse involves direct physical contact between cells, it is termed *electrical*; if the synapse involves a neurotransmitter, it is termed *chemical*. **21.** If the voltage-gated calcium ion channels at a cholinergic synapse were blocked, Ca^{2+} could not enter the axon terminal and trigger the release of ACh into the synapse, so no communication would take place across the synapse. **22.** Because of synaptic delay, the pathway with fewer neurons (in this case, 3) will transmit impulses more rapidly. **PAGE 470** **23.** Both neurotransmitters and neuromodulators are substances that are released by one neuron and affect another neuron. A neurotransmitter alters the membrane potential of the other neuron, whereas a neuromodulator alters the other neuron's response to specific neurotransmitters. **24.** Neurotransmitters and neuromodulators are either (1) compounds that have a direct effect on membrane potential, (2) compounds that have an indirect effect on membrane potential through G proteins, or (3) lipid-soluble gases that have an indirect effect on membrane potential through intracellular enzymes. **PAGE 474** **25.** No action potential will be generated. **26.** Yes, an action potential will be generated. **27.** Temporal summation would occur if the two EPSPs happened at the same time.

Answers to Review Questions

PAGE 476

Level 1 Reviewing Facts and Terms

1. (a) dendrite; **(b)** nucleolus; **(c)** nucleus; **(d)** axon hillock; **(e)** initial segment; **(f)** axolemma; **(g)** axon; **(h)** telodendria; **(i)** axon terminals **2.** c **3.** c **4.** c **5.** c **6.** a **7.** b **8.** b **9. (a)** the CNS: brain and spinal cord **(b)** the PNS: all the nervous tissue outside the CNS and ENS divided between the efferent division (which consists of the somatic nervous system and the autonomic nervous system) and the afferent division (which consists of receptors and sensory neurons) **(c)** the ENS: network of neurons and nerve networks in the walls of the digestive tract. **10.** Diphtheria and multiple sclerosis are demyelinating diseases. **11.** (1) sensory neurons: transmit impulses from the PNS to the CNS; (2) motor neurons: transmit impulses from the CNS to peripheral effectors; and (3) interneurons: analyze sensory inputs and coordinate motor outputs.

Level 2 Reviewing Concepts

12. b **13.** A multipolar neuron has a distinct axon, whereas an anaxonic neuron has dendrites but no obvious axons. **14.** Anterograde flow is the movement of materials from the cell body to the axon terminals. Retrograde flow is the movement of materials toward the cell body. **15.** Chemically gated (ligand-gated) ion channels open or close when they bind specific extracellular chemicals (ligands). Voltage-gated ion channels open or close in response to changes in the membrane potential. Mechanically gated ion channels open or close in response to physical distortion of the membrane surface. **16.** During the absolute refractory period, the plasma membrane cannot respond to further stimulation; whereas during the relative refractory period, the plasma membrane can respond only to a larger-than-normal stimulus. **17.** The membrane depolarizes to threshold. Next, voltage-gated sodium ion channels are activated, and the membrane rapidly depolarizes. These sodium channels are then inactivated, and voltage-gated potassium ion channels are activated. Finally, normal permeability returns. The voltage-gated sodium channels become activated once the repolarization is complete; the voltage-gated potassium channels begin closing as the membrane potential reaches the normal resting membrane potential. **18.** In saltatory propagation, which occurs in myelinated axons, only the nodes along the axon can respond to a depolarizing stimulus. In continuous propagation, which occurs in unmyelinated axons, an action potential appears to move across the membrane surface in a series of tiny steps. **19.** Type A fibers are myelinated and carry action potentials very quickly (120 m/sec). Type B fibers are also myelinated, but carry action potentials more slowly due to their smaller diameter. Type C fibers are extremely slow due to their small diameter and lack of myelination. **20.** (1) The action potential arrives at the axon terminal, depolarizing it; (2) extracellular calcium enters the axon terminal, triggering the exocytosis of ACh; (3) ACh binds to the postsynaptic membrane and depolarizes the next neuron in the chain; (4) ACh is removed by AChE. **21.** In presynaptic inhibition, GABA is released and that decreases postsynaptic effect. In presynaptic facilitation, serotonin is released and that increases postsynaptic effect.

Level 3 Critical Thinking and Clinical Applications

22. Harry's kidney condition is causing the retention of potassium ions. As a result, the K^+ concentration of the extracellular fluid is higher than normal. Under these conditions, less potassium diffuses from heart muscle cells than normal, resulting in a resting membrane potential that is less negative (more positive). This change in the resting membrane potential moves the membrane potential closer to threshold, so it is easier to stimulate the muscle. The ease of stimulation accounts for the increased number of contractions evident in the rapid heart rate. **23.** To reach threshold, the postsynaptic membrane must receive enough neurotransmitter to produce an EPSP of +20 mV (+10 mV to reach threshold and +10 mV to cancel the IPSPs produced by the 5 inhibitory neurons). Each neuron releases enough neurotransmitter to produce a change of +2 mV, so at least 10 of the 15 excitatory neurons must be stimulated to produce this effect by spatial summation. **24.** When the rabies virus enters a body part, the virus particles quickly enter axon terminals and peripheral axons. They are then transported in retrograde flow from the axon terminals toward cell bodies in the CNS. The virus particles travel the length of the axons on neurotubules in the axoplasm, carried by dynein, a protein molecular motor. The further from the brain the virus enters the body, the longer it takes for symptoms to develop. **25.** The absolute refractory period limits the number of action potentials that can travel along an axon in a given unit of time. During the absolute refractory period, the membrane

cannot conduct an action potential, so a new depolarization event cannot occur until after the absolute refractory period has passed. If the absolute refractory period for a particular axon is 0.001 sec, then the maximum frequency of action potentials propagated by this axon would be 1000/sec.

Answers to Clinical Case Wrap-Up

PAGE 477 **1.** The polio virus attacks the motor neurons located in the spinal cord. **2.** Guillain-Barré syndrome is an autoimmune disorder that attacks the myelin covering of peripheral nerves in adults. This causes both sensory and motor signs and symptoms because peripheral nerves are mixed nerves.

Chapter 13

Answers to Checkpoints

PAGE 481 **1.** The central nervous system (CNS) is made up of the brain and spinal cord, while cranial nerves and spinal nerves make up the peripheral nervous system (PNS). **2.** A spinal reflex is a rapid, automatic response triggered by specific stimuli that is controlled in the spinal cord. **PAGE 486** **3.** The three spinal meninges are the dura mater, arachnoid mater, and pia mater. **4.** Damage to the anterior root of a spinal nerve, which contains both visceral and somatic motor fibers, would interfere with motor function. **5.** The cerebrospinal fluid that surrounds the spinal cord is located in the subarachnoid space, which lies between the epithelium of the arachnoid mater and the pia mater. **PAGE 488** **6.** Sensory nuclei receive and relay sensory information from peripheral receptors. Motor nuclei issue motor commands to peripheral effectors. **7.** The polio virus–infected neurons would be in the anterior horns of the spinal cord, where the cell bodies of somatic motor neurons are located. **8.** A disease that damages myelin sheaths would affect the columns in the white matter of the spinal cord, because the columns are composed of bundles of myelinated axons. **PAGE 498** **9.** The major nerve plexuses are the cervical, brachial, lumbar, and sacral. **10.** An anesthetic that blocks the function of the posterior rami of the cervical spinal nerves would affect the skin and muscles of the back of the neck and of the shoulders. **11.** Damage to the cervical plexus—or more specifically to the left and right phrenic nerves, which originate in this plexus and innervate the diaphragm—would greatly interfere with the ability to breathe and might even be fatal. **12.** Compression of the sciatic nerve produces the sensation that your leg has "fallen asleep." **PAGE 499** **13.** A neuronal pool is a functional group of organized interneurons within the CNS. **14.** The five neuronal pool circuit patterns are divergence, convergence, serial processing, parallel processing, and reverberation. **PAGE 503** **15.** A reflex is a rapid, automatic response to a specific stimulus. It is an important mechanism for maintaining homeostasis. **16.** The minimum number of neurons required for a reflex arc is two. One must be a sensory neuron that brings impulses to the CNS, and the other a motor neuron that transmits a response to the effector. **17.** The suck reflex is an innate reflex. **PAGE 506** **18.** All polysynaptic reflexes involve pools of interneurons; are intersegmental in distribution; and involve reciprocal inhibition, reverberating circuits, and the cooperation of several reflexes. **19.** When intrafusal fibers are stimulated by gamma motor neurons, the muscle spindles become more sensitive. As a result, little if any stretching stimulus would be needed to stimulate the contraction of the quadriceps muscles in the patellar reflex. For this reason, the reflex response would appear more quickly. **20.** This response is the tendon reflex. **21.** During a withdrawal reflex, the limb on the opposite side is extended. This response is called a crossed extensor reflex. **PAGE 507** **22.** Reinforcement is an enhancement of spinal reflexes. It occurs when the postsynaptic neuron enters a state of generalized facilitation caused by chronically active excitatory synapses. **23.** A Babinski reflex is abnormal in adults. It indicates possible damage to descending tracts in the spinal cord.

Answers to Review Questions

PAGE 509

Level 1 Reviewing Facts and Terms

1. (a) white matter; **(b)** anterior root; **(c)** posterior root; **(d)** pia mater; **(e)** arachnoid mater; **(f)** gray matter; **(g)** spinal nerve; **(h)** posterior root ganglion; **(i)** dura mater **2.** b **3.** b **4.** d **5.** c **6.** c **7.** d **8.** b **9.** b **10.** d **11.** a **12.** b **13.** c **14.** a **15. (a)** 1 **(b)** 7 **(c)** 3 **(d)** 5 **(e)** 4 **(f)** 6 **(g)** 2 **(h)** 8

Level 2 Reviewing Concepts

16. The vertebral column continues to grow, extending beyond the spinal cord. The end of the spinal cord is visible as the conus medullaris near L_1, and the cauda equina extends the remainder of the vertebral column. **17.** (1) arrival of stimulus and activation of receptor; (2) activation of sensory neuron; (3) information processing; (4) activation of a motor neuron; and (5) response by an effector (muscle, gland, or adipose tissue) **18.** d **19.** In spinal anesthesia, a single dose of local anesthetic is injected into the subarachnoid space of the spinal cord. The movement of the cerebrospinal fluid distributes the anesthetic along the spinal cord. The effects include temporary muscle paralysis and sensory loss. **20.** The cell bodies of spinal sensory neurons are located in the spinal ganglia of the posterior roots. Damage to these roots would result in the loss of sensory information. **21.** Cerebrospinal fluid fills the subarachnoid space between the arachnoid mater and the pia mater. CSF acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemicals, and wastes. **22.** (1) involvement of pools of interneurons; (2) intersegmental distribution; (3) involvement of reciprocal inhibition; (4) motor response prolonged by reverberating circuits; and (5) cooperation of reflexes to produce a coordinated, controlled response **23.** Transection of the spinal cord at segment C_7 would most likely result in paralysis from the neck down. Transection at segment T_{10} would produce paralysis and eliminate sensory input in the lower half of the body only. **24.** b **25.** b **26.** d **27.** If a reflex fails to appear when it is tested using the reinforcement procedure, the likelihood of nerve or CNS damage is increased.

Level 3 Critical Thinking and Clinical Applications

28. The median nerve is involved. **29.** The radial nerve is involved. **30.** The individual would still exhibit a defecation (bowel) and urination (urinary bladder) reflex because these spinal reflexes are processed at the level of the spinal cord. Efferent impulses from the organs would stimulate specific interneurons in the sacral region that synapse with the motor neurons controlling the sphincters, thus

bringing about emptying when the organs began to fill. (This is the same situation that exists in a newborn infant who has not yet fully developed the descending tracts required for conscious control.) However, an individual with the spinal cord transection at L_1 would lose voluntary control of the bowel and bladder because these functions rely on impulses carried by motor neurons in the brain that must travel down the cord and synapse with the interneurons and motor neurons involved in the reflex. **31.** Jane's condition is called shingles. The virus that causes chickenpox also causes shingles. This herpesvirus often remains dormant in neurons of the anterior horns of the spinal cord. Sometimes the virus reactivates and attacks neurons within the posterior roots of spinal nerves and also sensory ganglia of cranial nerves.

Answers to Clinical Case Wrap-Up

PAGE 510 **1.** No. Recovery of motor activity or sensation is not expected inferior to the level of Joe's complete injury at T_{11}. Central nervous tissue (brain and spinal cord) has very limited healing ability. **2.** Joe would exhibit Babinski reflexes with toes going up (dorsiflexed), which is abnormal in adults (but not in infants). The descending motor pathways to the feet have been completely disrupted at T_{11}.

Answers to Figure-Based Questions

FIGURE 13–3 The area between the arachnoid mater and the pia mater is the subarachnoid space.

FIGURE 13–5 Somatic motor nuclei are located in the anterior horn.

FIGURE 13–9 The axillary, radial, and ulnar nerves branch from the brachial plexus.

FIGURE 13–15 Reflexes can be classified by development (innate or acquired), response (somatic or visceral), complexity (monosynaptic or polysynaptic), and processing site (spinal or cranial).

Chapter 14

Answers to Checkpoints

PAGE 515 **1.** The four major regions of the brain are the cerebrum, cerebellum, diencephalon, and brainstem. **2.** The brainstem is made up of the midbrain, pons, and medulla oblongata. **3.** The rhombencephalon or hindbrain develops into the cerebellum, pons, and medulla oblongata. **PAGE 520** **4.** The layers of the cranial meninges are the outer dura mater, the middle arachnoid mater, and the inner pia mater. **5.** If the normal circulation or resorption of cerebrospinal fluid (CSF) became blocked, CSF would continue to be produced at the choroid plexus in each ventricle, but the fluid would remain there, causing the ventricles to swell—a condition known as hydrocephalus. **6.** If diffusion across the arachnoid granulations decreased, less CSF would reenter the bloodstream, and CSF would accumulate in the ventricles. The increased pressure within the ventricles due to accumulated CSF could damage the brain. **7.** Many water-soluble molecules are rare or absent in the extracellular (ECF), or cerebrospinal fluid (CSF), of the brain because the blood brain barrier regulates the movement of such molecules from the blood to the ECF of the brain. **PAGE 523** **8.** The gracile nucleus and cuneate nucleus are responsible for relaying somatic sensory information to the thalamus. **9.** Damage to the medulla oblongata can be lethal because it contains many vital autonomic reflex centers, including those that control breathing and regulate heart rate and force of contraction, which affect blood pressure. **10.** The pons contains (1) sensory and motor nuclei of cranial nerves (V, VI, VII, and VIII), (2) nuclei involved with the control of respiration, (3) nuclei and tracts that process and relay information sent to or from the cerebellum, and (4) ascending, descending, and transverse pontine fibers. **11.** Damage to the respiratory centers of the pons could result in loss of ability to modify the respiratory rhythmicity centers of the medulla oblongata, which set the basic pace for respiratory movements. **PAGE 524** **12.** Two pairs of sensory nuclei make up the corpora quadrigemina: the superior colliculi and inferior colliculi. **13.** The superior colliculi of the midbrain control reflexive movements of the eyes, head, and neck to visual stimuli, such as a bright light. **PAGE 527** **14.** Components of the cerebellar gray matter include the cerebellar cortex and cerebellar nuclei. **15.** The arbor vitae, which is the internal, white matter part of the cerebellum, connects the cerebellar cortex and nuclei with the cerebellar peduncles. **PAGE 530** **16.** The main components of the diencephalon are the epithalamus, thalamus, and hypothalamus. **17.** Damage to the lateral geniculate body would interfere with the sense of sight. **18.** Changes in body temperature stimulate the pre-optic area of the hypothalamus, a component of the diencephalon. **PAGE 532** **19.** The limbic system is responsible for processing memories and creating emotional states, drives, and associated behaviors. **20.** Damage to the amygdaloid body would interfere with the sympathetic ("fight or flight") division of the autonomic nervous system (ANS). **PAGE 552** **21.** Projection fibers link the cerebral cortex to the spinal cord, passing through the diencephalon, brainstem, and cerebellum. **22.** Damage to the basal nuclei would result in decreased muscle tone and the loss of coordination of learned movement patterns. **23.** The primary motor cortex is located in the precentral gyrus of the frontal lobe of the cerebrum. **24.** Damage to the temporal lobes of the cerebrum would interfere with the processing of olfactory (smell) and auditory (sound) sensations. **25.** The stroke has damaged Broca's area (motor speech area), located in the left cerebral hemisphere. **26.** The temporal lobe of the cerebrum is probably involved, specifically the hippocampus and the amygdaloid body. His problems may also involve other parts of the limbic system that act as a gate for loading and retrieving long-term memories. **27.** Cranial reflexes are automatic responses to stimuli that involve the sensory and motor fibers of cranial nerves. Both monosynaptic and polysynaptic reflex arcs occur. Cranial reflex testing is often used to assess damage to cranial nerves or to the associated processing centers in the brain. **28.** Shining a light in a person's eye tests the pupillary reflex and the consensual light reflex, which are visceral reflexes.

Answers to Review Questions

PAGE 555

Level 1 Reviewing Facts and Terms

1. (a) cerebrum; **(b)** diencephalon; **(c)** midbrain; **(d)** pons; **(e)** medulla oblongata; **(f)** cerebellum **2. (a)** periosteal cranial dura; **(b)** dural sinus; **(c)** meningeal cranial dura; **(d)** subdural space; **(e)** arachnoid mater; **(f)** subarachnoid space; **(g)** pia mater **3.** d **4.** a **5.** b **6.** d **7.** c **8.** c **9.** a **10.** b **11.** a **12.** a **13.** b **14.** somatosensory association cortex, visual association area, auditory association area, and somatic motor association area **15.** (1) portions of the hypothalamus where the capillary endothelium is extremely permeable; (2) capillaries in the pineal gland; and (3) capillaries at the choroid plexus **16.** CN I: olfactory nerve; CN II: optic nerve; CN III: oculomotor nerve; CN IV: trochlear nerve; CN V: trigeminal nerve; CN VI: abducens nerve; CN VII: facial nerve;

CN VIII: vestibulocochlear nerve; CN IX: glossopharyngeal nerve; CN X: vagus nerve; CN XI: accessory nerve; and CN XII: hypoglossal nerve

Level 2 Reviewing Concepts

17. The brain can respond with greater versatility because it includes many more interneurons, pathways, and connections than the tracts of the spinal cord. **18.** The cerebellum adjusts voluntary and involuntary motor activities based on sensory information and stored memories of previous experiences. **19.** c **20.** When the prefrontal cortex is damaged, estimating temporal relationships between events, and interpreting ongoing events and predicting their consequences become difficult. Prefrontal lobotomy was used to treat mental illnesses associated with violent or antisocial behavior. **21.** Roles of the hypothalamus include (1) secretion of two hormones, (2) regulation of body temperature, (3) control of autonomic function, (4) coordination between voluntary and autonomic functions, (5) coordination of activities of the nervous and endocrine systems, (6) regulation of circadian rhythms, (7) subconscious control of skeletal muscle contractions, and (8) production of emotions and behavioral drives. **22.** The lateral geniculate body relays visual information to the visual cortex, whereas the medial geniculate body relays auditory information to the auditory cortex. **23.** This nucleus is the hippocampus, which is part of the limbic system. **24.** The left cerebral hemisphere contains the specialized language areas and speech centers and is responsible for analytical tasks, logical decision making, and language-based skills (reading, writing, and speaking). The right hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit the identification of familiar objects by touch, smell, sight, and taste. The right cerebral hemisphere is also important in understanding three-dimensional relationships and in analyzing the emotional context of a conversation. **25.** e **26.** a **27.** Lesions in Wernicke's area cause defective visual and auditory comprehension of language, repetition of spoken sentences, and defective naming of objects. Lesions in Broca's area result in hesitant and distorted speech.

Level 3 Critical Thinking and Clinical Applications

28. Sensory innervation of the nasal mucosa occurs by the maxillary nerve (V_2), a division of the trigeminal nerve (V). Irritation of the nasal lining by ammonia increases the frequency of action potentials along the maxillary nerve through the semilunar ganglion to reach centers in the midbrain, which in turn excite the neurons of the reticular activating system (RAS). Increased activity by the RAS can bring the cerebrum back to consciousness. **29.** The officer is testing the function of Bill's cerebellum. Many drugs, including alcohol, have pronounced effects on cerebellar function. A person who is under the influence of alcohol cannot properly anticipate the range and speed of limb movement, because processing and correction by the cerebellum are slow. Because of disturbance in muscular coordination (ataxia), Bill might have a difficult time walking a straight line or touching his finger to his nose. **30.** Increasing pressure in the cranium could compress important blood vessels, leading to further brain damage in areas not directly affected by the hematoma. Pressure on the brainstem could disrupt vital respiratory, cardiovascular, and vasomotor functions and possibly cause death. Pressure on the motor nuclei of the cranial nerves would lead to drooping eyelids and dilated pupils. Pressure on descending motor tracts would impair muscle function and decrease muscle tone in the affected areas of the body. **31.** The optic nerves converge at the optic chiasm. This chiasm lies in close contact with the pituitary gland. A growing tumor of the pituitary gland will exert pressure on and eventually damage these optic nerves. **32.** Most of the functional problems observed in shaken baby syndrome are the result of trauma to the cerebral hemispheres due to contact between the brain and the inside of the skull. Damage to and distortion of the brainstem and medulla oblongata can cause death.

Answers to Clinical Case Wrap-Up

PAGE 556 **1.** The speech center, also called *Broca's area*, or the *motor speech area*, is usually located in the left hemisphere. Dr. Taylor was unable to speak or understand speech after her stroke. The primary motor cortex that directs voluntary movements of the right side of the body is located in the left hemisphere, in the precentral gyrus of the cerebral cortex. Dr. Taylor was unable to use her right arm after her stroke. For these reasons, you would be able to determine that the left side of her brain was affected by the stroke. **2.** Neuroplasticity is the ability of the nerve cells in the brain to make new connections to other nerve cells. Following trauma to the brain, as in Dr. Taylor's stroke, brain cells that are still alive but dormant can make new connections with other nerve cells. We can think of these changes as healing after a stroke or other trauma to the brain.

Answers to Figure-Based Questions

FIGURE 14–1 The brainstem is made up of the midbrain, the pons, and the medulla oblongata.

FIGURE 14–3 The maters surrounding the brain (from deepest to most superficial) are the pia mater, the arachnoid mater, and the dura mater (meningeal cranial dura and periosteal cranial dura).

FIGURE 14–9 The cerebellar cortex and cerebellar nuclei make up the gray matter in the cerebellum.

FIGURE 14–13 The central sulcus divides the anterior frontal lobe from the more posterior parietal lobe.

FIGURE 14–15 The globus pallidus of the lentiform nucleus is more medial and the putamen of the lentiform nucleus is more lateral.

FIGURE 14–20 The lateral geniculate body of the thalamus receives visual information before it reaches the visual cortex.

FIGURE 14–22 The divisions of the trigeminal nerve are the ophthalmic nerve (V_1), the maxillary nerve (V_2), and the mandibular nerve (V_3).

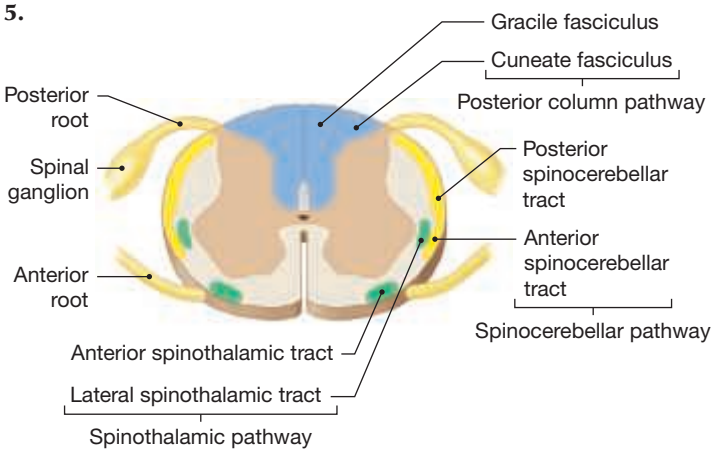
Chapter 15

Answers to Checkpoints

PAGE 560 **1.** The specialized cells that monitor specific conditions in the body or the external environment are sensory receptors. **2.** Yes, it is possible for somatic motor commands to occur at the subconscious (involuntary) level. They also occur at the conscious (voluntary) level. **PAGE 563** **3.** Receptor A provides more precise sensory information because it has a smaller receptive field on the skin surface. **4.** Adaptation is a decrease in receptor sensitivity or a decrease in perception during constant stimulation. **PAGE 568** **5.** The major types of general sensory receptors (and the stimuli that excite them) are nociceptors (pain), thermoreceptors (temperature), mechanoreceptors (physical distortion), and chemoreceptors (chemical concentration). **6.** The three classes of mechanoreceptors

are tactile receptors, baroreceptors, and proprioceptors. **7.** If proprioceptors in your legs could not relay information about limb position and movement to the CNS (especially the cerebellum), your movements would be uncoordinated and you likely could not walk. **PAGE 573** **8.** The tract being compressed is the gracile fasciculus in the posterior column of the spinal cord, which carries information about touch and pressure from the lower limbs to the brain. **9.** The tracts that carry action potentials generated by nociceptors (pain receptors) are the lateral spinothalamic tracts. **10.** The left cerebral hemisphere (specifically, the primary somatosensory cortex) receives impulses carried by the right gracile fasciculus. **PAGE 578** **11.** The anatomical basis for opposite-side motor control is crossing over (decussation) of axons, so the motor fibers of the corticospinal pathway innervate lower motor neurons on the opposite side of the body. **12.** An injury involving the superior portion of the motor cortex would affect the ability to control the muscles in the upper limb and the proximal portion of the lower limb. **13.** Increased stimulation of the motor neurons of the red nucleus would increase stimulation of the skeletal muscles in the upper limbs, thereby increasing their muscle tone.

ANSWERS



Answers to Review Questions

PAGE 579

Level 1 Reviewing Facts and Terms

1. c **2.** Tonic **3.** c **4.** d

5.

6. (1) free nerve endings: sensitive to touch and pressure; (2) root hair plexus: monitors distortions and movements across the body surface; (3) tactile discs: detect fine touch and pressure; (4) bulbous (Ruffini) corpuscles: sensitive to pressure and distortion of the skin; (5) lamellar (pacinian) corpuscles: sensitive to pulsing or vibrating stimuli (deep pressure); and (6) tactile (Meissner) corpuscles: detect fine touch and pressure **7.** The three major groups of proprioceptors are (1) muscle spindles, (2) Golgi tendon organs, and (3) receptors in joint capsules. **8.** (1) spinothalamic pathway: provides conscious sensations of poorly localized ("crude") touch, pressure, pain, and temperature; (2) posterior column pathway: provides conscious sensations of highly localized ("fine") touch, pressure, vibration, and proprioception; and (3) spinocerebellar pathway: carries proprioceptive information about the position of skeletal muscles, tendons, and joints to the cerebellum **9.** The corticobulbar tracts provide conscious motor control over skeletal muscles. **10.** lower motor neurons of anterior horns of spinal cord **11.** The cerebellum (1) integrates proprioceptive sensations with visual information from the eyes and equilibrium-related sensations from the internal ear, and (2) adjusts the activities of the voluntary and involuntary motor centers on the basis of sensory information and the stored memories of previous experiences. **12.** b **13.** (1) An arriving stimulus alters the membrane potential of the receptor cell. (2) The receptor potential directly or indirectly affects a sensory neuron. (3) Action potentials travel to the CNS along an afferent fiber.

Level 2 Reviewing Concepts

14. In transduction, a sensory receptor converts an arriving stimulus into an action potential. In adaptation, receptor sensitivity is reduced in the presence of a constant stimulus. **15.** A motor homunculus, a mapped-out area of the primary motor cortex, provides an indication of the degree of fine motor control available. A sensory homunculus indicates the relative density of peripheral sensory receptors. **16.** A sensory neuron that delivers sensations to the CNS is a first-order neuron. Within the CNS, the axon of the first-order neuron synapses on a second-order neuron, which is an interneuron located in the spinal cord or brainstem. The second-order neuron synapses on a third-order neuron in the thalamus. The axons of third-order neurons synapse on neurons of the primary somatosensory cortex of the cerebral hemispheres. **17.** Damage to the left side of the primary motor cortex in the region that controls the muscles of arm and hand would interfere with the movement of the right upper limb. **18.** Amyotrophic lateral sclerosis is caused by a defect in axonal transport. Destruction of the motor neurons controlling a muscle results in atrophy of the muscle concerned. **19.** Muscle tone is controlled by the basal nuclei, cerebellum, and red nuclei through commands distributed by the reticulospinal and rubrospinal tracts. **20.** Strong pain sensations arriving at a particular segment of the spinal cord can cause stimulation of the interneurons of the spinothalamic pathway. This stimulation is interpreted by the somatosensory cortex as originating in the region of the body surface associated with the origin of that same labeled line or pathway.

Level 3 Critical Thinking and Clinical Applications

21. The cerebellum adjusts the number of motor commands necessary for a movement in a pattern that changes from moment to moment, making the movement precisely controlled. **22.** Injuries to the primary motor cortex eliminate the ability to produce fine control of motor units. However, as long as the cerebral nuclei are functional, gross movements would still be possible. Harry should still be able to walk, maintain his balance, and perform voluntary and involuntary movements using the rubrospinal and reticulospinal tracts in place of the corticospinal tracts. Although these movements may be awkward or difficult, they will still be possible. **23.** Denzel is experiencing phantom pain. Since pain perception occurs in the somatosensory cortex of the brain, he can still feel pain in his fingers if the brain projects feeling to that area. When he bumps the arm at the elbow, sensory receptors are stimulated to send impulses to the somatosensory cortex. The brain perceives a sensation from a general area, and projects that feeling to a body part. Since more sensory information reaches the brain from the hands and fingers, it is not unusual for the brain to project to this area.

Answers to Clinical Case Wrap-Up

PAGE 580 **1.** All the principal descending motor pathways carry information that would have been affected by the brain damage causing Michael's cerebral palsy. They include the corticospinal pathway, the medial pathway, and the lateral pathway. **2.** Poor motor control of the muscles used in swallowing can contribute to an increased risk of choking and poor infant nutrition, which can affect development and even be life threatening.

Answers to Figure-Based Questions

FIGURE 15–1 The involuntary motor pathway directs a faster response than the voluntary motor pathway.

FIGURE 15–2 The area monitored by a single receptor cell is its receptive field. The branching free nerve endings extend across the area and are receptive to stimuli.

FIGURE 15–4 Root hair plexuses, bulbous (Ruffini) corpuscles, and lamellar (pacinian) corpuscles are located in the dermis.

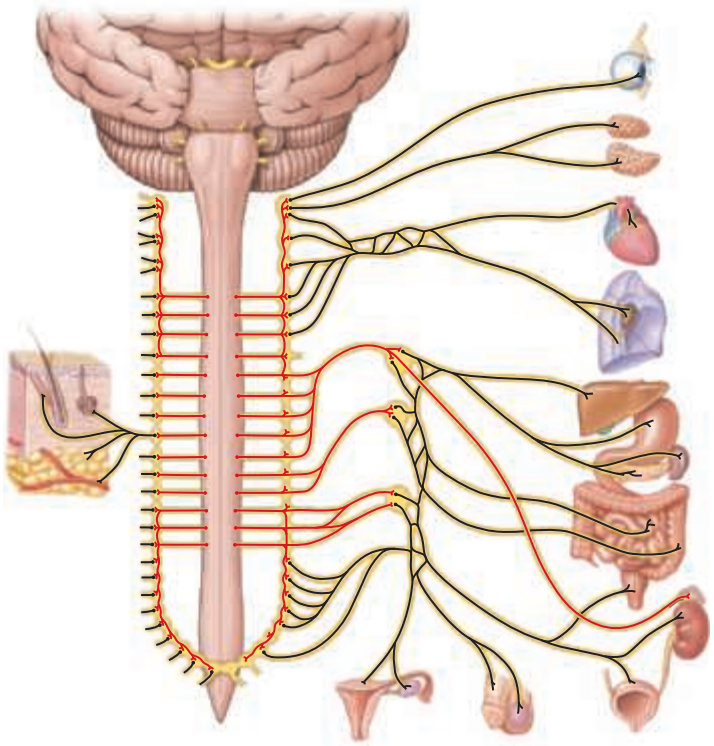
FIGURE 15–7 The lateral spinothalamic tracts sense pain and temperature.

FIGURE 15–10 The lateral pathway has one tract (the rubrospinal tract), the corticospinal pathway has two tracts (the lateral and anterior corticospinal tracts), and the medial pathway has three tracts (the reticulospinal, the tectospinal, and the vestibulospinal tracts).

Chapter 16

Answers to Checkpoints

PAGE 584 **1.** The two major divisions of the ANS are the sympathetic division and the parasympathetic division. **2.** Two neurons are needed to carry an action potential from the spinal cord to smooth muscles in the intestine. The first neuron carries the action potential from the spinal cord to the autonomic ganglion, and a second neuron carries the action potential from the autonomic ganglion to the smooth muscles in the intestinal wall. **3.** The sympathetic division of the ANS is responsible for the physiological changes that occur in response to stress (confronting an angry dog) and increased activity (running). **PAGE 589** **4.** Sympathetic chain ganglia lie on each side of the vertebral column; they are also called paravertebral ganglia. Collateral ganglia are anterior to the vertebral column; they are also called prevertebral ganglia. **5.** The nerves that synapse in collateral ganglia originate in the inferior thoracic and superior lumbar regions (between T_1 and L_2) of the spinal cord. The preganglionic fibers they contain pass through the sympathetic chain ganglia to the collateral ganglia. **PAGE 591** **6.** Because preganglionic fibers of the sympathetic nervous system release acetylcholine (ACh), a drug that stimulates cholinergic receptors would stimulate the postganglionic fibers of sympathetic nerves, resulting in increased sympathetic activity. **7.** Blocking the beta receptors on cells would decrease or prevent sympathetic stimulation of tissues containing those cells. Heart rate, force of contraction of cardiac muscle, and contraction of smooth muscle in the walls of blood vessels would decrease, lowering blood pressure. **PAGE 592** **8.** The vagus nerve (X) carries preganglionic parasympathetic fibers that innervate the lungs, heart, stomach, liver, pancreas, and parts of the small and large intestines (as well as several other visceral organs). **9.** The parasympathetic division is sometimes referred to as the anabolic system because parasympathetic stimulation leads to a general increase in the nutrient content of the blood. Cells throughout the body respond to the increase by absorbing the nutrients and using them to support growth and other anabolic activities. **PAGE 593** **10.** The neurotransmitter acetylcholine (ACh) is released by all parasympathetic neurons. **11.** The two types of cholinergic receptors on the postsynaptic membranes of parasympathetic neurons are nicotinic receptors and muscarinic receptors. **12.** Stimulation of muscarinic receptors, a type of cholinergic receptor located in postganglionic synapses of the parasympathetic nervous system, would cause K^+ channels to open, resulting in hyperpolarization of cardiac plasma membranes and a decreased heart rate. **PAGE 594** **13.** In the sympathetic division, axons emerge from the thoracic and lumbar segments of the spinal cord and innervate ganglia relatively close to the spinal cord, whereas in the parasympathetic division, axons emerge from the brainstem and sacral segments of the spinal cord and innervate ganglia very close to (or within) target organs. **14.** Divergence refers to the number of synapses a single preganglionic fiber may have with ganglionic neurons. The sympathetic division has a much higher degree of divergence than the parasympathetic division. A greater amount of divergence results in more complex and coordinated responses. **PAGE 597** **15.** General responses to increased sympathetic activity include heightened mental alertness, increased metabolic rate, reduced digestive and urinary functions, activation of energy reserves, increased respiratory rate and dilation of respiratory passageways, elevated heart rate and blood pressure, and activation of sweat glands. General responses to increased parasympathetic activity include decreased metabolic rate, decreased heart rate and blood pressure, increased secretion by salivary and digestive glands, increased motility and blood flow in the digestive tract, and stimulation of urination and defecation. **16.** Most blood vessels receive sympathetic stimulation, so a loss of sympathetic tone would relax the smooth muscles lining the vessels; the resulting vasodilation would increase blood flow to the tissue. **17.** In anxious individuals, an increase in sympathetic stimulation would probably cause some or all of the following changes: a dry mouth; increased heart rate, blood pressure, and rate of breathing; cold sweats; an urge to urinate or defecate; a change in the motility of the digestive tract (that is, "butterflies in the stomach"); and dilated pupils. **PAGE 599** **18.** A visceral reflex is an autonomic reflex initiated in the viscera. It is an automatic motor response that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus. **19.** A brain tumor that interferes with hypothalamic function would also interfere with autonomic function, because centers in the hypothalamus are involved with autonomic (visceral) function. **PAGE 604** **20.** Higher-order functions require action by the cerebral cortex, involve both conscious and unconscious information processing, and are subject to modification and adjustment over time. **21.** Test-taking involves short-term memory, although your instructor would like you to transfer this information to long-term memory. **22.** If your RAS were suddenly stimulated while you were asleep, it would rouse the cerebrum to a state of consciousness and you would wake up. **23.** A drug that increases the amount of serotonin released in the brain would produce a heightened perception of certain sensory stimuli (e.g., auditory or visual stimuli) and hallucinations. **24.** Amphetamines stimulate the secretion of dopamine. **PAGE 605** **25.** Some possible reasons for slower recall and for loss of memory in older people include a loss of neurons (possibly those involved in specific memories), changes in synaptic organization of the brain, changes in the neurons themselves, and decreased blood flow, which would affect the metabolic rate of neurons and perhaps slow the retrieval of information from



memory. **26.** Common age-related anatomical changes in the nervous system include a reduction in brain size and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in the synaptic organization of the brain, and intracellular and extracellular changes in CNS neurons. **27.** Alzheimer's disease is the most common form of senile dementia. **28.** The nervous system controls the actions of the arrector pili muscles and sweat glands of the integumentary system. It also controls skeletal muscle contractions of the muscular system, which, in turn, affects the thickening of bones of the skeletal system. It also coordinates muscular activities associated with the respiratory and cardiovascular systems.

Answers to Review Questions

Level 1 Reviewing Facts and Terms

1.

2. d **3.** b **4.** b **5.** d **6.** preganglionic neuron T_5–L_2 → collateral ganglia → postganglionic fibers → visceral effector in abdominopelvic cavity **7.** (1) ciliary ganglion; (2) pterygopalatine ganglion; (3) submandibular ganglion; and (4) otic ganglion **8.** Long visceral reflexes coordinate the activities of an entire organ and involve interneurons within the CNS. Short visceral reflexes bypass the CNS and control patterns of activity in one small part of a target organ. **9.** Increased neurotransmitter release, facilitation of synapses, and the formation of additional synaptic connections are thought to be involved in memory formation and storage. **10.** During non-REM sleep, the entire body relaxes, and activity at the cerebral cortex is at a minimum; heart rate, blood pressure, respiratory rate, and energy utilization decrease. During REM sleep, active dreaming occurs, accompanied by alterations in blood pressure and respiratory rates; muscle tone decreases markedly, and response to outside stimuli decreases. **11.** Aging causes a reduction in brain volume and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in synaptic organization, and intracellular and extracellular changes in CNS neurons. **12.** c **13.** a **14.** The sympathetic division stimulates glycogen breakdown and synthesis and release of glucose in the liver, and decreases exocrine secretion in the pancreas. The parasympathetic division stimulates synthesis of glycogen in the liver, and increases exocrine secretion in the pancreas. **15.** (1) celiac ganglion; (2) superior mesenteric ganglion; and (3) inferior mesenteric ganglion **16.** Stimulation of sympathetic ganglionic neurons causes (1) release of norepinephrine at specific locations and (2) secretion of epinephrine (and modest amounts of norepinephrine) into the bloodstream. **17.** The four pairs of cranial nerves are CN III, CN VII, CN IX, and CN X. **18.** (1) cardiac plexus: heart rate increases (sympathetic)/decreases (parasympathetic); force of heart contraction increases (sympathetic)/decreases (parasympathetic); blood pressure increases (sympathetic)/decreases (parasympathetic); (2) pulmonary plexus: respiratory passageways dilate (sympathetic)/constrict (parasympathetic); (3) esophageal plexus: respiratory rate increases (sympathetic)/decreases (parasympathetic); (4) celiac plexus: digestion inhibited (sympathetic)/stimulated (parasympathetic); (5) inferior mesenteric plexus: digestion inhibited (sympathetic)/stimulated (parasympathetic); and (6) hypogastric plexus: defecation inhibited (sympathetic)/stimulated (parasympathetic); urination inhibited (sympathetic)/stimulated (parasympathetic); sexual organs: stimulation of secretion (sympathetic)/erection (parasympathetic) **19.** Sleep and coma represent different degrees of the state of unconsciousness. A person who is asleep is unconscious, but can still be awakened by normal sensory stimuli. A person in a coma is unconscious and cannot be awakened, even by strong stimuli.

Level 2 Reviewing Concepts

20. a **21.** c **22.** The preganglionic fibers innervating the cervical ganglia originate in the anterior roots of the thoracic segments, which are undamaged. **23.** a **24.** a **25.** c **26.** Due to the stimulation of the sympathetic division, you would experience increased respiratory rate, increased peripheral vasoconstriction and elevation of blood pressure, increased heart rate and force of contraction, and an increased rate of glucose release into the bloodstream. **27.** If autonomic motor neurons maintain a background level of activity at all times, they can either increase or decrease their activity, providing a greater range of control options. **28.** Cholinergic receptors are found in all the ganglia of the ANS, so nicotine would stimulate both sympathetic and parasympathetic responses in cardiovascular tissues. Although increased sympathetic stimulation increases heart rate and force of contraction, increased parasympathetic stimulation simultaneously decreases blood flow to the heart muscle. In addition to elevating heart rate and force of contraction, sympathetic stimulation also constricts peripheral blood vessels, all of which contribute to increased blood pressure. **29.** The upsetting situation would be processed by the higher centers of the CNS and relayed to the hypothalamus. The hypothalamus could suppress the vasomotor center of the medulla oblongata, resulting in fewer sympathetic impulses to peripheral blood vessels. This would cause a decrease in sympathetic tone in the smooth muscle of the blood vessels, resulting in vasodilation. The vasodilation would cause blood to pool in the limbs, decreasing the amount of blood returning to the heart and producing shock.

Level 3 Critical Thinking and Clinical Applications

30. Epinephrine would be more effective, because it would reduce inflammation and relax the smooth muscle of the airways, making it easier for Phil to breathe. **31.** The molecule is probably mimicking NE and binding to alpha-1 receptors.

Answers to Clinical Case Wrap-Up

PAGE 610 **1.** The first part of Helen's brain to be affected is the hippocampus in the limbic system where memory is encoded. Later progressive losses in cognition involve wide areas of her cerebral cortex. **2.** First, Helen loses orientation to time, then to place, and finally to person. The memory of person is the last to go because it is a deep-seated, long-term, associative memory. **3.** A cholinesterase inhibitor will inactivate acetylcholinesterase, the enzyme whose role is to break down the neurotransmitter acetylcholine at the cholinergic synapse. This will help maintain ACh levels in the early phases of Alzheimer's disease.

Answers to Figure-Based Questions

FIGURE 16–11 Visual input arrives via CN II and auditory input arrives via CN VIII.

Chapter 17

Answers to Checkpoints

PAGE 616 **1.** Olfaction is the sense of smell; it involves olfactory sensory neurons in paired olfactory organs responding to airborne chemical stimuli. **2.** Axons from the olfactory epithelium collect into bundles that reach the olfactory bulb. In the olfactory pathway, axons leaving the olfactory bulb then travel along the olfactory tract to the olfactory cortex, hypothalamus, and portions of the limbic system. **3.** By the end of the lab period, central adaptation has occurred. Inhibition of synapses along the olfactory pathway reduces the amount of information reaching the olfactory cortex, even though the olfactory neurons remain active. **PAGE 618** **4.** Gustation is the sense of taste, provided by gustatory epithelial cells (taste receptors) responding to dissolved chemical stimuli. **5.** Gustatory epithelial cells (taste receptors in taste buds) are sensitive only to molecules and ions that are in solution. If you dry the surface of your tongue, the salt ions or sugar molecules have no moisture in which to dissolve, so they will not stimulate the cells. **6.** Your grandfather is experiencing the effects of several age-related gustatory and olfactory changes. The number of taste buds decreases dramatically after age 50, and those that remain are not as sensitive as they once were. In addition, the loss of olfactory sensory neurons contributes to the perception of fewer flavors in foods. **PAGE 626** **7.** The conjunctiva would be the first layer of the eye affected by inadequate tear production. Drying of the conjunctiva would produce an irritated, scratchy feeling. **8.** Sue will likely be unable to see at all. The fovea centralis (fovea) contains only cones, which need high-intensity light to be stimulated. The dimly lit room contains light that is too weak to stimulate the cones. **9.** If the scleral venous sinus (canal of Schlemm) were blocked, the aqueous humor could not drain, producing an eye condition called glaucoma. Accumulation of this fluid increases the pressure within the eye, distorting soft tissues and interfering with vision. If untreated, the condition would ultimately cause blindness. **PAGE 629** **10.** The focal point is the point at which the light rays from an object intersect on the retina. **11.** When the lens becomes more rounded, you are looking at an object that is close to you. **PAGE 637** **12.** If you were born without cones, you would still be able to see—so long as you had functioning rods—but you would lack color vision and see in black and white only. **13.** A vitamin A deficiency would reduce the quantity of retinal the body could produce, thereby interfering with night vision (which operates at the body's threshold ability to respond to light). **14.** Vision would be impaired. Decreased phosphodiesterase activity would increase intracellular cGMP levels, which, by keeping gated sodium ion channels open, would prevent both hyperpolarization of the photoreceptor and a decrease in its neurotransmitter release. There would be no signal to the bipolar cell that a photon had been absorbed. **PAGE 651** **15.** If the round window could not move, the perilymph would not be moved by the vibration of the stapes at the oval window, reducing or eliminating the perception of sound. **16.** The loss of stereocilia (as a result of constant exposure to loud noises, for instance) would reduce hearing sensitivity and could lead to deafness. **17.** If the auditory tube were blocked, it would not be possible to equalize the pressure on both sides of the tympanic membrane. If external pressure then decreases, the pressure in the middle ear would be greater than that on the outside, forcing the tympanic membrane outward and producing pain.

Answers to Review Questions

PAGE 654

Level 1 Reviewing Facts and Terms

1. **(a)** vascular layer; **(b)** iris; **(c)** ciliary body; **(d)** choroid; **(e)** inner layer (retina); **(f)** neural layer; **(g)** pigmented layer; **(h)** fibrous layer; **(i)** cornea; **(j)** sclera **2.** d **3.** c **4.** e **5.** c **6.** b **7.** b **8.** d **9.** c **10.** **(a)** auricle; **(b)** external acoustic meatus; **(c)** tympanic membrane; **(d)** auditory ossicles; **(e)** semicircular canals; **(f)** vestibule; **(g)** auditory tube; **(h)** cochlea; **(i)** vestibulocochlear nerve (VIII) **11.** d **12.** d **13.** c **14.** The vallate papillae appear near the posterior margin of the tongue as an inverted "V". **15.** The fibrous layer **(a)** is composed of the sclera and the cornea and **(b)** provides mechanical support and some physical protection, serves as an attachment site for the extrinsic eye muscles, and contains structures that assist in the focusing process. **16.** The vascular layer consists of the iris, ciliary body, and choroid. **17.** The two muscles found in the middle ear are tensor tympani and stapedius. They protect the tympanic membrane and ossicles from violent movements when we are exposed to very loud noises.

Level 2 Reviewing Concepts

18. Axons leaving the olfactory epithelium collect into 20 or more bundles that penetrate the cribriform plate of the ethmoid to reach the olfactory bulbs of the cerebrum. Axons leaving the olfactory bulb travel along the olfactory tract to reach the olfactory cortex, hypothalamus, and portions of the limbic system. **19.** The olfactory receptor surface of a dog is many times greater than that of a human and some other vertebrates, which makes the dog good at detecting drugs and explosives. **20.** When the ciliary muscle contracts, the shape of the lens becomes rounder, enabling it to produce sharp images of nearby objects. **21.** a **22.** c **23.** c

Level 3 Critical Thinking and Clinical Applications

24. Your medial rectus muscles would contract, directing your gaze more medially. In addition, your pupils would constrict and the lenses would become more spherical. **25.** Myopia is corrected by **(a)** concave lenses. **26.** In removing the polyps, some of the

olfactory epithelium was probably damaged or destroyed, decreasing the area available for the solution of odorants and reducing the intensity of the stimulus. As a result, after the surgery it would take a larger stimulus to provide the same level of smell. **27.** The auditory tube forms a direct connection between the nasopharynx and the middle ear. Microorganisms causing infection in the throat can reach the middle ear through this connecting tube, and cause infection in the middle ear. **28.** When Juan closes his eyes, visual cues are gone, and his brain must rely solely on proprioceptive information from the equilibrium centers of the internal ear to maintain normal posture. Because either the internal ear receptors or the sensory nerves are not functioning normally, he is unstable. The most likely reason for his drift to the left is that he is getting inappropriate sensations from equilibrium receptors, either at the maculae (affecting his ability to determine which way is "down") or one of the horizontal semicircular ducts (making him attempt to compensate for a perceived roll to the right).

Answers to Clinical Case Wrap-Up

PAGE 655 **1.** A visual acuity of 20/200 means Makena must be 20 feet away from an object to see it as clearly as someone with normal vision would see it at 200 feet. In the United States she would be considered legally blind. **2.** If Makena's vision is corrected to a state of emmetropia, her vision would be corrected to normal.

Answers to Figure-Based Questions

FIGURE 17–4 The lacrimal gland is located superior and lateral to the eye.

FIGURE 17–7 Amacrine cells are found where bipolar cells synapse with ganglion cells. Horizontal cells are found where photoreceptors (rods and cones) synapse with bipolar cells.

FIGURE 17–21 The tympanic cavity and auditory ossicles are found in the middle ear.

FIGURE 17–28 The scala vestibuli and scala tympani contain perilymph (a fluid similar in composition to cerebrospinal fluid). The cochlear duct contains endolymph (a fluid with electrolyte concentrations that differ from other bodily fluids).

Chapter 18

Answers to Checkpoints

PAGE 659 **1.** A hormone is a chemical messenger that is secreted by one cell and travels through the bloodstream to affect the activities of cells in other parts of the body. **2.** Paracrine communication is the use of chemical messengers (paracrines) to transfer information from cell to cell within a single tissue. **3.** The five mechanisms of intercellular communication are direct, paracrine, autocrine, endocrine, and synaptic. **PAGE 664** **4.** A cell's hormonal sensitivities are determined by the presence or absence of extracellular and intracellular receptors that bind a given hormone. **5.** A substance that inhibits adenylate cyclase, the enzyme that converts ATP to cAMP, would block the action of any hormone that requires cAMP as a second messenger. **6.** Humoral stimuli are those involving changes in the composition of the extracellular fluid. Such a stimulus triggers the secretion of a hormone, and the direct or indirect effects of the hormone reduce the intensity of the stimulus.
PAGE 673 **7.** The two lobes of the pituitary gland are the anterior lobe and the posterior lobe. **8.** In dehydration, blood osmotic concentration is increased, which would stimulate the posterior lobe of the pituitary gland to release more ADH. **9.** Somatomedins mediate the action of growth hormone. Elevated levels of growth hormone typically accompany elevated levels of somatomedins. **10.** An elevated circulating level of cortisol would inhibit the endocrine cells that control the release of ACTH from the pituitary gland, so the ACTH level would decrease. This is an example of a negative feedback mechanism.
PAGE 678 **11.** Thyroxine (T_4), triiodothyronine (T_3), and calcitonin (CT) are hormones associated with the thyroid gland. **12.** A person whose diet lacks iodine would be unable to form the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). As a result, you would expect to see signs and symptoms associated with their deficiency: decreased metabolic rate, decreased body temperature, a poor response to physiological stress, and an increase in the size of the thyroid gland (goiter). **13.** Most of the body's reserves of the thyroid hormones T_4 and T_3 are bound to blood-borne proteins called thyroid-binding globulins. Because these compounds represent such a large reservoir of T_4 and T_3, it takes several days after removal of the thyroid gland for the blood level of T_4 and T_3 to decrease. **PAGE 680** **14.** The parathyroid glands are embedded in the posterior surfaces of the lateral lobes of the thyroid gland.
15. The hormone secreted by the parathyroid glands is parathyroid hormone (PTH). **16.** The removal of the parathyroid glands would result in a decrease in the blood concentration of calcium ions. **PAGE 683** **17.** The two regions of the adrenal gland are the cortex and medulla. The cortex secretes mineralocorticoids (mainly aldosterone), glucocorticoids (mainly cortisol, corticosterone, and cortisone), and androgens; the medulla secretes epinephrine and norepinephrine. **18.** The three zones of the adrenal cortex from superficial to deep are the zona glomerulosa, zona fasciculata, and zona reticularis. **19.** One function of cortisol is to decrease the cellular use of glucose while increasing both the available glucose (by promoting the breakdown of glycogen) and the conversion of amino acids to carbohydrates. Therefore, the net result of elevated cortisol level would be an elevation of blood glucose. **20.** Pinealocytes are the hormone-secreting cells of the pineal gland. **21.** Increased amounts of light would inhibit the production (and release) of melatonin from the pineal gland, which receives neural input from the optic tracts. Melatonin secretion is influenced by day–night patterns. **22.** Melatonin influences circadian rhythms, inhibits reproductive functions, and protects against free radical damage.
PAGE 687 **23.** The cells of the pancreatic islets (and their hormones) are alpha cells (glucagon), beta cells (insulin), delta cells (GH–IH), and pancreatic polypeptide cells (pancreatic polypeptide). **24.** A person with Type 1 or Type 2 diabetes has such a high blood glucose level that the kidneys cannot reabsorb all the glucose; some glucose is lost in urine. Because the urine contains a high concentration of glucose, less water can be reclaimed by osmosis, so the volume of urine production increases. The water losses reduce blood volume and elevate blood osmotic pressure, promoting thirst and triggering the secretion of ADH. **25.** An increased blood level of glucagon stimulates the conversion of glycogen to glucose in the liver, which would in turn decrease the amount of glycogen in the liver. **PAGE 692** **26.** Two hormones secreted by the kidneys are erythropoietin (EPO) and calcitriol. **27.** Leptin is a hormone released by adipose tissue.
28. Once released into the bloodstream, renin functions as an enzyme, catalyzing the conversion of angiotensinogen to angiotensin I.

PAGE 695 **29.** The type of hormonal interaction in which two hormones have opposite effects on their target tissues is called antagonism. **30.** A lack of GH, thyroid hormone, PTH, and the gonadal hormones would inhibit the formation and development of the skeletal system. **31.** During the resistance phase of the general adaptation syndrome, there is a high demand for glucose, especially by the nervous system. The hormones GH–RH and CRH increase the levels of GH and ACTH, respectively. Growth hormone (GH) mobilizes fat reserves and promotes the catabolism of protein; ACTH increases cortisol, which stimulates both the conversion of glycogen to glucose and the catabolism of fat and protein. Together, these metabolic processes conserve glucose for use by nervous tissue. **32.** The endocrine system adjusts metabolic rates and substrate use, and regulates growth and development, in all other body systems. **33.** Hormones of the endocrine system adjust muscle metabolism, energy production, and growth; hormones also regulate calcium and phosphate levels, which are critical to normal muscle functioning. Skeletal muscles protect some endocrine organs.

Answers to Review Questions

PAGE 699

Level 1 Reviewing Facts and Terms

1. b **2.** c **3.** d **4.** c **5.** a **6.** d **7.** d **8. (a)** hypothalamus; **(b)** pituitary gland; **(c)** thyroid gland; **(d)** thymus; **(e)** adrenal glands; **(f)** pineal gland; **(g)** parathyroid glands; **(h)** heart; **(i)** kidneys; **(j)** adipose tissue; **(k)** digestive tract; **(l)** pancreas (pancreatic islets); **(m)** gonads **9.** (1) The hypothalamus releases ADH and oxytocin into the bloodstream at the posterior lobe of the pituitary gland. (2) The hypothalamus produces regulatory hormones that control secretion by endocrine cells in the anterior lobe of the pituitary gland. (3) The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medullae. These hypothalamic activities are adjusted through negative feedback loops involving hormones released by peripheral endocrine tissues and organs. **10.** The anterior lobe of the pituitary gland releases (1) thyroid-stimulating hormone (TSH); (2) adrenocorticotropic hormone (ACTH); (3) follicle-stimulating hormone (FSH); (4) luteinizing hormone (LH); (5) prolactin (PRL); (6) growth hormone (GH); and (7) melanocyte-stimulating hormone (MSH). **11.** The melanocyte-stimulating hormone is secreted by the pars intermedia of the pituitary gland. This hormone helps increase the production of melanin. **12.** Effects of thyroid hormones are (1) increased rate of energy consumption and utilization in cells; (2) accelerated production of sodium–potassium ATPase; (3) activation of genes coding for the synthesis of enzymes involved in glycolysis and energy production; (4) accelerated ATP production by mitochondria; and (5) in growing children, normal development of the skeletal, muscular, and nervous systems. **13.** The parathyroid glands contain (1) principal parathyroid cells and (2) parathyroid oxyphil cells. **14.** The thymus produces thymosins. These hormones promote the development and maturation of lymphocytes. **15.** The kidneys release (1) erythropoietin, which stimulates the production of RBCs by the red bone marrow, and (2) calcitriol, which stimulates calcium and phosphate absorption along the digestive tract. **16.** Natriuretic peptides (1) promote the loss of sodium ions and water at the kidneys; (2) inhibit the secretion of water-conserving hormones, such as ADH and aldosterone; (3) suppress thirst; and (4) inhibits the effects of angiotensin II and norepinephrine and decreases blood pressure. Angiotensin II opposes these actions by stimulating aldosterone secretion by the adrenal cortex and ADH by the posterior lobe of the pituitary gland, and further by retaining salt and water by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. **17.** (1) alpha (α) cells: glucagon; (2) beta (β) cells: insulin; (3) delta (δ) cells: growth hormone–inhibiting hormone (GH–IH, or somatostatin); and (4) pancreatic polypeptide cells: pancreatic polypeptide

Level 2 Reviewing Concepts

18. The primary difference involves speed and duration. In the nervous system, the source and destination of communication are quite specific, and the effects are extremely quick and short-lived. In endocrine communication, the effects are slow to appear and commonly persist for days. A single hormone can alter the metabolic activities of multiple tissues and organs simultaneously. **19.** Hormones can (1) direct the synthesis of an enzyme (or other protein) not already present in the cytoplasm, (2) turn an existing enzyme "on" or "off," and (3) increase the rate of synthesis of a particular enzyme or other protein. **20.** Since steroid hormones are bound to specific transport proteins in the plasma, they stay in circulation longer than peptide hormones. **21.** In men, oxytocin stimulates smooth muscle contractions in the walls of the sperm duct and prostate gland. In women, oxytocin promotes labor and delivery, and induces milk ejection post delivery. **22.** b **23.** d **24.** b

Level 3 Critical Thinking and Clinical Applications

25. Extreme thirst and frequent urination are characteristic of both diabetes insipidus and diabetes mellitus. To distinguish between the two, glucose levels in the blood and urine could be measured. A high glucose concentration would indicate diabetes mellitus. **26.** Sammy suffers from Type 1 diabetes, which is characterized by inadequate insulin production by the pancreatic beta cells, and requires insulin replacement. His grandmother has Type 2 diabetes, which means that insulin production is normal, but tissues are insulin resistant. Hence, there is a difference in treatment. **27.** Sherry's signs and symptoms suggest hyperthyroidism. Blood tests could be performed to assay the levels of TSH, T_3, and T_4. From these tests, the physician could make a positive diagnosis (hormone levels would be elevated in hyperthyroidism) and also determine whether the condition is primary (a problem with the thyroid gland) or secondary (a problem with hypothalamo-pituitary control of the thyroid gland). **28.** One benefit of a portal system is that it ensures that the regulatory hormones will be delivered directly to the target cells. Secondly, because the regulatory hormones go directly to their target cells without first passing through the general circulation, they are not diluted. The hypothalamus can control the cells of the anterior lobe of the pituitary gland with much smaller amounts of releasing and inhibiting hormones than would be necessary if the hormones had to first go through the circulatory pathway before reaching the pituitary. **29.** The natural effects of testosterone are to increase muscle mass, increase endurance, and enhance the "competitive spirit." Side effects in women include hirsutism (abnormal hair growth on the face or body), enlargement of the laryngeal cartilages, premature closure of the epiphyseal cartilages, liver dysfunction, and irregular menstrual periods.

Answers to Clinical Case Wrap-Up

PAGE 700 **1.** In addition to mobilizing Ca^{2+} from bone, PTH enhances the reabsorption of Ca^{2+} by the kidneys, decreasing urinary losses and keeping blood concentrations high. PTH also stimulates the

secretion of calcitriol by the kidneys, which enhances absorption of Ca^{2+} in the digestive tract, which also increases blood concentrations of Ca^{2+}. **2.** Calcitonin, produced by the thyroid, decreases blood Ca^{2+} levels indirectly. Calcitonin does this by causing an increased excretion of Ca^{2+} by the kidneys.

Answers to Figure-Based Questions

FIGURE 18–6 The endocrine cells whose secretion is controlled by regulatory hormones from the hypothalamus are located in the anterior lobe of the pituitary gland.

FIGURE 18–8 In a typical regulation pattern of endocrine secretion, hormone 2 (which is released from the target organ) is responsible for negative feedback.

FIGURE 18–9 Antidiuretic hormone (ADH) and oxytocin (OXT) are released from the posterior lobe of the pituitary gland. Posterior pituitary hormones are released directly from the hypothalamus, and regulatory hormones from the hypothalamus control the release of anterior pituitary hormones.

FIGURE 18–14 The zona glomerulosa produces mineralocorticoids. The primary mineralocorticoid is aldosterone.

FIGURE 18–17 Alpha cells secrete glucagon. Glucagon increases blood glucose level by (1) increasing the breakdown of glycogen to glucose in liver and skeletal muscle, (2) increasing the breakdown of fat to fatty acids in adipose tissue, and (3) increasing the synthesis and release of glucose by the liver.

ANSWERS

Chapter 19

Answers to Checkpoints

PAGE 705 **1.** Five major functions of blood are transporting dissolved gases, nutrients, hormones, and metabolic wastes; regulating the pH and ion composition of interstitial fluids; restricting fluid losses at injury sites; defending against toxins and pathogens; and stabilizing body temperature. **2.** The three types of formed elements in blood are red blood cells, white blood cells, and platelets. **3.** The three major types of plasma proteins are albumins, globulins, and fibrinogen. **4.** A decrease in the amount of plasma proteins in the blood would lower plasma osmotic pressure, reduce the ability to fight infection, and decrease the transport and binding of some ions, hormones, and other molecules. **PAGE 712** **5.** Hemoglobin is a protein composed of four globular subunits, each bound to a heme molecule, which gives red blood cells the ability to transport oxygen in the blood. **6.** After a significant loss of blood, the hematocrit—the amount of formed elements (mostly red blood cells) as a percentage of the total blood—would be reduced. **7.** The hematocrit would increase, because reduced blood flow to the kidneys triggers the release of erythropoietin, which stimulates an increase in erythropoiesis (red blood cell formation). **8.** Bilirubin would accumulate in the blood, producing jaundice, because diseases that damage the liver, such as hepatitis or cirrhosis, impair the liver's ability to excrete bilirubin in the bile. **PAGE 716** **9.** Surface antigens on RBCs are glycoproteins in the plasma membrane; they determine blood type. **10.** Only type O blood can be safely transfused into a person whose blood type is O. **11.** If a person with type A blood receives a transfusion of type B blood, which contains anti-A antibodies, the red blood cells will agglutinate (clump), potentially blocking blood flow to various organs and tissues. **PAGE 724** **12.** The five types of white blood cells are neutrophils, eosinophils, basophils, monocytes, and lymphocytes. **13.** An infected cut would contain a large number of neutrophils, because these phagocytic white blood cells are the first to arrive at the site of an injury. **14.** The blood of a person fighting a viral infection would contain elevated numbers of lymphocytes, because B cells (B lymphocytes) produce circulating antibodies. **15.** Basophils respond to an injury by releasing a variety of chemicals, including histamine and heparin. Histamine dilates blood vessels and heparin prevents blood clotting. Basophils also release other chemicals that attract eosinophils and other basophils to the injured area. **16.** Thrombocytopoiesis is the term for platelet production. **17.** Platelets release chemicals important to the clotting process, they form a temporary patch in the walls of damaged blood vessels, and they reduce the size of a break in a vessel wall. **PAGE 729** **18.** A decreased number of megakaryocytes would interfere with the blood's ability to clot properly, because fewer megakaryocytes would produce fewer platelets. **19.** Vitamin K is necessary for blood clotting, and fats are required for vitamin K absorption. So, if a person did not eat foods containing fat, this would lead to a vitamin K deficiency, which would, in turn, result in a decreased production of several clotting factors—most notably, prothrombin. As a result, clotting time would increase. **20.** The activation of Factor XII initiates the intrinsic pathway.

Answers to Review Questions

PAGE 731

Level 1 Reviewing Facts and Terms

1. (a) neutrophil; **(b)** eosinophil; **(c)** basophil; **(d)** monocyte; **(e)** lymphocyte **2.** c **3.** d **4.** a **5.** c **6.** a **7.** b **8.** d **9.** b **10.** Blood (1) transports dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulates pH and electrolyte composition of interstitial fluids throughout the body; (3) restricts fluid losses through damaged vessels or at other injury sites; (4) defends against toxins and pathogens; and (5) stabilizes body temperature. **11.** Major types of plasma proteins are (1) albumins, which maintain the osmotic pressure of plasma and are important in the transport of fatty acids; (2) globulins, which (a) bind small ions, hormones, or compounds that might otherwise be filtered out of the blood at the kidneys or have very low solubility in water (transport globulins), or (b) attack foreign proteins and pathogens (immunoglobulins); and (3) fibrinogen, which functions in blood clotting. **12. (a)** anti-B antibodies; **(b)** anti-A antibodies; **(c)** neither anti-A nor anti-B antibodies; **(d)** both anti-A and anti-B antibodies **13.** WBCs exhibit (1) emigration (diapedesis), squeezing between adjacent endothelial cells in the capillary wall; (2) amoeboid movement, a gliding movement that transports the cell; (3) positive chemotaxis, the attraction to specific chemical stimuli, and (4) phagocytosis (engulfing particles for neutrophils, eosinophils, and monocytes). **14.** The rate of platelet formation is influenced by (1) thrombopoietin or thrombocyte-stimulating factor, (2) interleukin-6, and (3) multi-CSF. **15.** The primary lymphocytes are (1) T cells, which are responsible for cell-mediated immunity; (2) B cells, which are responsible for humoral immunity; and (3) NK cells, which are responsible for immune surveillance. **16.** Prothrombin is an inactive precursor that is converted to thrombin during coagulation. Thrombin is an enzyme that causes the clotting of blood by converting fibrinogen to fibrin. **17.** Erythropoietin is released (1) during anemia, (2) when blood flow to the kidneys declines, (3) when the oxygen content of air in the lungs declines, and (4) when the respiratory surfaces of the lungs are damaged. **18.** Initiation of the common pathway requires the activation of Factor X by the extrinsic and/or intrinsic pathways.

Level 2 Reviewing Concepts

19. a **20.** d **21.** e **22.** c **23.** The hormone multi-CSF stimulates myeloid stem cells to become progenitor cells. Under the influence of the hormone erythropoietin, progenitor cells develop into proerythroblasts and eventually into RBCs. Under the influence of the hormone GM-CSF, progenitor cells develop into blast cells. The hormone G-CSF induces blast cells to become myeloblasts and eventually granulocytes, whereas the hormone M-CSF induces blast cells to become monoblasts and eventually monocytes. **24.** White blood cells defend against toxins and pathogens. Neutrophils, eosinophils, and monocytes engulf and digest bacteria, protozoa, fungi, viruses, and cellular debris. Lymphocytes are specialized to attack and destroy specific foreign cells, proteins, and cancerous cells, directly or through the production of antibodies. **25.** Blood stabilizes and maintains body temperature by absorbing and redistributing the heat produced by active skeletal muscles. **26.** Too much iron can cause problems due to excessive buildup in secondary storage sites, such as the liver and the heart. Too little iron can result in iron-deficiency anemia. **27.** Aspirin helps prevent vascular problems by inhibiting clotting. It inhibits platelet enzymes involved in the production of thromboxane A_2 and prostaglandins, thereby inhibiting clotting. It also prolongs bleeding time.

Level 3 Critical Thinking and Clinical Applications

28. A prolonged prothrombin time and a normal partial thromboplastin time indicate a deficiency in the extrinsic system but not in the intrinsic system or common pathway. Factor VII would be deficient. **29.** As the spleen enlarges, so does its capacity to store additional red blood cells, leading to fewer red blood cells in circulation, producing anemia. The decreased number of RBCs in circulation decreases the body's ability to deliver oxygen to the tissues, slowing their metabolism and producing the tired feeling and lack of energy. Because there are fewer RBCs than normal, the blood circulating through the skin is not as red, producing a pale complexion. **30.** Taking a broad-spectrum antibiotic kills a wide range of bacteria, both pathogenic and nonpathogenic, including many of the normal flora, or microbiota, of the intestine. Reducing the intestinal flora substantially decreases the amount of vitamin K they make available to the liver to produce prothrombin, a vital component of the common pathway. With decreased amounts of prothrombin in the blood, normal minor breaks in the vessels of the nasal passageways do not seal off as quickly, producing nosebleeds. **31.** Removal of most of Randy's stomach eliminated the production of intrinsic factor, which is essential for the absorption of vitamin B_{12} by intestinal cells. Thus Randy was prescribed vitamin B_{12} to prevent pernicious anemia, and he needed injections of vitamin B_{12} because if taken orally, his intestines could no longer absorb it.

Answers to Clinical Case Wrap-Up

PAGE 732 **1.** In Clare's sickle cell crisis, the sickled RBCs block blood vessels in her legs, producing severe pain. Additionally, sickled RBCs are piling up and blocking the circulation to her feet. The surrounding tissues are being starved of blood with its oxygen supply and its warmth (blood is 1 °C warmer than body temperature). So, her feet are freezing and the skin of her legs shows redness and swelling from local inflammation. **2.** Hydration is critical in sickle cell disease because water helps to maintain the proper volume of blood. When Clare's red blood cells become concentrated, the impact of the sickling process is increased.

Answers to Figure-Based Questions

FIGURE 19–5 Red blood cells are produced in the red bone marrow.

FIGURE 19–6 Type A blood has RBCs with surface antigen A only and contains anti-B antibodies.

FIGURE 19–10 Granulocytes consist of basophils, eosinophils, and neutrophils. Granulocytes differentiate from myeloblasts.

Chapter 20

Answers to Checkpoints

PAGE 748 **1.** Damage to the semilunar valve of the right ventricle, or pulmonary valve, would affect blood flow to the pulmonary trunk. **2.** Contraction of the papillary muscles (just before the rest of the ventricular myocardium contracts) pulls on the chordae tendineae, which prevent the AV valves from opening back into the atria. **3.** The left ventricle is more muscular than the right ventricle because the left ventricle must generate enough force to propel blood throughout the body, except the lungs, whereas the right ventricle must generate only enough force to propel blood a few centimeters to the lungs. **PAGE 757** **4.** Autorhythmicity is the ability of cardiac muscle tissue to contract without neural or hormonal stimulation. **5.** The sinoatrial (SA) node is known as the cardiac pacemaker or the natural pacemaker. **6.** If the cells of the SA node did not function, the AV node would act as the pacemaker and set the heart rhythm. The heart would still continue to beat, but at a slower rate. **7.** If the impulses from the atria were not delayed at the AV node, they would be conducted through the ventricles so quickly by the bundle branches and Purkinje cells that the ventricles would begin contracting immediately, before the atria had finished their contraction. As a result, the ventricles would not be as full of blood as they could be, and the pumping of the heart would not be as efficient, especially during physical activity. **PAGE 762** **8.** The technical term for heart contraction is systole, and the term for heart relaxation is diastole. **9.** The phases of the cardiac cycle are atrial systole, atrial diastole, ventricular systole, and ventricular diastole. **10.** No. When pressure in the left ventricle first rises, the heart is contracting but no blood is leaving the heart. During this initial phase of contraction, both the AV valves and the semilunar valves are closed. The increase in pressure is the result of increased tension as the cardiac muscle contracts. When the blood pressure in the ventricle exceeds the blood pressure in the aorta, the aortic semilunar valves are forced open, and blood is rapidly ejected from the ventricle. **11.** An increase in the size of the QRS complex indicates a larger-than-normal amount of electrical activity during ventricular depolarization. One possible cause is an enlarged heart. Because more cardiac muscle is depolarizing, the magnitude of the electrical event would be greater. **PAGE 769** **12.** Cardiac output is the amount of blood pumped by the left ventricle in 1 minute. **13.** Caffeine acts directly on the conducting system and contractile cells of the heart, increasing the rate at which they depolarize. Drinking large amounts of caffeinated drinks would increase the heart rate. **14.** The heart pumps in proportion to the amount of blood that enters. A heart that beats too rapidly does not have sufficient time to fill completely between beats. Thus, when the heart beats too fast, very little blood leaves the ventricles and enters the

circulation, so tissues suffer damage from inadequate blood supply. **15.** Stimulating the acetylcholine receptors of the heart would slow the heart rate (parasympathetic neurons release acetylcholine). Since cardiac output is the product of stroke volume and heart rate, a reduction in heart rate will lower the cardiac output (assuming that the stroke volume remains the same or doesn't increase). **16.** The venous return fills the heart with blood, stretching the heart muscle. According to the Frank–Starling principle, the more the heart muscle is stretched, the more forcefully it will contract (to a point). The more forceful the contraction, the more blood the heart will eject with each beat (stroke volume). Therefore, increased venous return would increase the stroke volume (if all other factors are constant).
17. SV = EDV − ESV, so SV = 125 mL − 40 mL = 85 mL

Answers to Review Questions

PAGE 770

Level 1 Reviewing Facts and Terms

1. d **2.** c **3.** d **4.** d **5.** d **6.** a and b **7. b** **8. (a)** superior vena cava; **(b)** auricle of right atrium; **(c)** right ventricle; **(d)** left ventricle; **(e)** aortic arch; **(f)** left pulmonary artery; **(g)** pulmonary trunk; **(h)** auricle of left atrium **9. (a)** ascending aorta; **(b)** opening of coronary sinus; **(c)** right atrium; **(d)** cusp of tricuspid valve; **(e)** chordae tendineae; **(f)** right ventricle; **(g)** pulmonary valve; **(h)** left pulmonary veins; **(i)** left atrium; **(j)** aortic valve; **(k)** cusp of mitral valve; **(l)** left ventricle; **(m)** interventricular septum **10.** d **11.** b **12.** During ventricular contraction, tension in the papillary muscles pulls against the chordae tendineae, which keep the cusps of the AV valve from swinging into the atrium. This action prevents the backflow, or regurgitation, of blood into the atrium as the ventricle contracts. **13.** (1) The epicardium is the visceral layer of the serous pericardium, which covers the outer surface of the heart. (2) The myocardium is the muscular wall of the heart, which forms both atria and ventricles. It contains cardiac muscle tissue and associated connective tissues, blood vessels, and nerves. (3) The endocardium is made up of a simple squamous epithelium and an areolar layer that covers the inner surfaces of the heart, including the valves. **14.** The tricuspid valve (right atrioventricular valve) and the mitral valve (left atrioventricular valve) prevent the backflow of blood from the ventricles into the atria. The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles. **15.** The Purkinje fibers radiate from the apex toward the base of the heart. They conduct action potentials very rapidly to all the ventricular cardiac contractile cells in order to start ventricular contraction. **16.** The cardiac cycle comprises the events in a complete heartbeat, including a contraction–relaxation period for both atria and ventricles. The cycle begins with atrial systole as the atria contract and push blood into the relaxed ventricles. As the atria relax (atrial diastole), the ventricles contract (ventricular systole), forcing blood through the semilunar valves into the pulmonary trunk and aorta. The ventricles then relax (ventricular diastole). For the rest of the cardiac cycle, both the atria and ventricles are in diastole; passive filling occurs. **17.** The factors that regulate stroke volume are (1) preload, the stretch on the heart before it contracts; (2) contractility, the force of contraction of individual ventricular contractile cells; and (3) afterload, the pressure that must be exceeded before blood can be ejected from the ventricles.

Level 2 Reviewing Concepts

18. c **19.** b **20.** d **21.** a **22.** Yes, there are blood tests that can help diagnose a myocardial infarction. Damaged myocardial cells release enzymes into the circulation, and these elevated enzymes can be measured in blood tests. These enzymes include cardiac troponin T, cardiac troponin I, and a special form of creatinine phosphokinase, CK-MB. **23.** The coronary arteries provide a constant blood supply to the heart muscle. The interconnections between the arteries, called arterial anastomoses, ensure constant blood supply to all parts of the myocardium, despite pressure fluctuations in the left and right coronary arteries as the heart beats. **24.** Cardiac reserve is the difference between resting and maximal cardiac outputs. Exercise increases cardiac output significantly. **25.** Stroke volume and heart rate influence cardiac output. **26.** Sympathetic activation increases the heart rate and the force of contractions; parasympathetic stimulation decreases the heart rate and the force of contractions. **27.** These drugs lower blood pressure as they block beta receptors, alpha receptors, or both, and prevent sympathetic stimulation of the heart.

Level 3 Critical Thinking and Clinical Applications

28. During tachycardia (an abnormally fast heart rate), there is less time between contractions for the heart to fill with blood again. Thus, over time the heart fills with less and less blood, and pumps less blood out. As the stroke volume decreases, the cardiac output decreases. When cardiac output decreases to the point where not enough blood reaches the brain, loss of consciousness occurs. **29.** Harvey probably has a regurgitating mitral valve, or left atrioventricular (AV) valve. When an AV valve fails to close properly, blood flowing back into the atrium produces a murmur. A murmur at the beginning of systole implicates the AV valve because this is the period when the valve has just closed and the blood in the ventricle is under increasing pressure; thus the likelihood of backflow is the greatest. A sound heard at the end of systole or the beginning of diastole would implicate a regurgitating semilunar valve—in this case, the aortic valve. **30.** Using CO = HR × SV, person 1 has a cardiac output of 4500 mL, and person 2 has a cardiac output of 8550 mL. According to the Frank–Starling principle, in a normal heart the cardiac output is directly proportional to the venous return. Thus, person 2 has the greater venous return. Ventricular filling decreases with increased heart rate; person 1 has the lower heart rate and therefore the longer ventricular filling time. **31.** By blocking calcium channels, verapamil will decrease the force of cardiac contraction, which directly lowers Karen's stroke volume.

Answers to Clinical Case Wrap-Up

PAGE 772 **1.** The "lubb" heard when the AV valves close, and the "dupp" heard when the semilunar valves close, would be muffled and difficult to hear because the sounds were transmitted through a pericardial cavity filled with blood. This dampens the sounds when heard through a stethoscope. **2.** The right atrium and right ventricle sit anteriorly, just deep to the sternum, and would likely be injured in this collision. Delicate structures that could also be injured include the anterior interventricular artery and great cardiac vein, running in the anterior interventricular sulcus. With a hard enough impact, the papillary muscles and chordae tendineae could rupture, leading to failure of the AV valves.

Answers to Figure-Based Questions

FIGURE 20–1 The **left** side of the heart supplies blood to the systemic circuit, while the **right** side of the heart supplies blood to the pulmonary circuit.

FIGURE 20–5 Blood will pass through the tricuspid valve (right AV valve), the pulmonary valve, the mitral valve (left AV valve), and finally the aortic valve.

FIGURE 20–11 When the electrical impulse reaches the AV node it is delayed about 100 msec.

FIGURE 20–15 The entry of sodium ions (Na^+) causes rapid depolarization. The entry of calcium ions (Ca^{2+}) causes the plateau. The exit of potassium ions (K^+) causes repolarization.

FIGURE 20–21 The sympathetic nervous system would increase heart rate. The cardioacceleratory center controls sympathetic neurons that increase heart rate.

FIGURE 20–24 Normal cardiac output at rest is about 5–7.5 L/min.

Chapter 21

Answers to Checkpoints

PAGE 782 **1.** The five general classes of blood vessels are arteries, arterioles, capillaries, venules, and veins. **2.** Blood vessels with thin walls and very little smooth muscle tissue in the tunica media are veins. Arteries and arterioles have a large amount of smooth muscle tissue in a thick, well-developed tunica media. **3.** In the arterial system, pressures are high enough to keep the blood moving forward. In the venous system, blood pressure is too low to keep the blood moving on toward the heart. Valves in veins prevent blood from flowing back toward the capillaries whenever the venous pressure drops. **4.** Fenestrated capillaries are located where fluids and small solutes move freely into and out of the blood, including endocrine glands, the choroid plexus of the brain, absorptive areas of the intestine, and filtration areas of the kidneys. **PAGE 791** **5.** The factors that contribute to total peripheral resistance are vascular resistance, vessel length, vessel luminal diameter, blood viscosity, and turbulence. **6.** In a healthy person, blood pressure is greater at the aorta than at the inferior vena cava. Blood, like other fluids, moves along a pressure gradient from areas of high pressure to areas of low pressure. If the pressure were higher in the inferior vena cava than in the aorta, the blood would flow backward. **7.** While Lailah was standing for a period of time, blood pooled in her lower limbs, which decreased venous return to her heart. In turn, cardiac output decreased, so less blood reached her brain, causing light-headedness and fainting. A hot day adds to this effect, because the loss of body water through sweating reduces blood volume. **8.** Mike's mean arterial pressure (MAP) is approximately 88.3 mm Hg; $70 + (125 - 70)/3 = 70 + 18.3 = 88.3$. **PAGE 798** **9.** Vasodilators promote the dilation of precapillary sphincters. Local vasodilators, such as decreased O_2 level or increased CO_2 level, act on tissues to accelerate blood flow. **10.** Pressure on the common carotid artery would decrease blood pressure at the baroreceptors in the carotid sinus. This decrease would lower the frequency of action potentials along the glossopharyngeal nerve (IX) to the medulla oblongata, and more sympathetic impulses would be sent to the heart. The net result would be an increase in the heart rate. **11.** Vasoconstriction of the renal artery would decrease both blood flow and blood pressure at the kidney. In response, the kidney would increase the amount of renin it releases, which in turn would lead to an increase in the level of angiotensin II. The angiotensin II would bring about increased blood pressure and increased blood volume. **PAGE 802** **12.** Blood pressure increases during exercise because (1) cardiac output increases and (2) resistance in visceral tissues increases. **13.** The immediate problem during hemorrhaging is maintaining adequate blood pressure and peripheral blood flow; the long-term problem is restoring normal blood volume. **14.** Both aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume. **PAGE 803** **15.** The two circuits of the cardiovascular system are the pulmonary circuit and the systemic circuit. **16.** The major patterns are as follows: (1) The peripheral distributions of arteries and veins on the body's left and right sides are generally identical, except near the heart, where the largest vessels connect to the atria or ventricles; (2) a single vessel may have several names as it crosses specific anatomical boundaries, making accurate anatomical descriptions possible; and (3) tissues and organs are usually serviced by several arteries and veins. **PAGE 804** **17.** The pulmonary arteries enter the lungs carrying deoxygenated blood, and the pulmonary veins leave the lungs carrying oxygenated blood. **18.** The path of blood through the lungs is right ventricle → pulmonary trunk → left and right pulmonary arteries → pulmonary arterioles → alveolar capillary network → pulmonary venules → pulmonary veins → left atrium. **PAGE 821** **19.** A blockage of the left subclavian artery would interfere with blood flow to the left arm. **20.** Compression of the common carotid arteries would decrease blood pressure at the carotid sinus and cause a rapid reduction in blood flow to the brain, resulting in a loss of consciousness. An immediate reflexive increase in heart rate and blood pressure would follow. **21.** Rupture of the celiac trunk would most directly affect the stomach, spleen, liver, and pancreas. **22.** The vein that is bulging in Noah's neck is the external jugular vein. **23.** A blockage of the popliteal vein would interfere with blood flow in the tibial and fibular veins (which form the popliteal vein) and the small saphenous vein (which joins the popliteal vein). **PAGE 824** **24.** Two umbilical arteries supply blood to the placenta, and one umbilical vein returns blood from the placenta. The umbilical vein then drains into the ductus venosus within the fetal liver. (Remember, arteries carry blood away from the heart, and veins carry blood to the heart.) **25.** This blood sample was taken from the umbilical vein, which carries oxygenated, nutrient-rich blood from the placenta to the fetus. **26.** Structures specific to the fetal circulation include two umbilical arteries, an umbilical vein, the ductus venosus, the foramen ovale, and the ductus arteriosus. In the newborn, the foramen ovale closes and persists as the fossa ovalis, a shallow depression; the ductus arteriosus persists as the ligamentum arteriosum, a fibrous cord; and the umbilical vessels and ductus venosus persist throughout life as fibrous cords. **27.** Components of the cardiovascular system affected by age include the blood, heart, and blood vessels. **28.** A thrombus is a stationary blood clot within the lumen of a blood vessel. **29.** An aneurysm is the ballooning out of a weakened arterial wall resulting from sudden pressure increases. **30.** The cardiovascular system provides other body systems with oxygen, hormones, nutrients, and white blood cells in blood, while removing carbon dioxide and metabolic wastes; it also transfers heat to body tissues. **31.** The skeletal system provides calcium needed for normal cardiac muscle contraction, and it protects developing blood cells in the red bone marrow. The cardiovascular system provides calcium and phosphate for bone deposition, delivers erythropoietin to red bone marrow, and transports parathyroid hormone and calcitonin to osteoblasts and osteoclasts.

Answers to Review Questions

PAGE 828

Level 1 Reviewing Facts and Terms

1. (a) brachiocephalic trunk; **(b)** brachial; **(c)** radial; **(d)** external iliac; **(e)** anterior tibial; **(f)** right common carotid; **(g)** left subclavian; **(h)** common iliac; **(i)** femoral **2.** b **3.** e **4.** b **5.** b **6.** b **7.** b **8.** d **9. (a)** external jugular; **(b)** brachial; **(c)** median cubital; **(d)** radial; **(e)** great saphenous; **(f)** internal jugular; **(g)** superior vena cava; **(h)** left and right common iliac; **(i)** femoral **10.** b **11.** b **12.** a **13.** c **14.** c **15.** b **16.** d **17. (a)** Capillary hydrostatic pressure forces fluid out of a capillary at the arterial end. **(b)** Blood colloid osmotic pressure causes the movement of fluid back into a capillary at its venous end. **18.** When an infant takes its first breath, the lungs expand and pulmonary vessels dilate. The smooth muscles in the ductus arteriosus contract, due to increased venous return from the lungs, isolating the pulmonary and aortic trunks, and blood begins flowing through the pulmonary circuit. As pressure increases in the left atrium, the valvular flap closes the foramen ovale, completing the vascular remodeling.

Level 2 Reviewing Concepts

19. b **20.** b **21.** b **22.** Artery walls are generally thicker and contain more smooth muscle and elastic fibers, enabling them to resist and adjust to the pressure generated by the heart. Venous walls are thinner; the pressure in veins is less than that in arteries. Arteries constrict more than veins do when not expanded by blood pressure, due to a greater degree of elastic tissue. Finally, the endothelial lining of an artery has a pleated appearance because it cannot contract and so forms folds. The lining of a vein looks like a typical endothelial layer. **23.** Bands of smooth muscles, called precapillary sphincters, are present at the entrances of the capillaries. Their contraction and relaxation control blood flow to the tissues. Contraction of the sphincters narrows the capillary entrances, reducing or stopping the flow of blood. When the sphincters relax, the entrances dilate, and blood flows into the capillaries. The central passageway in the arteriole system acts as a thoroughfare channel. Blood flow through this channel is controlled by the sphincter effect of the arteriole. **24.** Contraction of the surrounding skeletal muscles squeezes venous blood toward the heart. This mechanism, the muscular pump, is assisted by the presence of valves in the veins, which prevent backflow of the blood. The respiratory pump, which results from the increase in internal pressure of the thoracic cavity during exhalation, pushes venous blood into the right atrium. **25.** Abnormally high blood pressure is termed hypertension, whereas abnormally low blood pressure is called hypotension. Of the two, hypertension is more common. Many cases of hypotension result from aggressive drug treatment for hypertension. Smoking, stress, and obesity are some of the factors that lead to hypertension. **26.** The brain receives arterial blood from four arteries that form anastomoses within the cranium. An interruption of any one vessel will not compromise the blood flow to the brain. **27.** The cardioacceleratory and vasomotor centers are stimulated when general sympathetic activation occurs. The result is an increase in cardiac output and blood pressure. When the parasympathetic division is activated, the cardioinhibitory center is stimulated, reducing cardiac output.

Level 3 Critical Thinking and Clinical Applications

28. Fluid loss lowers blood volume, leading to sympathetic stimulation, which elevates blood pressure. So, Bob's blood pressure is high instead of low. **29.** Antihistamines and decongestants are sympathomimetic drugs; they have the same effects on the body as does stimulation of the sympathetic nervous system. In addition to the desired effects of counteracting the symptoms of the allergy, these medications can produce an increased heart rate, increased stroke volume, and increased peripheral resistance, all of which will contribute to elevating blood pressure. In a person with hypertension (high blood pressure), these drugs would aggravate this condition, with potentially hazardous consequences. **30.** When Jolene stood up rapidly, gravity caused her blood volume to move to the lower parts of her body away from the heart, decreasing venous return. The decreased venous return resulted in a decreased end-diastolic volume (EDV), leading to a decreased stroke volume and cardiac output. In turn, blood flow to the brain decreased, so the diminished oxygen supply caused her to be light-headed and feel faint. This reaction doesn't happen all the time because as soon as the pressure drops due to inferior movement of blood, baroreceptors in the aortic arch and carotid sinuses trigger the baroreceptor reflex. Action potentials are carried to the medulla oblongata, where appropriate responses are integrated. In this case, we would expect an increase in peripheral resistance to compensate for the decreased blood pressure. If this doesn't compensate enough for the drop, then an increase in heart rate and force of contraction would occur. Normally, these responses occur so quickly that changes in pressure following changes in body position go unnoticed.

Answers to Clinical Case Wrap-Up

PAGE 829 **1.** Calcification follows the degeneration of smooth muscle in the tunica media of arteries. Calcification in arteries is related to atherosclerotic injury of the vessels. Calcification does not occur in normal, young, healthy blood vessel walls. **2.** Atherosclerosis is never seen in the venous system because veins are never subjected to the pressures of the arterial system. In the average person the systemic arterial pressure is over 100 mm Hg. This causes wear and tear in the arterial walls, leading to gradual degeneration of the smooth muscle in the tunica media, followed by deposition of calcium salts, and then by deposition of atherosclerotic plaques. The pressure within the venous system is always quite low (usually around 16 mm Hg). Damage to the endothelial surfaces does not get started.

Answers to Figure-Based Questions

FIGURE 21–2 (a) Veins have larger lumens than arteries. (b) Arteries, specifically muscular arteries, have the thickest tunica media.

FIGURE 21–7 Factors that would increase vascular resistance would be increased vessel length and turbulence. Increased vessel luminal diameter would decrease vascular resistance.

FIGURE 21–12 For blood flow to be autoregulated, physical stress (such as trauma or high temperature), chemical changes, or increased tissue activity are stimuli that signal inadequate local blood pressure and blood flow.

FIGURE 21–15 For short-term regulation of a decrease in blood pressure and blood volume, sympathetic activation and the release of the adrenal hormones epinephrine (E) and norepinephrine (NE) increase cardiac output and peripheral vasoconstriction, which will increase blood pressure.

FIGURE 21–21 The superficial temporal, maxillary, occipital, facial, and lingual arteries are all branches of the external carotid artery.

FIGURE 21–29 The right and left brachiocephalic veins, the mediastinal veins, and the azygos vein directly drain into the superior vena cava.

Chapter 22

Answers to Checkpoints

PAGE 842 **1.** A pathogen is any disease-causing organism, such as a virus, bacterium, fungus, or parasite that can survive and even thrive inside the body. **2.** The components of the lymphatic system are lymph, lymphatic vessels, lymphoid cells (lymphocytes and other cells), primary lymphoid tissues and organs (red bone marrow and the thymus), and secondary lymphoid tissues and organs (lymph nodes, tonsils, MALT, the appendix, and the spleen). **3.** A blockage of the thoracic duct would impair the drainage of lymph from inferior to the diaphragm and from the left side of the head and thorax, slowing the return of lymph to the venous blood and promoting the accumulation of fluid in the limbs (lymphedema). **4.** A lack of thymic hormones would drastically reduce the population of T lymphocytes. **5.** Lymph nodes enlarge during some infections because lymphocytes and phagocytes in the nodes multiply to defend against the infectious agent. **PAGE 843** **6.** Immunity is the body's ability to resist infectious organisms or other substances that could damage tissues and organs. Resistance is the ability of the body to maintain its immunity. **7.** Innate (nonspecific) immunity is a type of body defense that you are born with and does not distinguish among different threats. Adaptive (specific) immunity is acquired after birth and after exposure to a particular antigen. **PAGE 851** **8.** A decrease in the number of monocyte-forming cells in red bone marrow would result in fewer macrophages of all types, including stellate macrophages (Kupffer cells) of the liver, microglia of the central nervous system, and alveolar macrophages. **9.** A rise in the level of interferon suggests a viral infection. Interferon does not help an infected cell, but "interferes" with replication of the virus and thus the virus's ability to infect other cells. **10.** Pyrogens increase body temperature (produce a fever) by stimulating the temperature control area of the pre-optic nucleus of the hypothalamus. **PAGE 855** **11.** In cell-mediated (cellular) immunity, T cells defend against abnormal cells and pathogens inside cells. In antibody-mediated (humoral) immunity, B cells secrete antibodies that defend against antigens and pathogens in body fluids. **12.** The four major types of T cells are cytotoxic T cells, helper T cells, regulatory T cells, and memory T cells. **13.** The two forms of active immunity are naturally acquired active immunity and artificially acquired active immunity; the two forms of passive immunity are naturally acquired passive immunity and artificially acquired passive immunity. **14.** The four general properties of adaptive immunity are specificity, versatility, memory, and tolerance. **PAGE 862** **15.** Abnormal peptides in the cytoplasm of a cell can become attached to MHC (major histocompatibility complex) proteins and then be displayed on the surface of the cell's plasma membrane. The recognition of such displayed peptides by T cells can initiate an immune response. **16.** A decrease in the number of cytotoxic T cells would affect cell-mediated immunity, reducing the effectiveness of cytotoxic T cells in killing foreign cells and virus-infected cells. **PAGE 867** **17.** Without helper T cells—which promote B cell division, the maturation of plasma cells, and antibody production by plasma cells—the antibody-mediated immune response would probably not occur. **18.** Sensitization is the process by which a B cell becomes able to react with a specific antigen. **19.** Plasma cells produce and secrete antibodies, so observing an elevated number of plasma cells would lead us to expect increasing levels of antibodies in the blood. **20.** An antibody molecule consists of two parallel pairs of polypeptide chains: one pair of heavy chains and one pair of light chains. Each chain contains both constant segments and variable segments. **21.** Because production of a secondary response depends on the presence of memory B cells and memory T cells formed during a primary response, the secondary response would be more negatively affected by a lack of memory B cells for a particular antigen. **PAGE 872** **22.** A developing fetus is protected primarily by naturally acquired passive immunity, through the maternal production of IgG antibodies that have crossed the placenta from the mother's bloodstream. **23.** Stress can interfere with the immune response by depressing inflammation, reducing the number and activity of phagocytes, and inhibiting interleukin secretion. **24.** An autoimmune disorder is a condition that results when the immune system's sensitivity to normal cells and tissues causes the production of autoantibodies. **PAGE 875** **25.** Elderly people are more susceptible to viral and bacterial infections because the number of helper T cells declines with age and B cells are less responsive, so antibody levels rise more slowly after antigen exposure. **26.** As one ages, immune surveillance declines, so cancerous cells are not eliminated as effectively. **27.** Glucocorticoids released by the endocrine system have anti-inflammatory effects; thymic hormones stimulate the development and maturation of lymphocytes; and many hormones affect immune function. The thymus secretes thymic hormones, and cytokines affect cells throughout the body. **28.** The lymphatic system provides defenses against infection; performs immune surveillance to eliminate cancer cells; and returns tissue fluid to the circulation.

Answers to Review Questions

PAGE 878

Level 1 Reviewing Facts and Terms

1. **(a)** tonsil; **(b)** cervical lymph nodes; **(c)** right lymphatic duct; **(d)** thymus; **(e)** cisterna chyli; **(f)** lumbar lymph nodes; **(g)** appendix; **(h)** lymphatics of lower limb; **(i)** lymphatics of upper limb; **(j)** axillary lymph nodes; **(k)** thoracic duct; **(l)** lymphatics of mammary gland; **(m)** spleen; **(n)** mucosa-associated lymphoid tissue (MALT); **(o)** pelvic lymph nodes; **(p)** inguinal lymph nodes; **(q)** red bone marrow **2.** d **3.** b **4.** d **5.** c **6.** d **7.** c **8.** a **9.** d **10.** d **11.** c **12.** Primary lymphoid tissues and organs: (1) red bone marrow: maintain normal lymphocyte populations and other defense cells, such as monocytes and macrophages; (2) thymus: production of mature T cells and hormones that promote immune function. Secondary lymphoid tissues and organs: (1) spleen: filtration of blood, recycling of red blood cells, detection of blood-borne pathogens or toxins; (2) lymph nodes: filtration of lymph, detection of pathogens, initiation of immune response; (3) lymphoid nodules and MALT: defense of entrance and passageways of digestive tract and protection of epithelia lining the respiratory, urinary, and reproductive tracts against pathogens and foreign proteins or toxins. **13.** **(a)** lymphocytes responsible for cell-mediated immunity; **(b)** stimulate the activation and function of T cells and B cells; **(c)** inhibit the activation and function of both T cells and B cells; **(d)** produce and secrete antibodies; **(e)** recognize and destroy abnormal cells; **(f)** produce interleukin-7, which promotes the

differentiation of B cells; **(g)** regulate T cell development and function; **(h)** interfere with viral replication inside the cell and stimulate the activities of macrophages and NK cells; **(i)** reset the body's thermostat, causing a rise in body temperature (fever); **(j)** provide cell-mediated immunity, which defends against abnormal cells and pathogens inside cells; **(k)** provide humoral immunity, which defends against antigens and pathogens in the body (but not inside cells); **(l)** enhance innate (nonspecific) defenses and increase T cell sensitivity and stimulate B cell activity; **(m)** slow tumor growth and kill sensitive tumor cells; **(n)** stimulate the production of blood cells in the red bone marrow and lymphocytes in lymphoid tissues and organs **14.** (1) T cells, derived from the thymus; (2) B cells, derived from red bone marrow; and (3) NK cells, derived from red bone marrow **15.** Innate (nonspecific) immunity: (1) physical barriers; (2) phagocytic cells; (3) immune surveillance; (4) interferons; (5) complement system; (6) inflammation; and (7) fever

Level 2 Reviewing Concepts

16. d **17.** e **18.** a **19.** b **20.** Complement activation can rupture the target cell by forming a membrane attack complex (MAC). It also enhances phagocytosis (opsonization) and inflammation. Interferon interferes with viral replication inside virus-infected cells by triggering the production of antiviral proteins. **21.** Cytotoxic T cells kill by rupturing the target cell's plasma membrane, by stimulating lymphotoxin secretion, or by activating genes in the nucleus that program cell death (apoptosis). **22.** Formation of an antigen–antibody complex eliminates antigens by neutralization; by agglutination and precipitation; by activating complement; by attracting phagocytes; by opsonization; by stimulating inflammation; or by preventing bacterial and viral adhesion. **23.** Innate immunity is genetically programmed; an example is immunity to fish diseases. Naturally acquired active immunity develops after birth from contact with pathogens; an example is exposure to chickenpox in grade school. Artificially acquired active immunity develops after intentional exposure to a pathogen; an example is administration of measles vaccine. Artificially acquired passive immunity is temporary immunity provided by injection with antibodies produced in another organism, such as antibodies against rabies. Naturally acquired passive immunity is gained by acquiring antibodies from mother's milk or placental exchange. **24.** The injections are timed to trigger the primary and secondary responses of the immune system. Upon first exposure to hepatitis antigens, B cells produce daughter cells that differentiate into plasma cells and memory B cells. The plasma cells begin producing antibodies, which represent the primary response to exposure. However, the primary response does not maintain elevated antibody levels for long periods, so the second and third injections are necessary to trigger secondary responses, when memory B cells differentiate into plasma cells and produce antibody concentrations that remain high much longer.

Level 3 Critical Thinking and Clinical Applications

25. Yes, the crime lab could determine whether the sample is blood plasma, which contains IgM, IgG, IgD, and IgE, or semen, which contains only IgA. **26.** Ted cannot yet know whether he'll come down with the measles. Ted's elevated blood IgM level and antibody titer indicates that he is in the early stages of a primary response to the measles virus. If his immune response proves unable to control and then eliminate the virus, Ted will develop the measles. **27.** In a radical mastectomy, lymph nodes in the nearby axilla and surrounding region are removed along with the cancerous breast to try to prevent the spread of cancer cells by the lymphatic system. Lymphatic vessels from the limb on the affected side are tied off, and because there is no place for the lymph to drain, over time lymphedema causes swelling of the limb. **28.** A key characteristic of cancer cells is their ability to metastasize—to break free from a tumor and form new tumors in other tissues. The primary route of metastasis is the lymphatic system, including the lymph nodes. Examination of regional lymph nodes for the presence of cancer cells can help the physician determine if the cancer was caught in an early stage or whether it has started to spread to other tissues. **29.** HIV is a retrovirus. It binds to CD4 T cells and can also affect dendritic cells, macrophages, and microglia. Regulatory T cells are relatively unaffected. The gradual destruction of helper T cells impairs the immune response. Circulating antibody levels decline and cell-mediated immunity is reduced. The body can no longer defend itself against a variety of normally harmless microorganisms.

Answers to Clinical Case Wrap-Up

PAGE 879 **1.** Innate immunity is genetically determined and present at birth. For example, skin and mucous membranes provide an innate physical and chemical barrier to infecting organisms. All humans are susceptible to chickenpox, an infectious disease. The immunity developed after a chickenpox vaccination is artificially acquired adaptive immunity, developed to a specific antigen, the varicella-zoster virus (VZV). **2.** Baby Ruthie has developed lifelong immunity to chickenpox as a result of having the disease. Her immune memory will provoke a secondary immune response if she is exposed to the varicella-zoster virus again. The recommended schedule (according to the Centers for Disease Control and Prevention, CDC) for varicella-zoster vaccination is 12–15 months of age. However, there is no need for Ruthie to get a chickenpox vaccination after having had the disease.

Answers to Figure-Based Questions

FIGURE 22–3 Lymphatic vessels have valves, similar to veins, which allow lymph to flow in only one direction.

FIGURE 22–8 Lymphocytes are found in the white pulp of the spleen, whereas red blood cells are found in the red pulp of the spleen.

FIGURE 22–12 Interferon alpha attracts and stimulates NK cells as a way to enhance viral resistance to viral infection.

FIGURE 22–17 Artificially acquired active immunity develops after receiving a vaccine.

FIGURE 22–25 During the primary response, IgM peaks sooner than IgG. During the secondary response, the level of IgG is higher than the level of IgM.

FIGURE 22–26 After the appearance of bacteria, NK cells are present for the shortest amount of time (typically less than 1 week).

Chapter 23

Answers to Checkpoints

PAGE 884 **1.** Functions of the respiratory system include providing an extensive surface area for gas exchange between air and circulating blood; moving air to and from exchange surfaces along the respiratory passageways; protecting respiratory surfaces from dehydration, temperature changes, and pathogens; producing sounds; and detecting odors. **2.** The two anatomical divisions of the respiratory system are the upper respiratory system and the lower respiratory

system. **3.** The respiratory mucosa lines the conducting portion of the respiratory tract. **PAGE 887** **4.** The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. **5.** The rich vascularization of the nose delivers body heat to the nasal cavity, so inhaled air is warmed before it leaves the nasal cavity and moves toward the lungs. The heat also evaporates moisture from the epithelium to humidify the incoming air. **6.** The lining of the nasopharynx, which receives air from only the nasal cavity, is the same as that of the nasal cavity: a pseudostratified ciliated columnar epithelium. Because the oropharynx and laryngopharynx receive air from the nasal cavity and potentially abrasive food from the oral cavity, they have a more protective lining: a stratified squamous epithelium. **PAGE 892** **7.** The unpaired laryngeal cartilages include the thyroid cartilage, cricoid cartilage, and epiglottis. The paired cartilages are the arytenoid cartilages, corniculate cartilages, and cuneiform cartilages. **8.** The trachea conveys air between the larynx and main bronchi; cilia and the mucus produced by epithelial cells also protect the respiratory tree by trapping inhaled debris and sweeping it toward the pharynx, where it is removed through coughing or swallowing. **9.** The tracheal cartilages are C-shaped to allow space for expansion of the esophagus when food or liquid is swallowed. **10.** Objects are more likely to be lodged in the right main bronchus because it is slightly larger and more vertical than the left main bronchus. **PAGE 894** **11.** Without surfactant, the alveoli would collapse as a result of surface tension in the thin layer of water that moistens the alveolar surfaces. **12.** Air passing through the glottis flows into the larynx and through the trachea. From there, the air flows into a main bronchus, which supplies the lungs. In the lungs, the air passes to lobar bronchi, segmental bronchi, bronchioles, a terminal bronchiole, a respiratory bronchiole, an alveolar duct, an alveolar sac, an alveolus, and ultimately to the blood air barrier. **PAGE 897** **13.** The pulmonary arteries supply blood to the gas-exchange surfaces; the bronchial capillaries, supplied by the bronchial arteries, which branch from the thoracic aorta, supply the conducting portions of the respiratory system. **14.** The pleura is a serous membrane that secretes pleural fluid, which lubricates the opposing parietal and visceral surfaces to prevent friction during breathing. **PAGE 898** **15.** External respiration includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. Internal respiration is the absorption of oxygen and the release of carbon dioxide by the body's cells. **16.** The integrated steps involved in external respiration are pulmonary ventilation (breathing), gas diffusion across the blood air barrier, and the transport of oxygen and carbon dioxide. **PAGE 905** **17.** Compliance is the ease with which the lungs expand. Factors affecting compliance include (a) the connective tissue structure of the lungs, (b) the level of surfactant production, and (c) the mobility of the thoracic cage. **18.** The measurable pulmonary volumes are tidal volume (V_T), expiratory reserve volume (ERV), residual volume, and inspiratory reserve volume (IRV). **19.** When the rib penetrates Mark's chest wall, it also penetrates the left pleural cavity, allowing atmospheric air to enter and increase the intrapleural pressure within the pleural cavity (a condition called pneumothorax). As a result, the natural elasticity of the left lung may cause the lung to collapse, a condition called atelectasis. **20.** Because the fluid produced in pneumonia takes up space that would normally be occupied by air, vital capacity would decrease. **PAGE 910** **21.** Dalton's law states that each gas in a mixture exerts a pressure equal to its relative abundance. **22.** Henry's law states that at a constant temperature, the quantity of a particular gas that will dissolve in a liquid is directly proportional to the partial pressure of that gas. **PAGE 914** **23.** Carbon dioxide is transported in the bloodstream as bicarbonate ions, bound to hemoglobin, or dissolved in the plasma. **24.** During exercise, active skeletal muscles generate heat, lactate, and hydrogen ions. A combination of increased body temperature and decreased pH causes hemoglobin to release more oxygen when you are exercising than when you are resting. **25.** Blockage of the trachea would interfere with the body's ability to gain oxygen and eliminate carbon dioxide. Because most carbon dioxide is transported in blood as bicarbonate ions formed from the dissociation of carbonic acid, an inability to eliminate carbon dioxide would result in an excess of hydrogen ions, which decreases blood pH. **PAGE 922** **26.** Exciting the pneumotaxic centers would inhibit the inspiratory and apneustic centers, which would result in shorter and more rapid breaths. **27.** Peripheral chemoreceptors are more sensitive to the carbon dioxide level than to the oxygen level. When carbon dioxide dissolves, it forms carbonic acid, which dissociates and releases hydrogen ions, thereby decreasing pH and altering cell or tissue activity. **28.** Johnny isn't likely to turn blue and die. When he holds his breath, the blood carbon dioxide level is increasing, causing increased stimulation of the inspiratory center and forcing him to breathe again. **PAGE 923** **29.** Aging results in deterioration of elastic tissue (reducing compliance), decreased vital capacity, arthritic changes in rib articulations, decreased flexibility at costal cartilages, and some degree of emphysema. **PAGE 925** **30.** The respiratory system provides oxygen and eliminates carbon dioxide for all body systems. **31.** The respiratory system provides alveolar phagocytes and respiratory defenses to trap pathogens and protect deeper tissues. Tonsils within the lymphatic system protect against respiratory infection, and lymph drainage from the lungs mobilizes defenses to ward off infection.

Answers to Review Questions

PAGE 928

Level 1 Reviewing Facts and Terms

1. a **2.** b **3.** a **4.** d **5.** e **6.** **(a)** nasal cavity; **(b)** pharynx; **(c)** right lung; **(d)** nose; **(e)** larynx; **(f)** trachea; **(g)** bronchus; **(h)** bronchioles; **(i)** left lung **7.** Since the air Brad is breathing is dry, large amounts of moisture are leaving the mucus in his respiratory tract to humidify inhaled air. Drying makes the mucus viscous and makes it difficult for the cilia to move, so mucus builds up, producing nasal congestion by morning. When Brad showers and drinks fluids, body water is replaced, so the mucus loosens up and can be moved along as usual. **8.** The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. The lower respiratory system consists of the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. **9.** The larger part of the nasal cavity is covered by respiratory mucosa, which contributes to the quality of inhaled air; whereas the upper part is covered by olfactory mucosa, which contains the receptors providing the sense of smell. **10.** The thyroid cartilage forms the anterior walls of the larynx; the cricoid cartilage protects the glottis and the entrance to the trachea; the epiglottis forms a lid over the glottis; the arytenoid cartilages and the corniculate cartilages are involved in the formation of sound; and the cuneiform cartilages are found in the folds of the larynx. **11.** The steps of external respiration are **(a)** pulmonary ventilation (breathing); **(b)** gas diffusion across the blood air barrier and between blood and

interstitial fluids; and **(c)** the transport of oxygen and carbon dioxide between alveolar and peripheral capillaries. **12.** Fetal hemoglobin has a higher affinity for oxygen than does adult hemoglobin. Thus, it binds more of the oxygen that is present, enabling it to "steal" oxygen from the maternal hemoglobin. **13.** Carbon dioxide is transported in the blood as bicarbonate ions, bound to hemoglobin, and dissolved in the plasma.

Level 2 Reviewing Concepts

14. c **15.** c **16.** c **17.** d **18.** The nasal cavity cleanses, moistens, and warms inhaled air, whereas the mouth does not. Drier air entering through the mouth can irritate the trachea and cause throat soreness. **19.** Smooth muscle tissue in the walls of bronchioles allows changes in airway diameter (bronchodilation or bronchoconstriction), which provides control of the flow and distribution of air within the lungs, just as vasodilation and vasoconstriction of the arterioles control blood flow and blood distribution. **20.** The epiglottis forms a lid over the entrance of the larynx. During swallowing, the larynx is elevated and the epiglottis folds back over the glottis, preventing food from entering the respiratory tract. **21.** Pulmonary ventilation, the physical movement of air into and out of the respiratory tract, maintains adequate alveolar ventilation. Alveolar ventilation, air movement into and out of the alveoli, prevents the buildup of carbon dioxide in the alveoli and ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream. **22. (a)** Boyle's law describes the inverse relationship between gas pressure and volume: If volume decreases, pressure rises; if volume increases, pressure falls. It is the basis for the direction of air movement in pulmonary ventilation. **(b)** Dalton's law states that each of the gases that make up a mixture of gases contributes to the total pressure in proportion to its relative abundance; that is, all the partial pressures added together equal the total pressure exerted by the gas mixture. This relationship is the basis for the calculation of the partial pressures of oxygen and carbon dioxide, and their exchange between blood and alveolar air. **(c)** Henry's law states that, at a given temperature, the amount of a particular gas that dissolves in a liquid is directly proportional to the partial pressure of that gas. Henry's law underlies the diffusion of gases between capillaries, alveoli, and interstitial fluid. **23.** A fish bone or a fine chicken bone that pierces the laryngeal wall can cause a laryngeal spasm and swelling, restricting the airway. **24.** During diaphragmatic breathing, air is drawn into the lungs mainly by contraction of the diaphragm. Air is exhaled passively when the diaphragm relaxes. In costal breathing, inhalation takes place mainly by contractions of the external intercostal muscles. Exhalation occurs passively when these muscles relax. Pregnant women rely more on costal breathing as the enlarging uterus pushes the abdominal organs against the diaphragm, restricting diaphragmatic movements. **25.** The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. The apneustic centers promote inhalation by stimulating the dorsal respiratory group in response to input from the vagus nerves.

Level 3 Critical Thinking and Clinical Applications

26. AVR = respiratory rate × (tidal volume – dead space). In this case, the dead air space is 200 mL (the anatomical dead air space [150 mL] plus the volume of the snorkel [50 mL]); therefore, AVR = respiratory rate × (500 − 200). To maintain an AVR of 6.0 L/min, or 6000 mL/min, the respiratory rate must be 6000/(500 − 200), or 20 breaths per minute. **27.** A person with chronic emphysema has constantly elevated blood levels of P_{CO_2} due to an inability to eliminate CO_2 efficiently because of physical damage to the lungs. Over time, the brain ignores the stimulatory signals produced by the increased CO_2 and begins to rely on information from peripheral chemoreceptors to set the pace of breathing. (In other words, accommodation has occurred.) The peripheral chemoreceptors also accommodate to the elevated CO_2 and respond primarily to the level of O_2 in the blood, increasing breathing when O_2 levels are low and decreasing breathing when O_2 levels are high. When pure O_2 was administered, chemoreceptors responded with fewer action potentials to the medulla oblongata, so Mr. B. stopped breathing. **28.** At puberty, the larynx of males enlarges. The vocal cords become thicker and longer and this results in the production of lower tones. In females, this does not happen, so Susy's voice will remain high pitched. **29.** In anemia, the blood's ability to carry oxygen is decreased due to the lack of functional hemoglobin, red blood cells, or both. Anemia does not interfere with the exchange of carbon dioxide within the alveoli, nor with the amount of oxygen that will dissolve in the plasma. Because chemoreceptors respond to dissolved gases and pH, as long as the pH and the concentrations of dissolved carbon dioxide and oxygen are normal, ventilation patterns should not change significantly. **30.** The obstruction in Doris's right lung would prevent gas exchange. Thus, blood moving through the right lung would not be oxygenated and would retain carbon dioxide, which would lead to a lower blood pH than that of blood leaving the left lung. The lower pH for blood in the right lung would shift the oxygen–hemoglobin saturation curve to the left (the Bohr effect) as compared with the curve for the left lung.

Answers to Clinical Case Wrap-Up

PAGE 929 **1.** Breathing can be obstructed in the nose (a bad cold, growths such as nasal polyps, a broken nasal septum), in the sinuses (a seasonal allergy or sinus infection), in the oral cavity (an enlarged or swollen tongue), or in the pharynx (a swollen, sore throat). **2.** Children who have frequent URT infections often have huge, infected tonsils whose locations (*lingual, palatine,* and *pharyngeal*) crowd the back of the throat. These children can become mouth-breathers. A tonsillectomy (surgical removal of the tonsils) may be indicated to help the child breathe better and sleep through the night.

Answers to Figure-Based Questions

FIGURE 23–2 The conducting portion of the respiratory tract is lined with pseudostratified ciliated columnar epithelium.

FIGURE 23–8 Smooth muscle wraps around a respiratory bronchiole and can change the diameter of the airway.

FIGURE 23–9 The right lung has three lobes, the left lung has two lobes, and the left lung has a cardiac notch.

FIGURE 23–14 The primary muscles of respiration are the diaphragm and the external intercostal muscles.

FIGURE 23–16 The inspiratory capacity is a total of the tidal volume and inspiratory reserve volume.

FIGURE 23–20 More oxygen is released when the pH is *lower* than normal and when temperature is *higher* than normal.

FIGURE 23–26 Inhibition of medulla oblongata chemoreceptors and respiratory muscles will decrease respiratory rate, the elimination of CO_2 at alveoli, and increase **arterial** P_{CO_2}.

Chapter 24

Answers to Checkpoints

PAGE 938 **1.** Organs of the digestive system include the oral cavity, pharynx, esophagus, stomach, small intestine, large intestine, and accessory organs (teeth, tongue, salivary glands, liver, pancreas, and gallbladder). **2.** The main function of the digestive system is to break down food, absorb the nutrients that can be used by body cells, and eliminate the remaining waste. **3.** The six primary processes of the digestive system include the following: (1) ingestion = entry of food; (2) mechanical digestion and propulsion = crushing and shearing of food to make it more susceptible to enzymes and the propelling of food along the digestive tract; (3) chemical digestion = the chemical breakdown of food into smaller products for absorption; (4) secretion = the release of water, acids, and other substances by the epithelium of the digestive tract and by glandular organs; (5) absorption = movement of digested particles across the digestive epithelium and into the interstitial fluid of the digestive tract; and (6) defecation= the elimination of wastes as feces from the body. **4.** The mesenteries—sheets consisting of two layers of serous membrane connected by their loose connective tissue—support and stabilize the organs in the abdominopelvic cavity and provide a route for the associated blood vessels, nerves, and lymphatic vessels. **5.** The layers of the gastrointestinal tract, beginning at the surface of the lumen, are the mucosa (adjacent to the lumen), submucosa, muscular layer, and serosa. **6.** The waves of contractions responsible for peristalsis are more efficient in propelling intestinal contents than segmentation, which is basically a churning action that mixes intestinal contents with digestive fluids. **7.** A drug that blocks parasympathetic stimulation, which increases muscle tone and activity in the digestive tract, would slow peristalsis. **PAGE 944** **8.** Structures associated with the oral cavity include the tongue, teeth, and salivary glands. **9.** Stratified squamous epithelium lines the oral cavity. It protects against friction or abrasion by food. **10.** Damage to the parotid glands, which secrete the carbohydrate-digesting enzyme salivary amylase, would interfere with the digestion of complex carbohydrates. **11.** The incisors are the teeth most useful for chopping (or cutting or shearing) pieces of relatively rigid food, such as raw vegetables. **12.** The fauces are the dividing line between the oral cavity and the pharynx. **PAGE 946** **13.** The pharynx is an anatomical space that receives a food bolus or liquid and passes it to the esophagus as part of the swallowing process. Air also passes through the pharynx. **14.** The structure connecting the pharynx to the stomach is the esophagus. **15.** The muscular layer of the esophagus is an unusual segment of the digestive tract because it (1) contains skeletal muscle cells along most of the length of the esophagus and (2) is surrounded by an adventitia. **16.** Muscles associated with the pharynx and deglutition are the palatal muscles, the palatopharyngeus, stylopharyngeus, and pharyngeal constrictors. **17.** When the soft palate and larynx elevate and the glottis closes, swallowing (deglutition) is occurring. **PAGE 951** **18.** The four major regions of the stomach are the cardia, fundus, body, and pyloric part. **19.** The low pH of the stomach creates an acidic environment that kills most microorganisms ingested with food, denatures proteins and inactivates most enzymes in food, helps break down plant cell walls and meat connective tissue, and activates pepsin. **20.** Large meals, especially meals with a high protein content, stimulate increased stomach acid secretion. When gastric glands are secreting, bicarbonate ions enter the bloodstream and increase the blood pH. This phenomenon is referred to as the alkaline tide. **21.** The vagus nerves (X) contain parasympathetic motor fibers that can stimulate gastric secretions, even if food is not present in the stomach (the cephalic phase of gastric activity). Cutting the branches of the vagus nerves that supply the stomach would prevent this type of secretion from occurring and thereby reduce the likelihood of ulcer formation. **PAGE 961** **22.** Damage to the exocrine pancreas would most impair the digestion of fats (lipids), because it is the primary source of lipases. Even though such damage would also reduce carbohydrate and protein digestion, enzymes for digesting these nutrients are produced by other digestive system structures, including the salivary glands (carbohydrates), the small intestine (carbohydrates and proteins), and the stomach (proteins). **23.** The portal triad is a region of a hepatic lobule made up of the interlobular artery, interlobular vein, and interlobular bile duct. **24.** The gallbladder concentrates and stores bile before secreting it into the small intestine. **PAGE 967** **25.** The three regions of the small intestine from proximal to distal are the duodenum, jejunum, and ileum. **26.** The small intestine has several adaptations that increase its surface area and thus its absorptive capacity for nutrients. The walls of the small intestine have folds called circular folds. The mucosa that covers the circular folds has fingerlike projections, the villi. The epithelial cells that cover the villi have an exposed surface covered by small fingerlike projections, the microvilli. In addition, the small intestine has a very rich supply of blood vessels and lymphatic vessels, which transport the nutrients that are absorbed. **27.** A high-fat meal would raise the cholecystokinin level in the blood. **28.** The hormone secretin, among other things, stimulates the pancreas to release fluid high in buffers to neutralize the chyme that enters the duodenum from the stomach. If the small intestine did not produce secretin, the pH of the intestinal contents would be lower than normal. **PAGE 972** **29.** The four regions of the colon are the ascending colon, transverse colon, descending colon, and sigmoid colon. **30.** The large intestine is larger in luminal diameter than the small intestine. The thin walls of the large intestine lack villi and have an abundance of mucous cells and intestinal glands. **31.** In haustral churning, segmentation movements mix the contents of nearby haustra. In mass movements, which occur a few times per day, strong peristaltic contractions move material from the transverse colon through the rest of the large intestine. **PAGE 977** **32.** The nutrients the body requires are carbohydrates, lipids, proteins, vitamins, electrolytes, minerals, and water. **33.** Because chylomicrons are formed from the fats digested in a meal, fats increase the number of chylomicrons in the lacteals. **34.** Removal of the stomach would interfere with the absorption of vitamin B_{12}. Parietal cells of the stomach are the source of intrinsic factor, which is required for the vitamin's absorption. **35.** When someone with diarrhea loses fluid and electrolytes faster than they can be replaced, the resulting dehydration can be fatal. Although constipation can be quite uncomfortable, it does not interfere with any life-supporting processes; the few toxic wastes normally eliminated by the digestive system can move into the blood and be eliminated by the kidneys. **PAGE 978** **36.** General age-related digestive system changes include decreased mitotic activity of epithelial cells, decreased secretory mechanisms, decreased gastric and intestinal motility, and loss of muscle tone associated with tract sphincters; cumulative damage becomes more apparent, cancer rates increase, and dehydration occurs as a result of decreased osmoreceptor sensitivity. **37.** The digestive system

absorbs the organic substrates, vitamins, ions, and water required by cells of all other body systems. **38.** The skeletal, muscular, nervous, endocrine, and cardiovascular systems may all be affected by inadequate absorption of calcium ions.

Answers to Review Questions

PAGE 982

Level 1 Reviewing Facts and Terms

1. a **2.** b **3.** c **4.** c **5. (a)** oral cavity (mouth); **(b)** liver; **(c)** gallbladder; **(d)** pancreas; **(e)** large intestine; **(f)** salivary glands; **(g)** pharynx; **(h)** esophagus; **(i)** stomach; **(j)** small intestine; **(k)** anus **6. (a)** mucosa; **(b)** submucosa; **(c)** muscular layer; **(d)** serosa **7.** b **8.** b **9.** d **10. (a)** duodenum; **(b)** jejunum; **(c)** ileum **11.** d **12.** b **13.** a **14.** The three major pairs of salivary glands are (1) the parotid glands, (2) the submandibular glands, and (3) the sublingual glands. **15.** Layers of the digestive tract from the innermost layer nearest the lumen to the outermost layer are (1) the mucosa: the epithelial layer that performs chemical digestion and absorption of nutrients; (2) the submucosa: the connective tissue layer containing lymphatic and blood vessels and the submucosal nerve plexus; (3) the muscular layer: the smooth muscle layer containing the myenteric nerve plexus; and (4) the serosa: the outermost layer, epithelium and connective tissue that forms the visceral peritoneum (or connective tissue that forms the adventitia). **16.** Activities of the digestive tract are regulated by local, neural, and hormonal mechanisms. **17.** The three phases of swallowing—the buccal, pharyngeal, and esophageal phases—are controlled by the swallowing center of the medulla oblongata by the trigeminal and glossopharyngeal cranial nerves. The motor commands originating at the swallowing center are distributed by cranial nerves V, IX, X, and XII. Along the esophagus, primary peristaltic contractions are coordinated by afferent and efferent fibers within the glossopharyngeal and vagus cranial nerves, but secondary peristaltic contractions occur in the absence of CNS instructions. **18.** The pancreas provides digestive enzymes, plus bicarbonate ions that elevate the pH of the chyme. The liver produces bile and is also the primary organ involved in regulating the composition of circulating blood. The gallbladder stores and releases bile, which contains additional buffers and bile salts that aid in the digestion and absorption of lipids. **19.** The hormones include the following: enterocrinin, which stimulates the submucosal glands of the duodenum; secretin, which stimulates the pancreas and liver to increase the secretion of water and bicarbonate ions; cholecystokinin (CCK), which causes an increase in the release of pancreatic secretions and bile into the duodenum, inhibits gastric activity, and appears to have CNS effects that reduce the sensation of hunger; gastric inhibitory peptide (GIP), which stimulates insulin release at pancreatic islets and the activity of the duodenal submucosal glands; vasoactive intestinal peptide (VIP), which stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach; gastrin, which is secreted by G cells in the duodenum when they are exposed to large quantities of incompletely digested proteins; and, in small quantities, motilin, which stimulates intestinal contractions; villikinin, which promotes the movement of villi and associated lymph flow; and somatostatin, which inhibits gastric secretion. **20.** The large intestine reabsorbs water and compacts the intestinal contents into feces, absorbs important vitamins liberated by bacterial action, and stores fecal material prior to defecation. **21.** Positive feedback loops in the defecation reflex involve (1) stretch receptors in the rectal walls, which promote a series of peristaltic contractions in the colon and rectum, moving feces toward the anus in the intrinsic myenteric defecation reflex; and (2) the sacral parasympathetic defecation reflex, also activated by the stretch receptors, which stimulates peristalsis by motor commands.

Level 2 Reviewing Concepts

22. e **23.** c **24.** a **25.** Your wisdom tooth has developed in a location that will not allow it to erupt. **26.** The stomach is protected from digestion by mucous secretions of its epithelial lining and by neural and hormonal control over the times and rates of acid secretion. **27.** (1) The cephalic phase of gastric secretion begins with the sight or thought of food. Directed by the CNS, this phase prepares the stomach to receive food. (2) The gastric phase begins with the arrival of food in the stomach; this phase is initiated by distension of the stomach, an increase in the pH of the gastric contents, and the presence of undigested materials in the stomach. (3) The intestinal phase begins when chyme starts to enter the small intestine. This phase controls the rate of gastric emptying and ensures that the secretory, digestive, and absorptive functions of the small intestine can proceed reasonably efficiently. **28.** After a heavy meal, bicarbonate ions pass from the parietal cells of the stomach into the interstitial fluid. The diffusion of bicarbonate ions from the interstitial fluid into the bloodstream increases blood pH. This sudden influx of bicarbonate ions into the bloodstream has been called the alkaline tide.

Level 3 Critical Thinking and Clinical Applications

29. Alcohol is absorbed by the digestive tract and transported to the liver for processing. The cells of the liver are not immune to toxic compounds and chronic exposure to alcohol can lead to cirrhosis. Cirrhosis is characterized by the replacement of healthy liver lobules by fibrous scar tissue. **30.** The darker color of his urine is probably due to increased amounts of the pigment urobilin, which gives urine its normal yellow color. Urobilin is derived from urobilinogen, which is formed in the large intestine by the action of intestinal bacteria on bile pigments. In an intestinal obstruction, the bile pigments cannot be eliminated by their normal route, so a larger-than-normal amount diffuses into the bloodstream, where the kidneys eliminate it. **31.** If an individual cannot digest lactose, this sugar passes into the large intestine in an undigested form. The presence of extra sugar in the chyme increases its osmolarity, so less water is reabsorbed by the intestinal mucosa. The bacteria that inhabit the large intestine can metabolize the lactose, and in the process they produce large amounts of carbon dioxide. This gas overstretches the intestine, which stimulates local reflexes that increase peristalsis. The combination of more-fluid contents and increased peristalsis causes diarrhea. The overexpansion of the intestine by gas, which is directly related to increased gas production by the bacteria, causes the severe pain and abdominal cramping. **32.** The primary effect of such surgeries would be a reduction in the volume of food (and thus in the amount of calories) consumed because the person feels full after eating a small amount. This can result in significant weight loss.

Answers to Clinical Case Wrap-Up

PAGE 984 **1.** If Mirasol's *Clostridium difficile* colitis is not successfully treated with a fecal transplant, she is likely to continue to experience bloody diarrhea. This may result in progressive dehydration that can eventually lead to her death. She may also continue to experience abdominal pain and blood loss. Eventually she may suffer from a lack of vitamin K (required for clotting factor

production), biotin, and vitamin B_5. **2.** If you could look at the lining of Mirasol's large intestine with a colonoscope, the surface would look inflamed, swollen, reddened. You would likely see areas of raw, bleeding mucosa. You might even see areas of white cells, accumulated in pockets of pus, as Mirasol's immune system tries to fight this *C. difficile* infection.

Answers to Figure-Based Questions

FIGURE 24–4 Circular muscles contract behind the bolus to force the bolus forward. Longitudinal muscles contract ahead of the bolus to shorten that segment of the digestive tract.

FIGURE 24–9 The submandibular glands produce glycoproteins called mucins.

FIGURE 24–12 The cardia is the region of the stomach that connects to the esophagus.

FIGURE 24–23 Chyme in the duodenum stimulates the secretion of GIP, secretin, CCK, and VIP.

FIGURE 24–26 Feces moving into the rectum cause distension, which stimulates stretch receptors.

Chapter 25

Answers to Checkpoints

PAGE 988 **1.** Metabolism is the sum of all biochemical processes under way within the human body; it includes anabolism and catabolism. Catabolism is the breakdown of organic molecules into simpler components, accompanied by the release of energy. Anabolism is the synthesis of new organic molecules from simpler components, and it requires energy. **2.** Oxidation is a gain of oxygen, or loss of hydrogen or electrons, from an atom or molecule. Reduction is the loss of oxygen, or gain of hydrogen or electrons, to an atom or molecule. **PAGE 997** **3.** The primary role of the citric acid cycle in ATP production is to transfer electrons from substrates to coenzymes. These electrons provide energy for the production of ATP by the electron transport chain. **4.** The process of oxidative phosphorylation releases energy from high-energy electrons that powers proton (hydrogen ion) pumps. These pumps move hydrogen ions from the mitochondrial matrix into the intermembrane space, creating an electrochemical proton gradient. In chemiosmosis, protons pass through hydrogen ion channels providing the energy necessary to bind ADP and P_i together into ATP. **5.** A decrease in cytosolic NAD would reduce ATP production in mitochondria. Decreased NAD would reduce the amount of pyruvate produced by glycolysis; less pyruvate means that the citric acid cycle could produce less ATP in mitochondria. **PAGE 1001** **6.** Beta-oxidation is fatty acid catabolism that produces molecules of acetyl-CoA. **7.** The four major groups of lipoproteins are chylomicrons, very low density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). **8.** High-density lipoproteins (HDLs) are considered beneficial to health because they reduce the amount of cholesterol in the bloodstream by transporting it to the liver for storage or excretion in the bile. **PAGE 1003** **9.** Transamination is the removal and transfer of an amino group from one molecule to another, especially from an amino acid to a keto acid. Deamination is the removal of an amino group from an amino acid. **10.** A diet deficient in pyridoxine (vitamin B_6), an important coenzyme in deaminating and transaminating amino acids in cells, would interfere with the body's ability to metabolize proteins. **PAGE 1005** **11.** Glycogenesis (the formation of glycogen) in the liver increases after a high-carbohydrate meal. **12.** Blood levels of urea increase during the postabsorptive state because the deamination of many amino acids at that time yields ammonium ions, which are then converted to urea by the liver. **13.** Accumulated acetyl-CoA is likely to be converted into ketone bodies. **PAGE 1012** **14.** The two classes of vitamins are fat soluble and water soluble. **15.** An athlete who is adding muscle mass through extensive training would try to maintain a positive nitrogen balance. **16.** A decrease in the amount of bile salts, which are necessary for digesting and absorbing fats and fat-soluble vitamins (including vitamin A), would result in less vitamin A in the body, and perhaps a vitamin A deficiency. **PAGE 1018** **17.** The BMR of a pregnant woman would be higher than her own BMR when she is not pregnant, due to both the increased metabolism associated with supporting the fetus and the contribution of fetal metabolism. **18.** The vasoconstriction of peripheral vessels would decrease blood flow to the skin and thus the amount of heat the body can lose. As a result, body temperature would increase. **19.** Infants have higher surface-to-volume ratios than do adults, and the body's temperature-regulating mechanisms are not fully functional at birth. As a result, infants must expend more energy to maintain body temperature, and they get cold more easily than do healthy adults.

Answers to Review Questions

PAGE 1020

Level 1 Reviewing Facts and Terms

1. a **2.** e **3.** d **4.** a **5.** d **6.** a **7. (a)** evaporation; **(b)** radiation; **(c)** convection; **(d)** conduction **8.** c **9.** Lipoproteins are lipid–protein complexes that contain large insoluble glycerides and cholesterol, with a superficial coating of phospholipids and proteins. The major groups are chylomicrons, which consist of 95 percent triglyceride, are the largest lipoproteins, and carry absorbed lipids from the intestinal tract to the bloodstream; very low density lipoproteins (VLDLs), which consist of triglyceride, phospholipid, and cholesterol, and transport triglycerides to peripheral tissues; low-density lipoproteins (LDLs, or "bad cholesterol"), which are mostly cholesterol and deliver cholesterol to peripheral tissues; and high-density lipoproteins (HDLs, or "good cholesterol"), which are equal parts protein and lipid (cholesterol and phospholipids) and transport excess cholesterol to the liver for storage or excretion in bile.

Level 2 Reviewing Concepts

10. Oxidative phosphorylation is the generation of ATP as the result of the transfer of electrons from the coenzymes NADH and $FADH_2$ to oxygen by a sequence of electron carriers within mitochondria. The electrons are carried by the electron transport chain in the inner mitochondrial membrane. Energy from the stepwise passage of electrons (from H atoms) along the electron transport chain is used to pump hydrogen ions from the matrix into the intermembrane space. This forms an electrochemical proton (hydrogen ion) gradient across the inner mitochondrial membrane. Through the process of chemiosmosis, the hydrogen ions diffuse back through ATP synthase and generate ATP. The electrons, hydrogen ions, and oxygen combine to produce water as a by-product. **11.** When glucose supplies are low and lipid reserves are inadequate, cells use amino acids to generate ATP by breaking them down in the citric acid cycle. All amino acids do not enter the cycle at the same point, so the ATP yield varies. **12.** During the absorptive state, insulin prevents a large surge in blood glucose after a meal by causing the liver to remove glucose from the hepatic portal circulation. During the postabsorptive state, blood glucose begins to decline, triggering the liver to release glucose

produced through glycogenolysis and gluconeogenesis. **13.** Proteins are the most abundant organic components of the body, and they contain a great deal of nitrogen. Therefore, nitrogen balance equals protein balance. And, since a number of vital functions are performed by proteins, nitrogen balance is important for maintaining homeostasis. **14.** Vitamins and minerals are essential components of the diet because the body cannot synthesize most of the vitamins and minerals it requires. **15.** These terms refer to lipoproteins in the blood that transport cholesterol. "Good cholesterol" (high-density lipoproteins, or HDLs) transports excess cholesterol to the liver for storage or breakdown, whereas "bad cholesterol" (low-density lipoproteins, or LDLs) transports cholesterol to peripheral tissues, which unfortunately may include the arteries. The buildup of cholesterol in the arteries is linked to cardiovascular disease.

Level 3 Critical Thinking and Clinical Applications

16. d **17.** Based just on the information given, Charlie would appear to be in good health, at least relative to his diet and probable exercise. Problems are associated with elevated levels of LDLs, which carry cholesterol to peripheral tissues and make it available for the formation of atherosclerotic plaques in blood vessels. High levels of HDLs indicate that a considerable amount of cholesterol is being removed from the peripheral tissues and carried to the liver for disposal. You would encourage Charlie not to change, and keep up the good work. **18.** It appears that Jill is suffering from ketoacidosis as a consequence of her anorexia. Because she is literally starving herself, her body is metabolizing large amounts of fatty acids and amino acids to provide energy, and in the process is producing large quantities of ketone bodies (normal metabolites from these catabolic processes). One of the ketones formed is acetone, which can be eliminated through the lungs. Acetone has a fruity aroma, so her breath would also smell fruity. The ketones are also converted into keto acids such as acetic acid. In large amounts, this lowers the body's pH. This is probably the cause of her arrhythmias.

Answers to Clinical Case Wrap-Up

PAGE 1021 **1.** Diet and vitamin supplementation are the only known sources of vitamin A. Unlike some other vitamins that can be made by our skin (vitamin D_3) or by intestinal bacteria [vitamin K, biotin (B_7), pantothenic acid(B_5)], vitamin A is a true *essential* vitamin that must be consumed orally. **2.** Justine's vitamin-deficient diet is likely to lead to deficiencies of all the fat-soluble and water-soluble vitamins, including D, E, K, all the B vitamins, and vitamin C.

Answers to Figure-Based Questions

FIGURE 25–2 Glycolysis produces 2 pyruvate molecules with a net gain of 2 ATP molecules.

FIGURE 25–5 The energy produced from aerobic metabolism comes from the electron transport chain and the citric acid cycle.

FIGURE 25–7 Beta-oxidation, the breakdown of fatty acids, takes place within the mitochondria.

FIGURE 25–8 The liver manufactures very low density lipoproteins (VLDLs) and low-density lipoproteins (LDLs).

FIGURE 25–14 In a warm environment, more blood returns to the trunk through superficial veins. This allows heat to radiate to the environment through the skin instead of conserving heat.

Chapter 26

Answers to Checkpoints

PAGE 1024 **1.** The three major functions of the urinary system include (1) the excretion of metabolic wastes from body fluids, (2) the elimination of body wastes to the exterior, and (3) the regulation of homeostasis by maintaining the volume and solute concentration of blood. **2.** The urinary system consists of two kidneys, two ureters, a urinary bladder, and a urethra. **PAGE 1032** **3.** The renal corpuscle, proximal convoluted tubule, distal convoluted tubule, and the proximal part of the nephron loop and collecting duct are all in the renal cortex. (In a cortical nephron, most of the nephron loop is in the renal cortex; in a juxtamedullary nephron, most of the nephron loop is in the renal medulla.) **4.** Plasma proteins are too large to pass through the pores of the glomerular capillaries; only the smallest plasma proteins can pass between the foot processes of the podocytes. **5.** Damage to the juxtaglomerular complex of a nephron would interfere with blood pressure regulation. **PAGE 1034** **6.** The three distinct processes that form urine in the kidney are filtration, reabsorption, and secretion. **PAGE 1039** **7.** The parts of the glomerulus involved in filtration are the glomerular capillaries, the basement membrane, and the foot processes of the podocytes. **8.** The factors that influence net filtration pressure are net hydrostatic pressure and blood colloid osmotic pressure. **9.** The factors that influence the rate of filtrate formation are the filtration pressure across glomerular capillaries, plus interactions among the responses by autoregulation, hormonal regulation (endocrine), and autonomic regulation (neural). **10.** A decrease in blood pressure would decrease the GFR by decreasing the blood hydrostatic pressure within the glomerulus. **PAGE 1046** **11.** When the plasma concentration of a substance exceeds its tubular maximum, the excess is not reabsorbed, so it is excreted in the urine. **12.** Increased amounts of aldosterone, which promotes Na^+ retention and K^+ secretion by the kidneys, would increase the K^+ concentration of urine. **13.** If the concentration of Na^+ in the filtrate decreased, fewer hydrogen ions could be secreted by the countertransport mechanism involving these two ions. As a result, the pH of the tubular fluid would increase. **14.** When the amount of Na^+ in the tubular fluid passing through the distal convoluted tubule decreases, the cells of the macula densa are stimulated to release renin. The resulting activation of angiotensin II increases blood pressure. **PAGE 1055** **15.** Without juxtamedullary nephrons, a steep osmotic concentration gradient could not exist in the medulla, and the kidneys would be unable to form concentrated urine. **16.** Digestion of a high-protein diet would lead to increased production of urea, a nitrogenous waste formed from the metabolism of amino acids during the breakdown of proteins. As a result, the urine would contain more urea, and urine volume might also increase as a result of the need to flush the excess urea. **PAGE 1059** **17.** An obstruction of a ureter would interfere with the passage of urine between the renal pelvis and the urinary bladder. **18.** The ability to control the urinary reflexes depend on the ability to control the external urethral sphincter, a ring of skeletal muscle, which acts as a valve. **PAGE 1060** **19.** Four general age-related changes in the urinary system are a decrease in the number of functional nephrons, a reduction in the GFR, a reduced sensitivity to ADH, and problems with the urinary reflex. **20.** Nephrolithiasis is the formation of renal calculi, or kidney stones. **21.** Incontinence may develop in elderly individuals as a result of either decreased muscle tone of the sphincter

muscles controlling micturition or disorders of the CNS affecting the ability to control urination. **PAGE 1060** **22.** For all systems, the urinary system excretes wastes collected from blood and maintains normal body fluid pH and ion composition. **23.** Body systems that make up the body's excretory system include the urinary, integumentary, respiratory, and digestive systems.

Answers to Review Questions

PAGE 1064

Level 1 Reviewing Facts and Terms

1. **(a)** renal sinus; **(b)** renal pelvis; **(c)** hilum; **(d)** renal papilla; **(e)** ureter; **(f)** renal cortex; **(g)** renal medulla; **(h)** renal pyramid; **(i)** minor calyx; **(j)** major calyx; **(k)** kidney lobe; **(l)** renal columns; **(m)** fibrous capsule **2.** b **3.** e **4.** c **5.** b **6.** d **7.** The urinary system excretes the metabolic wastes generated by cells throughout the body and eliminates them from the body in urine. It also regulates the volume and solute concentration of body fluids. **8.** The kidneys, ureters, urinary bladder, and urethra are the organs of the urinary system. **9.** renal corpuscle (glomerulus/glomerular capsule) → proximal convoluted tubule → nephron loop → distal convoluted tubule → collecting duct → papillary duct → renal pelvis **10.** proximal convoluted tubule: reabsorbs all the useful organic substrates from the filtrate; nephron loop: reabsorbs over 90 percent of the water in the filtrate; and distal convoluted tubule: secretes wastes into the tubular fluid that were not filtered or reabsorbed **11.** The juxtaglomerular complex secretes the enzyme renin and the hormone erythropoietin. **12.** renal artery → segmental arteries → interlobar arteries → arcuate arteries → cortical radiate arteries → afferent arterioles → glomerulus → venules → cortical radiate veins → arcuate veins → interlobar veins → renal vein **13.** Processes in urine production are (1) filtration: the selective removal of large solutes and suspended materials from a solution on the basis of size; requires a filtration membrane and hydrostatic pressure, as provided by gravity or by blood pressure; (2) reabsorption: the removal of water and solute molecules from the filtrate after it enters the renal tubules; and (3) secretion: the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid **14.** In peripheral capillary beds, angiotensin II causes powerful vasoconstriction of precapillary sphincters, increasing pressures in the renal arteries and their branches. At the nephron, angiotensin II causes the efferent arteriole to constrict, increasing glomerular pressures and filtration rates. At the PCT, it stimulates the reabsorption of sodium ions and water. In the CNS, angiotensin II triggers the release of ADH, stimulating the reabsorption of water in the distal portion of the DCT and the collecting system, and it causes the sensation of thirst. At the adrenal gland, angiotensin II stimulates the secretion of aldosterone by the cortex. Aldosterone accelerates sodium reabsorption in the DCT and the cortical portion of the collection system. **15.** In urine, urea is the most abundant waste product, followed by creatinine, ammonia, and uric acid.

Level 2 Reviewing Concepts

16. d **17.** d **18.** a **19.** a **20.** a **21.** Creatinine clearance is a test that compares the creatinine level in urine with the creatinine level in blood by estimating the glomerular filtration rate (GFR). It is used as an index of overall kidney function. **22.** Controls on GFR are autoregulation at the local level, hormonal regulation initiated by the kidneys, and autonomic regulation (by the sympathetic division of the ANS). **23.** GHP is the blood pressure in the glomerular capillaries. This pressure tends to push water and solute molecules out of the plasma and into the filtrate. CsHP opposes GHP. CsHP tends to push water and solutes out of the filtrate and into the plasma, and results from the resistance of filtrate already present in the nephron that must be pushed toward the renal pelvis. The difference between GHP and CsHP is the net hydrostatic pressure (NHP). **24.** Countercurrent multiplication (1) is an efficient way to reabsorb solutes and water before the tubular fluid reaches the DCT and collecting system, and (2) establishes an osmotic concentration gradient in the medulla that permits the passive reabsorption of water from urine in the collecting system. **25.** Urine storage occurs by spinal reflexes and the pontine storage center. When urine is being stored, afferent impulses from stretch receptors in the bladder wall stimulate sympathetic outflow to the detrusor and internal urethral sphincter, inhibiting contraction of the detrusor and stimulating contraction of the internal urethral sphincter. The pontine storage center inhibits urination by decreasing parasympathetic activity and increasing somatic motor nerve activity at the external urethral sphincter. Urine cannot pass through the urethra and remains stored.

Level 3 Critical Thinking and Clinical Applications

26. d **27.** c **28.** Increasing the volume of urine produced decreases the total blood volume of the body, which in turn leads to a decreased blood hydrostatic pressure. Edema frequently results when the hydrostatic pressure of the blood exceeds the opposing forces at the capillaries in the affected area. Depending on the actual cause of the edema, decreasing the blood hydrostatic pressure would decrease edema formation and possibly cause some of the fluid to move from the interstitial spaces back to the blood. **29.** Renal arteriosclerosis restricts blood flow to the kidneys and produces renal ischemia. Decreased blood flow and ischemia trigger the juxtaglomerular complex to produce more renin, which leads to elevated levels of angiotensin II and aldosterone. Angiotensin II causes vasoconstriction, increased peripheral resistance, and thus increased blood pressure. The aldosterone promotes sodium retention, which leads to more water retained by the body and an increase in blood volume. This too contributes to a higher blood pressure. Additionally, in response to tissue hypoxia, erythropoietin release is increased, stimulating the formation of red blood cells, which leads to increased blood viscosity and again contributes to hypertension. **30.** Bert probably has kidney stones. Kidney stones create urinary obstruction. This condition can cause extreme pain and decrease or even prevent filtration in the affected kidney. **31.** Carbonic anhydrase catalyzes the reaction that forms carbonic acid, a source of hydrogen ions that are excreted by the kidneys. Hydrogen ion excretion occurs by countertransport in which sodium ions are exchanged for hydrogen ions. Fewer hydrogen ions would be available, so less sodium would be reabsorbed, causing an increased osmolarity of the filtrate. In turn, an increased volume of urine and more frequent urination would result.

Answers to Clinical Case Wrap-Up

PAGE 1065 **1.** Mike's x-rays show fractures of the left 11th and 12th ribs, overlying the left kidney. They also show fractures of the transverse processes of the first three lumbar vertebrae on the left. The left renal hilum lies between the fractured ribs and the fractured lumbar vertebral transverse processes. These visible fractures are a strong indication that the soft tissues and organs in this area are also injured. **2.** If Mike survives this trauma, the GFR of his solitary

right kidney is likely to increase to compensate for the loss of his left kidney. This is to be expected if there has been no trauma to his right kidney.

Answers to Figure-Based Questions

FIGURE 26–5 A glomerulus is located in the renal cortex.

FIGURE 26–6 The proximal convoluted tubule is connected to the distal convoluted tubule by the nephron loop, which consists of the descending thin limb (DTL), ascending thin limb (ATL), and the thick ascending limb (TAL).

FIGURE 26–11 An increased blood volume results from increased Na^+ retention, increased fluid consumption, increased fluid retention, and constriction of systemic veins.

FIGURE 26–13 Aldosterone-sensitive portions of the distal convoluted tubule and collecting duct allow for sodium ions to be reabsorbed in exchange for potassium ions to be passively lost.

FIGURE 26–15 ADH creates a small volume of concentrated urine.

FIGURE 26–18 The ureter transports urine *to* the bladder.

Chapter 27

Answers to Checkpoints

PAGE 1069 **1.** The three interrelated processes essential to stabilizing body fluid volumes are fluid balance, electrolyte balance, and acid-base balance. **PAGE 1073** **2.** The components of extracellular fluid (ECF) are interstitial fluid, plasma, and other body fluids; the intracellular fluid (ICF) is the cytosol of a cell. **3.** Three hormones affecting fluid and electrolyte balance are antidiuretic hormone (ADH), aldosterone, and natriuretic peptides (ANP and BNP). **4.** Drinking a half-gallon of distilled water might temporarily decrease your blood osmolarity (osmotic concentration). This decrease in osmolarity would lead to a decrease in the level of ADH in your blood, because ADH release is triggered by increases in osmolarity. **PAGE 1076** **5.** Edema (swelling) results from the movement of abnormally large amounts of water from plasma into interstitial fluid. **6.** A fluid shift is a rapid movement of water between the ECF and ICF in response to an osmotic gradient. **7.** Dehydration is a decrease in the water content of the body that develops when water losses outpace water gains, and this threatens homeostasis. **8.** Being in the desert without water, you would lose fluid through perspiration, urination, and breathing. As a result, the osmotic concentration of your blood plasma (and other body fluids) would increase. **PAGE 1081** **9.** In the ECF, four important cations are sodium, potassium, calcium, and magnesium; two important anions are phosphate and chloride. **10.** Sweat is a hypotonic solution with lower sodium ion concentration than the ECF. Sweating causes a greater loss of water than of sodium, increasing the blood plasma sodium ion level. **11.** Potassium ion imbalances are more dangerous than sodium ion imbalances because they can lead to extensive muscle weakness or even paralysis when blood concentrations are too low, and to cardiac arrhythmias when the levels are too high. Disturbances in sodium balance, by contrast, produce dehydration or tissue edema. **PAGE 1088** **12.** The body's three major buffer systems are the phosphate buffer system, the protein buffer systems, and the carbonic acid–bicarbonate buffer system. **13.** A decrease in the pH of body fluids accompanies an increase in the partial pressure of carbon dioxide. Chemoreceptors sensitive to P_{CO_2} would stimulate the respiratory centers of the medulla oblongata, resulting in an increase in the respiratory rate. **14.** Tubular fluid in nephrons must be buffered to avoid decreasing the pH below approximately 4.5, at which point H^+ secretion cannot continue because the H^+ concentration gradient becomes too steep. The hydrogen ions would leak out of the tubule as fast as they are pumped in. **PAGE 1095** **15.** In a prolonged fast, fatty acids are catabolized, producing large numbers of ketone bodies, which are metabolic acids that decrease the blood pH. (The decreased pH would eventually lead to ketoacidosis.) **16.** When a person has prolonged vomiting, large amounts of stomach hydrochloric acid (HCl) are lost from the body. More H^+ and Cl^- are then formed by the parietal cells of the stomach. The H^+ that are released were produced by the dissociation of carbonic acid and exchange of bicarbonate ions with chloride ions from the blood. The alkaline tide of released bicarbonate ions increases the blood pH, leading to metabolic alkalosis. **PAGE 1097** **17.** A decrease in the glomerular filtration rate and the number of functional nephrons reduces the body's ability to regulate pH through renal compensation. **18.** Total body water content gradually decreases with age.

Answers to Review Questions

PAGE 1099

Level 1 Reviewing Facts and Terms

1. c **2.** c **3.** a **4. (a)** carbonic acid (H_2CO_3); **(b)** bicarbonate ion (HCO_3^-); **(c)** sodium bicarbonate ($NaHCO_3$) **5.** d **6.** d **7.** b **8.** d **9.** a **10.** The primary role of the carbonic acid–bicarbonate buffer system is to prevent changes in pH caused by metabolic acids and fixed acids in the ECF. The three limitations are as follows: (1) It cannot protect the ECF from changes in pH that result from an increased or decreased level of CO_2; (2) it can function only when the respiratory system and the respiratory control centers are working normally; and (3) the ability to buffer acids is limited by the availability of bicarbonate ions.

Level 2 Reviewing Concepts

11. c **12.** b **13.** c **14.** b **15.** Fluid balance is a state in which the amount of water gained each day is equal to the amount lost to the environment. It is vital that the water content of the body remain stable, because water is an essential ingredient of cytoplasm and accounts for about 99 percent of ECF volume. Electrolyte balance exists when there is neither a net gain nor a net loss of any ion in body fluids. It is important that the ionic concentrations in body water remain within normal limits; if levels of calcium or potassium become too high, for instance, cardiac arrhythmias can develop. Acid-base balance exists when the production of hydrogen ions precisely offsets their loss. The pH of body fluids must remain within a relatively narrow range; variations outside this range can be life threatening. **16.** Fluid shifts are rapid water movements between the ECF and the ICF that occur in response to increases or decreases in the osmotic concentration of the ECF. Such water movements dampen extreme shifts in electrolyte balance. **17.** A person with a fever should increase fluid intake because for each degree (Celsius) the body temperature increases above normal, daily water loss increases by 200 mL. **18. (a)** Acids that can leave solution and enter the atmosphere, such as carbonic acid, are volatile acids. **(b)** Acids that do not leave solution, such as sulfuric acid, are fixed acids. **(c)** Acids produced during metabolism, such as pyruvic acid, lactic acid, and ketones, are metabolic acids. Volatile acids are the

greatest threat because of the large amounts generated by normal cellular processes. **19.** (1) Phosphate buffer system: This buffer system consists of dihydrogen phosphate ($H_2PO_4^-$) a weak acid that, in solution, reversibly dissociates into a hydrogen ion and monohydrogen phosphate (HPO_4^{2-}). The phosphate buffer system plays a relatively small role in regulating the pH of the ECF, because the ECF contains far higher concentrations of bicarbonate ions than phosphate ions; however, it is important in buffering the pH of the ICF. (2) Protein buffer systems: These depend on the ability of amino acids to respond to changes in pH by accepting or releasing hydrogen ions. If the pH rises, the carboxyl group of the amino acid dissociates to release a hydrogen ion; if the pH drops, the amino group accepts an additional hydrogen ion to form an amino ion (NH_3^+) and the carboxylate ion can accept a hydrogen ion to form a carboxyl group. Plasma proteins contribute to the buffering capabilities of the blood; inside cells, protein buffer systems stabilize the pH of the ECF by absorbing extracellular hydrogen ions or exchanging intracellular hydrogen ions for extracellular potassium. (3) Carbonic acid–bicarbonate system: Most carbon dioxide generated in tissues is converted to carbonic acid, which dissociates into a hydrogen ion and a bicarbonate ion. Hydrogen ions released by dissociation of organic or fixed acids combine with bicarbonate ions, elevating the P_{CO_2}; additional CO_2 is lost at the lungs. **20.** A patient with hypocalcemia can develop osteoporosis and muscle spasms, and can also have convulsions. **21.** Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Increasing or decreasing the rate of respiration alters pH by decreasing or increasing the P_{CO_2}. When the P_{CO_2} decreases, the pH increases; when the P_{CO_2} increases, the pH decreases. Renal compensation is a change in the rates of hydrogen and bicarbonate ion secretion or reabsorption in response to changes in blood pH. The secretion of hydrogen ions into tubular fluid results in the diffusion of bicarbonate ions into the ECF. **22.** Respiratory disorders result from abnormal CO_2 levels in the ECF. An imbalance exists between the rate of CO_2 removal by the lungs and its generation in other tissues. Metabolic disorders are caused by the generation of metabolic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF. **23.** After the age of 60, the total body water content declines to about 50 percent for males and 45 percent for females. This decrease reduces the dilution of waste products. **24.** Drinks with low glucose concentrations are useful in replenishing exhausted metabolic reserves. Drinks with high glucose concentrations can lead to cramps and diarrhea. **25.** Since sweat is usually hypotonic, the loss of a large volume of sweat causes hypertonicity in body fluids. The loss of fluid volume is primarily from the interstitial space, which leads to a decrease in plasma volume and an increase in the hematocrit. Severe dehydration can cause the blood viscosity to increase substantially, resulting in an increased workload on the heart, ultimately increasing the probability of heart failure.

Level 3 Critical Thinking and Clinical Applications

26. The young boy has metabolic and respiratory acidosis. The metabolic acidosis resulted primarily from the large amounts of lactate and H^+ generated by the boy's muscles as he struggled in the water. Sustained hypoventilation during drowning contributed to both tissue hypoxia and respiratory acidosis. Respiratory acidosis developed as the P_{CO_2} increased in the ECF, increasing the production of carbonic acid and its dissociation into H^+ and HCO_3^-. Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance (to increase the respiratory rate and decrease in the ECF) coupled with the intravenous infusion of a buffered isotonic solution containing sodium lactate, sodium gluconate, or sodium bicarbonate that would absorb the H^+ in the ECF and increase body fluid pH. **27.** b **28.** When tissues are burned, cells are destroyed and their cytoplasmic contents leak into the interstitial fluid and then move into the plasma. Since potassium ions are normally found within the cell, damage to a large number of cells releases relatively large amounts of potassium ions into the blood. The elevated potassium level stimulates cells of the adrenal cortex to produce aldosterone and cells of the juxtaglomerular complex to produce renin. Renin activates the renin-angiotensin-aldosterone system. Ultimately, angiotensin II stimulates increased aldosterone secretion, which promotes sodium retention and potassium secretion by the kidneys, thereby accounting for the elevated potassium levels in the patient's urine. **29.** Digestive secretions contain high levels of bicarbonate, so individuals with diarrhea can lose significant amounts of this important ion, leading to acidosis. We would expect Milly's blood pH to be lower than 7.35, and that of her urine to be low (due to increased renal excretion of hydrogen ions). We would also expect an increase in the rate and depth of breathing as the respiratory system tries to compensate by eliminating carbon dioxide. **30.** The hypertonic solution will cause fluid to move from the ICF to the ECF, further aggravating Yuka's dehydration. The slight increase in pressure and osmolarity of the blood should lead to an increase in ADH, even though ADH levels are probably quite high already. Despite the high ADH levels, urine volume would probably increase, because the kidneys could not reabsorb much of the glucose. The remaining glucose would increase the osmolarity of the tubular filtrate, decreasing water reabsorption and increasing urine volume. **31.** Patient 1 has compensated respiratory alkalosis. Patient 2 has acute metabolic acidosis due to the generation or retention of metabolic or fixed acids. Patient 3 has acute respiratory acidosis. Patient 4 has metabolic alkalosis.

Answers to Clinical Case Wrap-Up

PAGE 1100 **1.** Marquis should be treated with potassium replacement. He can take K^+ orally, or it can be given intravenously (IV) for faster replacement. His doctor should consider changing his blood pressure medication to one that does not cause a loss of K^+. (These are often called potassium-sparing diuretics.) **2.** When Marquis complains of a "frog jumping around" in his chest with dizziness, he is likely describing a cardiac arrhythmia. This can be the most serious complication of hypokalemia and can lead to sudden cardiac death.

Answers to Figure-Based Questions

FIGURE 27–2 Mg^{2+} and K^+ are found in higher concentrations in the intracellular fluid, while Na^+ and Cl^- are found in higher concentrations in the extracellular fluid.

FIGURE 27–7 If the K^+ concentration rises above 7 mEq/L (hyperkalemia), a serious condition that could occur is a cardiac arrhythmia.

FIGURE 27–10 The phosphate and protein buffer systems help regulate the pH of the intracellular fluid (ICF).

FIGURE 27–14 The kidney's response to alkalosis is to conserve H^+ and secrete HCO_3^-.

FIGURE 27–16 In metabolic acidosis, arterial and CSF chemoreceptors are stimulated, which results in increased respiratory rate and a decrease in P_{CO_2}.

Chapter 28

Answers to Checkpoints

PAGE 1103 **1.** A gamete is a functional male or female reproductive cell. **2.** Basic structures of the reproductive system are gonads (reproductive organs), ducts (which receive and transport gametes), accessory glands (which secrete fluids), and external genitalia (perineal structures). **3.** Gonads are reproductive organs that produce gametes and hormones. **PAGE 1111** **4.** Male reproductive structures are the scrotum, testes, epididymides, ductus deferentia, ejaculatory duct, urethra, seminal glands, prostate, bulbo-urethral glands, and penis. **5.** On a warm day, the cremaster (as well as the dartos muscle) would be relaxed so that the scrotum could descend away from the warmth of the body, thereby cooling the testes. **6.** The pathway of sperm is as follows: seminiferous tubule → straight tubule → rete testis → efferent ductules → epididymis → ductus deferens → ejaculatory duct → urethra. **PAGE 1118** **7.** Low FSH levels would lead to low levels of testosterone in the seminiferous tubules, decreasing both the sperm production rate and sperm count. **PAGE 1128** **8.** Structures of the female reproductive system include the ovaries, uterine tubes, uterus, vagina, and external genitalia (mons pubis, the clitoris and the labia majora and labia minora). **9.** The blockage of both uterine tubes would cause sterility. **10.** The acidic pH of the vagina helps prevent bacterial, fungal, and parasitic infections in this region. **11.** Blockage of a single lactiferous sinus would not interfere with the delivery of milk to the nipple because the mammary gland of each breast generally has 15–20 lactiferous sinuses. **PAGE 1137** **12.** The functional layer of the endometrium is sloughed off, or shed, during menstruation. **13.** If the LH surge did not occur during an ovarian cycle, ovulation and corpus luteum formation would not occur. **14.** Blockage of progesterone receptors in the uterus would inhibit the development of the endometrium, making the uterus unprepared for pregnancy. **15.** A decrease in the levels of estrogens and progesterone signals the beginning of menstruation, the end of the uterine cycle. **PAGE 1139** **16.** When the arteries within the penis dilate, the increased blood flow causes the erectile tissues of the corpora cavernosa and corpus spongiosum to engorge with blood, producing an erection. **17.** The physiological events of sexual intercourse in both sexes are arousal, erection, lubrication, orgasm, and resolution. Emission and ejaculation are additional phases that occur only in males. **18.** An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with a male's ability to ejaculate and to experience orgasm. **19.** Parasympathetic stimulation in females during sexual arousal causes **(a)** engorgement of the erectile tissue of the clitoris and vestibular bulbs, **(b)** increased secretion of cervical and greater vestibular glands, **(c)** increased blood flow to the wall of the vagina, and **(d)** engorgement of the blood vessels in the nipples. **PAGE 1142** **20.** The genital tubercle of a sexually indifferent embryo will develop into a penis in the presence of testosterone or a clitoris without testosterone. **21.** The male climacteric, or andropause, is a period of declining reproductive function in men, typically between the ages of 50 and 60. **22.** Menopause is the time when ovulation and menstruation cease, typically around ages 45–55. **23.** At menopause, circulating estrogen levels begin to decrease. Estrogen has an inhibitory effect on FSH (and on GnRH). As the level of estrogen decreases, the levels of FSH increase and remain high. **PAGE 1144** **24.** The cardiovascular system distributes reproductive hormones; provides nutrients, oxygen, and waste removal for the fetus; and produces local blood pressure changes responsible for the physical changes that occur during sexual intercourse. The reproductive system supplies estrogens that may help maintain healthy blood vessels and slow the development of atherosclerosis. **25.** Pelvic bones protect reproductive organs in females and portions of the ductus deferens and accessory glands in males; sex hormones stimulate growth and maintenance of bones, and accelerate growth and closure of epiphyseal cartilages at puberty.

Answers to Review Questions

PAGE 1146

Level 1 Reviewing Facts and Terms

1. e **2.** d **3.** d **4.** c **5.** a **6.** The accessory structures include the seminal glands (seminal vesicles), which provide the nutrients that sperm need for motility; prostaglandins that stimulate smooth muscle contractions along the male and female reproductive tracts thereby propelling sperm and fluids; fibrinogen that temporarily clots the ejaculate within the vagina; buffers that counteract the acidity of the prostatic secretions and urethral and vaginal contents; the prostate gland, which aids the activation of the sperm (with seminal gland secretions); and the bulbo-urethral glands, which buffer acids in the penile urethra and lubricate the glans penis. The fluids secreted by the accessory glands make up about 95 percent of the volume of semen. **7.** Interstitial endocrine cells (Leydig cells) produce male sex hormones (androgens), the most important of which is testosterone; nurse cells maintain the blood testis barrier, support spermatogenesis and spermiogenesis, and secrete inhibin, and androgen-binding protein. **8.** The parasympathetic division of the autonomic nervous system controls sexual arousal. **9.** In males, testosterone stimulates spermatogenesis and promotes the functional maturation of sperm; maintains the male accessory reproductive organs; determines male secondary sex characteristics; stimulates metabolic pathways, especially those concerned with protein synthesis and muscle growth; and affects CNS function, by stimulating sexual drive and sexual behaviors. **10.** Steps of the ovarian cycle are (1) the development of a dominant tertiary follicle, or mature graafian follicle, (2) ovulation, and (3) the formation of the corpus luteum and its degeneration into the corpus albicans. **11.** The myometrium is the middle, muscular layer of the uterine wall; the endometrium is the inner, glandular layer; and the perimetrium is an incomplete outer serosal layer. **12.** The clitoris—a part of the external genitalia of females that is derived from the same embryonic structures as the penis—contains erectile tissue that becomes engorged with blood during sexual arousal and provides pleasurable sensations. **13.** Path of milk flow: secretory lobules of glandular tissue (lobes) → ducts → lactiferous duct → lactiferous sinus, which opens onto the surface of the nipple. **14.** **(a)** prostatic urethra; **(b)** spongy urethra; **(c)** ductus deferens; **(d)** penis; **(e)** epididymis; **(f)** testis; **(g)** external urethral orifice; **(h)** scrotum; **(i)** seminal gland; **(j)** prostate; **(k)** ejaculatory duct; **(l)** bulbo-urethral gland.

Level 2 Reviewing Concepts

15. a **16.** The hypothalamic secretion of GnRH triggers the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian thecal endocrine cells produce

estrogens. High estrogen levels stimulate LH secretion and increase anterior pituitary lobe sensitivity to GnRH, causing the release of LH. Progesterone is the main hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for maintaining the uterine cycle. **17.** To produce gametes, diploid parent cells undergo meiosis (I and II) and give rise to four cells, among which the chromosomes are evenly distributed. In males, four spermatids of identical size are produced, and each develops into a functional sperm. In females, one oocyte and three polar bodies are produced, and the oocyte completes meiosis II only if fertilization takes place. **18.** The corpora cavernosa extend along the length of the penis as far as the neck of the penis, and the erectile tissue within each corpus cavernosum surrounds a central artery. The slender corpus spongiosum surrounds the urethra and extends from the superficial fascia of the urogenital diaphragm to the tip of the penis, where it expands to form the glans penis. The sheath surrounding the corpus spongiosum contains more elastic fibers than the corpora cavernosa, and the erectile tissue contains a pair of arteries. When parasympathetic neurons innervating the penile arteries release nitric oxide, smooth muscles in the arterial walls relax, dilating the vessels and increasing blood flow; the resulting engorgement of the vascular channels with blood causes erection of the penis. **19.** (1) The menstrual phase is the interval marked by the degeneration and loss of the functional layer of the endometrium, lasts 1–7 days, and 35–50 mL (1.2–1.7 oz) of blood is lost. (2) The proliferative phase features growth and vascularization, resulting in the complete restoration of the functional layer; it lasts from the end of menstruation until the beginning of ovulation, around day 14. (3) During the secretory phase, the uterine glands enlarge, accelerating their rates of secretion, and the arteries elongate and spiral through the tissues of the functional layer; this phase begins at ovulation, occurs under the combined stimulatory effects of progesterone and estrogens from the corpus luteum, and persists as long as the corpus luteum remains intact. **20.** As follicular development proceeds, the concentration of circulating estrogen rises and the level of circulating inhibin rises. The rising estrogen and inhibin levels inhibit hypothalamic secretion of GnRH and pituitary production and release of FSH. (GnRH pulse frequency is increased by estrogens and decreased by progesterone.) As tertiary ovarian follicles develop and estrogen levels rise, the pituitary output of LH gradually increases. Estrogens, FSH, and LH continue to support follicular development and maturation despite a gradual decline in FSH levels. In the second week of the ovarian cycle, estrogen levels sharply increase, and the dominant tertiary ovarian follicle enlarges in preparation for ovulation. By day 14, estrogen levels peak, triggering a massive outpouring of LH from the anterior lobe of the pituitary gland. The rupture of the follicular wall results in ovulation. Next, LH stimulates the formation of the corpus luteum, which secretes moderate amounts of estrogens but large amounts of progesterone, the principal hormone of the postovulatory period. About 12 days after ovulation, declining progesterone and estrogen levels stimulate hypothalamic receptors and GnRH production increases, leading to increased FSH and LH production in the anterior lobe of the pituitary gland; the cycle begins again. **21.** The corpus luteum degenerates and progesterone and estrogen levels decrease, causing degeneration of the endometrium and the onset of menstruation. Next, rising levels of FSH, LH, and estrogen stimulate the repair and regeneration of the functional layer of the endometrium. During the postovulatory phase, the combination of estrogen and progesterone causes the enlargement of the uterine glands and an increase in their secretory activity. **22.** During fetal development, the testes form inside the body cavity adjacent to the kidneys. As the body enlarges, the testes gradually move inferiorly and anteriorly toward the anterior abdominal wall. During the seventh developmental month, each testis moves through the abdominal musculature. This process is called the descent of the testes into the scrotum. Descent of the female gonads is much less than that in males. The ovaries come to lie below the rim of the true pelvis. They are held in place by ligaments. **23.** Men aged 50–60 experience the male climacteric, a time when circulating testosterone levels begin to decline and circulating levels of FSH and LH rise. Although sperm production continues, a gradual reduction in sexual activity occurs in older men. Women ages 45–55 experience menopause—the time that ovulation and menstruation cease, accompanied by a sharp and sustained rise in the production of GnRH, FSH, and LH and a drop in the concentrations of circulating estrogen and progesterone. The decline in estrogen levels leads to reductions in the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal walls. In addition to neural and cardiovascular effects, reduced estrogen concentrations have been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate.

Level 3 Critical Thinking and Clinical Applications

24. An enlargement of the prostate or benign prostatic hyperplasia is common in elderly men as testosterone production decreases with age and the interstitial endocrine cells begin releasing small quantities of estrogens into the blood. The combination of a lower testosterone level and the presence of estrogens stimulates prostatic growth. Prostatic swelling can constrict and block the urethra. **25.** Regardless of their location, endometrial cells have receptors that respond to estrogen and progesterone. Under the influence of estrogen at the beginning of the menstrual cycle, any endometrial cells in the peritoneal cavity proliferate and begin to develop glands and blood vessels, which then further develop under the control of progesterone. The dramatic increase in size of this tissue presses on neighboring abdominal tissues and organs, causing periodic painful sensations. **26.** Slightly elevated levels of estrogen and progesterone inhibit both GnRH release at the hypothalamus and the release of FSH and LH from the anterior lobe of the pituitary gland. Without FSH, tertiary ovarian follicles do not begin to develop, and levels of estrogen remain low. An LH surge, triggered by the peaking of estradiol, is necessary for ovulation to occur. If the level of estradiol is not allowed to rise above the critical level, the LH surge will not occur, and thus ovulation will not occur, even if a tertiary ovarian follicle managed to develop to a stage at which it could ovulate. Any mature follicles would ultimately degenerate, and no new follicles would mature to take their place. Although the ovarian cycle is interrupted, the level of hormones is still adequate to regulate a normal menstrual cycle. **27.** These observations suggest that a certain amount of body fat is necessary for menstrual cycles to occur. The nervous system appears to respond to circulating levels of the adipose tissue hormone leptin; when leptin levels fall below a certain set point, menstruation ceases. Because a woman lacking adequate fat reserves might not be able to have a successful pregnancy, the body prevents pregnancy by shutting down the ovarian cycle, and thus the menstrual cycle. Once sufficient energy reserves become available, the cycles begin again.

Answers to Clinical Case Wrap-Up

PAGE 1147 **1.** Susan's secondary oocyte leaves the tertiary ovarian follicle and is picked up by the fimbriae of the uterine tube. The oocyte is moved by cilia through the infundibulum, ampulla, and isthmus of the uterine tube. Tim's spermatozoa will meet and fertilize the oocyte at the junction of ampulla and isthmus. The fertilized oocyte, now an ovum, will continue into the uterine cavity where it will attach to the endometrium. **2.** Ovulation occurs at the midpoint, or day 14, of a 28-day cycle. Susan might experience "mittelschmerz" (German, "middle pain"), a discrete painful sensation as the secondary oocyte bursts out of the ovary. Blood tests will show a surge in LH from the anterior lobe of the pituitary gland. Her basal body temperature will rise and stay high until the end of her cycle.

Answers to Figure-Based Questions

FIGURE 28–7 The corpora cavernosa is split into two cylindrical masses and surrounds a central artery. The corpus spongiosum surrounds the urethra.

FIGURE 28–9 During mitosis, the spermatogonium divides, forming another spermatogonium and a primary spermatocyte. During meiosis I, the primary spermatocyte divides into two secondary spermatocytes. During meiosis II, each secondary spermatocytes divides into two spermatids. During spermiogenesis (the physical maturation), the four spermatids develop into four sperm.

FIGURE 28–11 The centrioles are found in the neck of the sperm.

FIGURE 28–22 During ovulation, the oocyte is a secondary oocyte.

FIGURE 28–23 The functional layer of the endometrium is affected most during the uterine cycle. During menstruation, the entire functional layer is sloughed off and lost.

FIGURE 28–25 Cholesterol is the precursor for all steroid hormones in both males and females.

Chapter 29

Answers to Checkpoints

PAGE 1151 **1.** Differentiation is the formation of different types of cells during development. **2.** Development begins at fertilization (conception), the union of a male gamete (a sperm) and a female gamete (oocyte). **3.** Inheritance refers to the transfer of genetically determined characteristics from one generation to the next.
PAGE 1153 **4.** Two sperm enzymes important to secondary oocyte penetration are hyaluronidase and acrosin. **5.** A normal human zygote contains 46 chromosomes. **6.** Gestation is the period of prenatal development. It consists of three trimesters. **7.** The first trimester is the time of pre-embryonic, embryonic, and early fetal development. The second trimester is a time of organ and organ system development. By the end of this stage, the fetus appears distinctly human. The third trimester is characterized by rapid fetal growth and the deposition of adipose tissue. **PAGE 1161** **8.** The inner cell mass of the blastocyst eventually develops into the embryo. **9.** Improper development of the yolk sac—the mesoderm-derived structure that gives rise to blood vessels and is an important site of blood cell formation—would affect the development and function of the cardiovascular system. **10.** Blood flows from the fetus to the placenta through paired umbilical arteries and returns in a single umbilical vein. **PAGE 1163** **11.** From 8 weeks to about 20 weeks, the fetus is measured from crown to rump. From 20 weeks to birth, the baby is measured from crown to heel. **PAGE 1167** **12.** Yes, Sue is pregnant. After fertilization, the developing trophoblast (and later, the placenta) produce and release the hormone hCG. **13.** Pregnant women experience an increase in respiratory rate and tidal volume. **14.** A mother's blood volume increases during pregnancy to compensate for the reduction in maternal blood volume resulting from blood flow through the placenta. **PAGE 1172** **15.** Three factors opposing the calming action of progesterone on the uterus are increasing estrogen levels, increasing oxytocin levels, and prostaglandin production. **16.** The three stages of labor are the dilation stage, expulsion stage, and placental stage. **17.** Immature delivery is the birth of a fetus weighing at least 500 g (17.6 oz), which is the normal weight near the end of the second trimester. Premature delivery usually refers to birth at 28–36 weeks at a weight of more than 1 kg (2.2 lb). **18.** Fraternal twins are dizygotic twins, and identical twins are monozygotic twins. **PAGE 1177** **19.** The postnatal stages of development are the neonatal period, infancy, childhood, adolescence, and maturity. These stages are followed by senescence, or aging, and death. **20.** The neonatal period is the time from birth to 1 month. Infancy continues from the neonatal period to age 1. Adolescence is the period after childhood in which sexual and physical maturity occur. **21.** Colostrum is produced by the mammary glands from the end of the sixth month of pregnancy until a few days after birth. After that, the glands begin producing breast milk, which contains fewer proteins (including antibodies) and far more fat than colostrum. **22.** Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of puberty. **PAGE 1185** **23.** Genotype is a person's genetic makeup. Phenotype is a person's physical and physiological characteristics. It results from the interaction between the person's genotype and the environment. **24.** Heterozygous refers to a genotype possessing two different alleles at corresponding sites of a chromosome pair. For a heterozygous trait, one or both of the alleles determines the individual's phenotype. **25.** The phenotype of a person who is heterozygous for tongue rolling—who has one dominant allele for tongue-rolling and one recessive allele for non-tongue-rolling—would be "tongue roller." **26.** One reason children are not identical copies of their parents is that during meiosis, parental chromosomes are randomly distributed such that each gamete has a unique set of chromosomes. Additionally, crossing over and mutations during meiosis introduce new variations in gametes. Besides gene interactions, environmental factors can also affect the expression of genes and the resulting phenotype through epigenetic mechanisms.

Answers to Review Questions

PAGE 1188

Level 1 Reviewing Facts and Terms

1. e **2. (a)** parietal decidua; **(b)** basal decidua; **(c)** amnion; **(d)** chorion; **(e)** capsular decidua **3.** b **4.** b **5.** d **6.** b **7.** b **8.** a **9.** When a sperm contacts the secondary oocyte, their plasma membranes fuse. The oocyte is then activated: Its metabolic rate rises; it completes meiosis II; and the cortical reaction prevents additional sperm from entering. (Vesicles beneath the oocyte surface fuse with the plasma membrane and discharge their contents.) The male and female pronuclei replicate their DNA, fuse (amphimixis), and the zygote begins preparing for the first cleavage division. **10. (a)** The four extra-embryonic membranes are the yolk sac, amnion, allantois, and chorion. **(b)** The yolk sac forms from endoderm and mesoderm; it is an important site of blood cell formation. The amnion forms from ectoderm and mesoderm; it encloses the fluid

that surrounds and cushions the developing embryo and fetus. The allantois forms from endoderm and mesoderm; its base gives rise to the urinary bladder. The chorion forms from mesoderm and trophoblast; circulation through chorionic vessels provides a "rapid-transit system" for blood and nutrients. **11.** The dilation stage begins with the onset of true labor, as the cervix dilates and the fetus begins to move toward the cervical canal; late in this stage, the amniochorionic membrane ruptures. The expulsion stage begins as the cervix dilates completely and continues until the fetus has completely emerged from the vagina (delivery). In the placental stage, the uterus gradually contracts, tearing the connections between the endometrium and the placenta and ejecting the placenta. **12.** The fetal pituitary secretes oxytocin, which is released into the maternal bloodstream at the placenta. This release may be the trigger for the onset of true labor. **13.** (1) Neonatal period (birth to 1 month): The newborn becomes relatively self-sufficient and begins performing respiration (breathing), digestion, and excretion on its own. Heart rates and fluid requirements are higher than those of adults. Neonates have little ability to thermoregulate. (2) Infancy (1 month to 1 year): Major organ systems (other than those related to reproduction) become fully operational. (3) Childhood (1 year to puberty): Growth continues; body proportions change significantly. **14.** Three events interact to promote increased hormone production and sexual maturation at puberty: (1) The hypothalamus increases its production of GnRH; (2) the anterior lobe of the pituitary gland becomes more sensitive to the presence of GnRH, and circulating levels of FSH and LH rise rapidly; and (3) ovarian or testicular cells become more sensitive to FSH and LH. Puberty initiates adolescence, which includes gametogenesis (gamete production) and the production of sex hormones that stimulate the appearance of secondary sexual characteristics and behaviors.

Level 2 Reviewing Concepts

15. c **16.** d **17.** a **18.** Many of the proteins present in colostrum are antibodies that help the neonate ward off infections. The mucins in colostrum provide protection against rotaviruses. Oxytocin induces the milk ejection reflex. **19.** The placenta produces (1) human chorionic gonadotropin, which maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone (keeping the endometrial lining functional); and (2) human placental lactogen and placental prolactin, which help prepare the mammary glands for milk production. Human placental lactogen also ensures adequate levels of glucose and protein for the developing fetus. (3) The placenta also produces relaxin, which increases the flexibility of the pubic symphysis, causes dilation of the cervix, and suppresses the release of oxytocin by the hypothalamus, delaying the onset of labor contractions. (4) The placenta becomes the main source of progesterone to maintain the endometrial lining after the first trimester. (5) Placental estrogen production rapidly increases in the third trimester and plays a role in stimulating labor and delivery. **20.** Respiratory rate and tidal volume increase, allowing the lungs to obtain the extra oxygen the fetus needs, and to remove the excess carbon dioxide the fetus generates. Maternal blood volume increases, compensating for blood flowing into the placenta. Nutrient and vitamin requirements increase 10–30 percent, reflecting the fact that some of the mother's nutrients go to nourish the fetus. Glomerular filtration rate increases by about 50 percent, which corresponds to the increased blood volume, and this accelerates the excretion of metabolic wastes generated by the fetus. The uterus and mammary glands increase in size, and secretory activity begins in the mammary glands. **21.** In breech births, risks to the fetus are high as the umbilical cord can become constricted and cut off placental blood flow. **22.** A neonate must fill its lungs (which are collapsed and filled with fluid at birth) with air, which alters the pattern of cardiovascular circulation due to changes in blood pressure and flow rates. It must excrete the mixture of debris (meconium) that has collected in the fetal digestive system. The neonate must obtain nourishment from a new source—the mother's mammary glands. Neonatal fluid requirements are high, because the newborn cannot concentrate its urine significantly. The infant also has little ability to thermoregulate, although as it grows its insulating adipose tissue increases, and its metabolic rate also rises. **23. (a)** Genotype refers to an individual's genetic makeup; phenotype refers to the individual's physical and physiological characteristics. **(b)** A heterozygous genotype carries different alleles for a given gene; a homozygous genotype carries identical alleles for that gene. **(c)** In simple inheritance, phenotypes are determined by interactions between a single pair of alleles; in polygenic inheritance, interactions occur among multiple genes. **24. (a)** dominant; **(b)** recessive; **(c)** X-linked; **(d)** autosomal

Level 3 Critical Thinking and Clinical Applications

25. The probability that this couple's daughters will have hemophilia is 0, because each daughter will receive a normal allele from her father. There is a 50 percent chance that a son will have hemophilia, because each son has a 50 percent chance of receiving the mother's normal allele and a 50 percent chance of receiving the mother's recessive allele. **26.** Although technically it only takes one sperm to fertilize an egg, the probability of this occurring is very low if too few sperm are present. Most sperm that enter the female reproductive tract are killed or disabled before they reach the uterus. Many of the sperm reaching the uterus are incapable of reaching the secondary oocyte, which is in a uterine tube. Once at the oocyte, the sperm must penetrate the corona radiata, which requires the combined acrosomal enzymes of dozens of sperm. If too few sperm are present in the vagina, the number reaching the uterine tube is too low for any one sperm to penetrate the corona radiata. **27.** The most obvious possibility is that the infant has a problem with the cardiovascular supply to the lungs. A good guess would be a patent ductus arteriosus (the ductus arteriosus has failed to close off completely). When the baby is not being stressed (bathing creates heat loss and thermal stress) or eating (less air is entering the lungs), the infant appears normal. Because some of the blood flow to the lungs is being shunted over to the aorta during stress and eating, too little blood is being oxygenated, so the infant becomes cyanotic. **28.** In Jie's case, the implantation of the blastocyst most likely did not occur in the fundus or in the body of the uterus, but in one of the uterine tubes. The walls of the uterine tubes are not adapted to sustain a growing embryo and will rupture, causing life-threatening bleeding.

Answers to Clinical Case Wrap-Up

PAGE 1189 **1.** Implanting the blastocysts on the sixth day after ovulation matches the fertility cycle in nature. This timing ensures the blastocysts are available for implantation in the uterine wall by days 7 through 10 after ovulation. **2.** Hans and Willem are not monozygotic twins because they did not result from the fertilization of a single oocyte with a single sperm, forming a single zygote that subsequently split. Neither are they technically dizygotic twins.

They are the developmental result of two separate oocytes from the same mother, but unlike dizygotic twins, they have different *biological* fathers. In terms of biological inheritance, they are half brothers. Socially they are fraternal twins.

Answers to Figure-Based Questions

FIGURE 29–2 The outer cell layer of a blastocyst is called the trophoblast. The function of the trophoblast is to provide nutrients to the developing embryo.

FIGURE 29–4 The third germ layer that forms during gastrulation is called mesoderm.

FIGURE 29–10 Oxytocin and prostaglandins stimulate and increase the excitability of the myometrium.

FIGURE 29–14 The 23rd pair of chromosomes in this karyotype are the sex chromosomes. They are characteristic of a male because both X and Y sex chromosomes are present. A female karyotype would have two X sex chromosomes.

FIGURE 29–15 Simple inheritance is involved in determining nearsightedness (dominant trait) and normal vision (recessive trait), and sex-linked inheritance is involved in determining red-green color blindness.

Appendices

Appendix A Normal Physiological Values

Tables 1 and 2 present normal averages or ranges for the chemical composition of body fluids. These values are approximations rather than absolute values, because test results vary from laboratory to laboratory as a result of differences in procedures, equipment, normal solutions, or other factors. Blanks in the tabular data appear where data are not available. The following locations in the text contain additional information about body fluid analysis:

Table 19–3 (p. 722) presents data on the formed elements of the blood.

Table 26–2 (p. 1033) compares the normal values for solutes in plasma and urine.

Table 26–5 (p. 1051) gives the general characteristics of normal urine, and Table 26–6 (p. 1054) shows the typical values of substances in a standard urinalysis.

Ketone bodies	S: 0.3–2.0	1.3–1.6	10–100
Lactic acid	WB: 0.7–2.5 mEq/L§	10–20	100–600
Lipids (total)	P: 450–1000	0.8–1.7	0.002
Cholesterol (total)	S: 150–300	0.2–0.8	1.2–3.8
Triglycerides	S: 40–150	0–0.9	0
Urea	P: 8–25	12.0	1800
Uric acid	P: 2.0–6.0	0.2–1.5	250–750
Proteins	(g/dL)	(mg/dL)	(urinary loss, mg per 24-hour period‡)
Total	P: 6.0–8.0	2.0–4.5	0–8
Albumin	S: 3.2–4.5	10.6–32.4	0–3.5
Globulins (total)	S: 2.3–3.5	2.8–15.5	7.3
Immunoglobulins	S: 1.0–2.2	1.1–1.7	3.1
Fibrinogen	P: 0.2–0.4	0.65	0

*S = serum, P = plasma, WB = whole blood.

†Because urinary output averages just over 1 liter per day, these electrolyte values are comparable to mEq/L.

‡Because urinary metabolite and protein data approximate mg/L or g/L, these data must be divided by 10 for comparison with CSF or blood concentrations.

§Venous blood sample.

Appendix B Gas Pressure Measurements and Cell Turnover Times

To understand the principles of blood flow, capillary exchange, respiratory gas exchange, and the mechanics of breathing, we must know the pressures of blood and gases in peripheral tissues, in the bloodstream, and inside and outside the respiratory tract. Blood and gas pressures are measured and reported in several ways. Table 3 shows four common reporting methods.

Table 3 Four Common Methods of Reporting Gas Pressure

Measurement Units	Description
millimeters of mercury (mm Hg)	This is the most common method of reporting blood pressure and gas pressures. Normal atmospheric pressure is approximately 760 mm Hg.
torr	This unit of measurement is preferred by many respiratory therapists; it is also commonly used in Europe and in some technical journals. Note that 1 torr is equivalent to 1 mm Hg; in other words, normal atmospheric pressure is equal to 760 torr.
centimeters of water (cm H_2O)	In a hospital setting, anesthetic gas pressures and oxygen pressures are commonly measured in centimeters of water. Note that 1 cm H_2O is equivalent to 0.735 mm Hg; normal atmospheric pressure is 1033.6 cm H_2O.
pounds per square inch (psi)	Pressures in compressed gas cylinders and other industrial applications are generally reported in psi. Normal atmospheric pressure at sea level is approximately 15 psi.

Appendix B Turnover Times for Selected Cells

Most of the organic molecules in a cell are replaced at intervals ranging from hours to months. The average time between synthesis and breakdown is known as the *turnover time*. This table lists the turnover times of the organic components of representative cells.

Table 4 Turnover Times of the Organic Components of Four Cell Types

Cell Type	Component	Average Recycling Time*
Liver	Total protein	5–6 days
	Enzymes	1 hour to several days, depending on the enzyme
	Glycogen	1–2 days
	Cholesterol	5–7 days
Muscle	Total protein	30 days
	Glycogen	12–24 hours
Nerve	Phospholipids	200 days
	Cholesterol	100+ days
Fat	Triglycerides	15–20 days

*Most values were obtained from studies on mammals other than humans.

Appendix C Codon Chart

A codon is a sequence of three consecutive nucleotides in mRNA that codes for a particular amino acid or signals to stop protein synthesis. Because each mRNA codon consists of three nucleotides, the four nucleotides in mRNA (A, U, G, and C) can produce 64 different combinations. Of these, 61 codons correspond to amino acids and 3 act as stop signals of protein synthesis. Only 20 different amino acids are used to synthesize proteins, so most amino acids are represented by more than one codon. One codon, AUG, has a dual role. It codes for the amino acid methionine and also acts as the start signal for protein synthesis. It is always the first codon in a strand of mRNA.

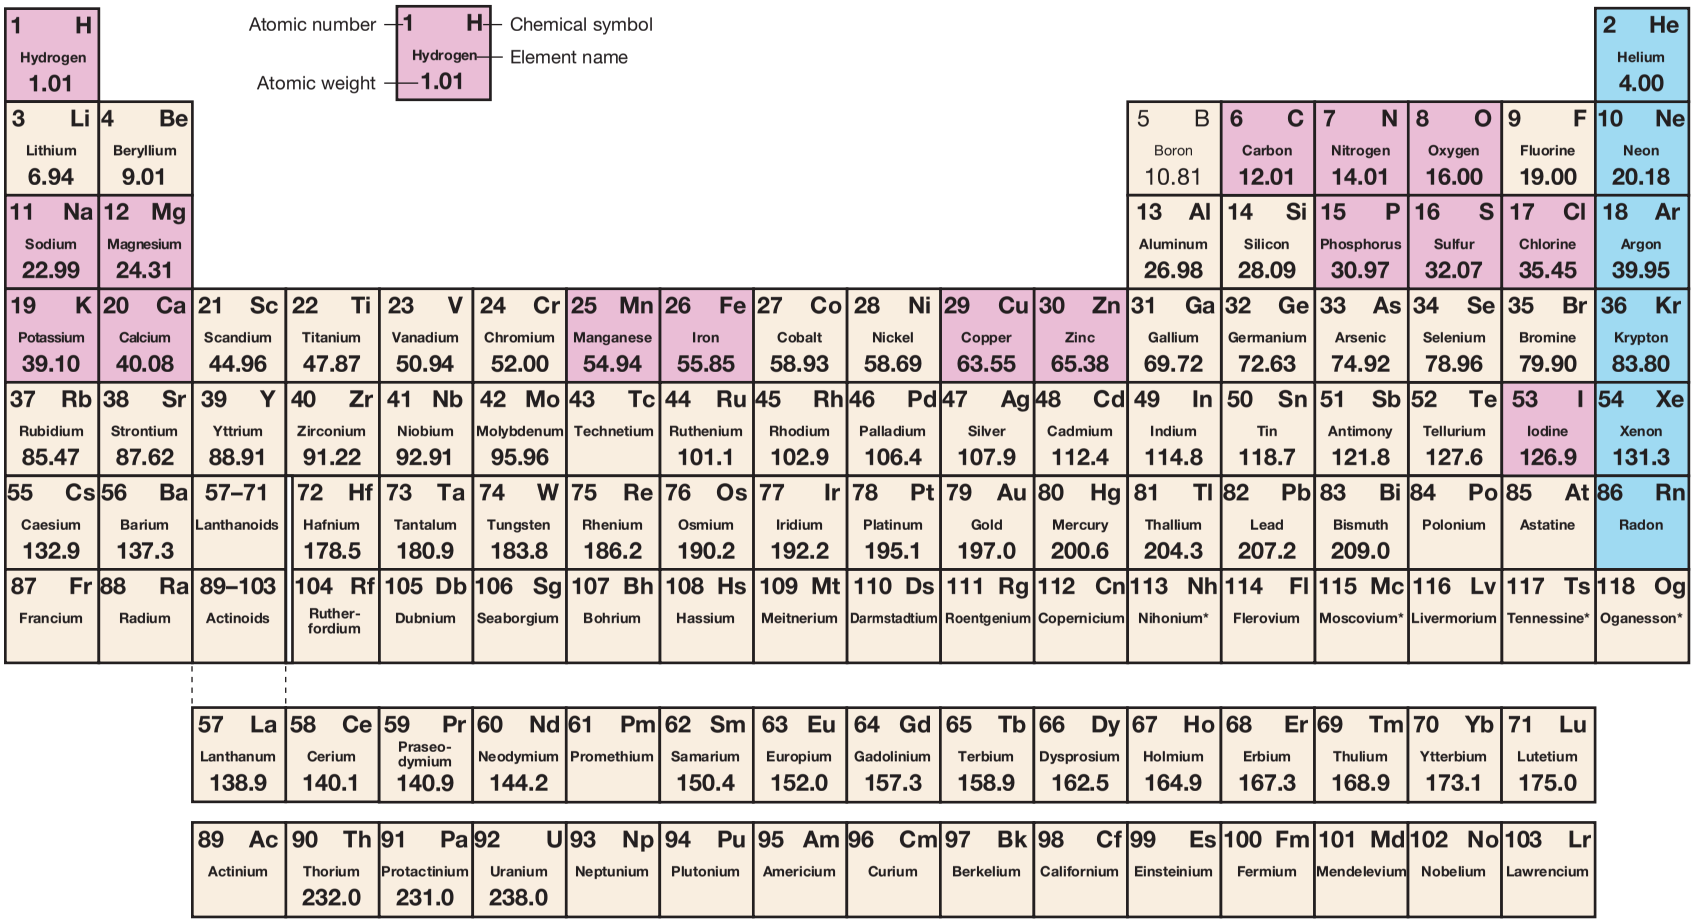

Table 5 The Genetic Code

Genetic Code (mRNA codons)

First nucleotide	Second nucleotide: U	Second nucleotide: C	Second nucleotide: A	Second nucleotide: G	Third nucleotide
U	UUU Phenylalanine UUC Phenylalanine UUA Leucine UUG Leucine	UCU Serine UCC Serine UCA Serine UCG Serine	UAU Tyrosine UAC Tyrosine UAA **Stop** UAG **Stop**	UGU Cysteine UGC Cysteine UGA **Stop** UGG Tryptophan	U C A G
C	CUU Leucine CUC Leucine CUA Leucine CUG Leucine	CCU Proline CCC Proline CCA Proline CCG Proline	CAU Histidine CAC Histidine CAA Glutamine CAG Glutamine	CGU Arginine CGC Arginine CGA Arginine CGG Arginine	U C A G
A	AUU Isoleucine AUC Isoleucine AUA Isoleucine AUG **Start** *or* Met*	ACU Threonine ACC Threonine ACA Threonine ACG Threonine	AAU Asparagine AAC Asparagine AAA Lysine AAG Lysine	AGU Serine AGC Serine AGA Arginine AGG Arginine	U C A G
G	GUU Valine GUC Valine GUA Valine GUG Valine	GCU Alanine GCC Alanine GCA Alanine GCG Alanine	GAU Aspartic acid GAC Aspartic acid GAA Glutamic acid GAG Glutamic acid	GGU Glycine GGC Glycine GGA Glycine GGG Glycine	U C A G

*Abbreviation for methionine

The periodic table presents the known elements in order of their atomic weights. Each horizontal row represents a single electron shell. The number of elements in that row is determined by the maximum number of electrons that can be stored at that energy level. The element at the left end of each row contains a single electron in its outermost electron shell; the element at the right end of the row has a filled outer electron shell. This organization highlights similarities that reflect the composition of the outer electron shell, or valence shell. These similarities are evident when you examine the vertical columns. All the elements of the right-most column—helium, neon, argon, krypton, xenon, and radon—have full electron shells; each is a gas at normal atmospheric temperature and pressure, and none reacts readily with other elements. These elements, highlighted in blue, are known as the noble, or inert, gases. In contrast, the elements of the left-most column below hydrogen—lithium, sodium, potassium, rubidium, caesium, and francium—are silvery, soft metals that are so highly reactive that pure forms cannot be found in nature. The fourth and fifth electron levels can each hold up to 18 electrons. Table inserts are used for the so-called lanthanoids (atomic numbers 57–71) and actinoids (atomic numbers 89–103) to save space, as higher levels can store up to 32 electrons. Elements of particular importance to our discussion of human anatomy and physiology are highlighted in pink.

*Pending formal approval

Glossary of Key Terms

This glossary is an alphabetical list of key terms related to topics covered in the textbook. Brief explanations, along with the chapter number(s) where the topic was covered, are given.

A

abdomen: The region of the trunk between the inferior margin of the rib cage and the superior margin of the pelvis. (1)

abdominopelvic cavity: The term used to refer to the general region bounded by the abdominal wall and the pelvis; it contains the peritoneal cavity and visceral organs. (1)

abducens nerve: Cranial nerve VI, which innervates the lateral rectus muscle of the eye. (14)

abduction: Movement away from the midline of the body, as viewed in the anatomical position. (9)

abortion: The premature loss or expulsion of an embryo or fetus. (29)

abscess: A localized collection of pus within a damaged tissue. (4, 22)

absorption: The active or passive uptake of gases, fluids, or solutes. (24, 25)

accommodation: An alteration in the curvature of the lens of the eye to focus an image on the retina. (17)

acetabulum: The fossa on the lateral aspect of the pelvis that accommodates the head of the femur. (8)

acetylcholine (ACh): A chemical neurotransmitter in the brain and peripheral nervous system; the dominant neurotransmitter in the peripheral nervous system, released at neuromuscular junctions and synapses of the parasympathetic division. (10, 12, 16)

acetylcholinesterase (AChE): An enzyme found in the synaptic cleft, bound to the postsynaptic membrane, and in tissue fluids; breaks down and inactivates acetylcholine molecules; also called *cholinesterase*. (10, 12)

acetyl-CoA: An acetyl group bound to coenzyme A, a participant in the anabolic and catabolic pathways for carbohydrates, lipids, and many amino acids. (25)

acetyl group: —CH_3CO; an acetic acid molecule without the hydroxyl group. (25)

acid: A compound whose dissociation in solution releases a hydrogen ion and an anion; an acidic solution has a pH below 7.0 and has an excess of hydrogen ions. (2, 27)

acidosis: An abnormal physiological state characterized by blood pH below 7.35. (2, 25, 26, 27)

acinus/acini: A histological term referring to a blind pocket, pouch, or sac.

acoustic: Pertaining to sound or the sense of hearing. (17)

acquired immunodeficiency syndrome (AIDS): A disease caused by the human immunodeficiency virus (HIV); characterized by the destruction of helper T cells and a resulting severe impairment of the immune response. (22)

acromegaly: A condition caused by the overproduction of growth hormone in adults, characterized by a thickening of bones and an enlargement of cartilages and other soft tissues. (6, 18)

acromion: A continuation of the scapular spine that projects superior to the capsule of the glenohumeral joint. (8)

acrosome: A membranous sac at the tip of a sperm that contains hyaluronidase; also called *acrosomal cap*. (28)

actin: The protein component of microfilaments that forms thin filaments in skeletal muscles and produces contractions of all muscles through interaction with thick (myosin) filaments; *see also* **sliding-filament theory**. (3, 10)

action potential: A propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions; *see also* **nerve impulse**. (10, 12)

active transport: The ATP-dependent absorption or secretion of solutes across a plasma membrane. (3, 26)

acute: Sudden in onset, typically severe in intensity, and brief in duration.

adaptation: A decrease in receptor sensitivity or perception after chronic stimulation (15); a change in pupillary size in response to changes in light intensity (17); physiological responses that produce acclimatization. (25)

Addison disease: A condition resulting from the hyposecretion of glucocorticoids; characterized by lethargy, weakness, hypotension, and increased skin pigmentation. (5, 18)

adduction: Movement toward the axis or midline of the body, as viewed in the anatomical position. (9)

adenine (A): A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

adenohypophysis: The anterior lobe of the pituitary gland. (18)

adenoid: The pharyngeal tonsil. (22, 23)

adenosine: A compound consisting of adenine and ribose. (2)

adenosine diphosphate (ADP): A compound consisting of adenosine with two phosphate groups attached. (2, 25)

adenosine monophosphate (AMP): A nucleotide consisting of adenosine plus a phosphate group (PO_4^{3-}); also called *adenosine phosphate*. (2)

adenosine triphosphate (ATP): A high-energy compound consisting of adenosine with three phosphate groups attached; the third is attached by a high-energy bond. (2, 10, 25)

adenylate cyclase: An enzyme bound to the inner surfaces of plasma membranes that can convert ATP to cyclic AMP; formerly called *adenylyl cyclase*. (12, 18)

adhesion: The fusion of two mesenterial layers after damage or irritation of their opposing surfaces; this process restricts relative movement of the organs involved (4); the binding of a phagocyte to its target (22).

adipocyte: A fat cell. (4)

adipose tissue: Loose connective tissue dominated by adipocytes. (4, 18, 28)

adrenal cortex: The superficial region of the adrenal gland that produces steroid hormones; also called the *suprarenal cortex*. (18)

adrenal gland: A small endocrine gland that secretes steroids and catecholamines and is located superior to each kidney; also called *suprarenal gland*. (18)

adrenal medulla: A modified sympathetic ganglion that secretes catecholamines into the blood during sympathetic activation; also called *suprarenal medulla* (16); the core of the adrenal gland (18).

adrenergic: An axon terminal that, when stimulated, releases norepinephrine. (12)

adrenocortical hormone: Any steroid produced by the adrenal cortex. (18)

adrenocorticotropic hormone (ACTH): The hormone that stimulates the production and secretion of glucocorticoids by the zona fasciculata of the adrenal cortex; released by the anterior lobe of the pituitary gland (adenohypophysis) in response to corticotropin-releasing hormone. (18)

adventitia: The superficial layer of connective tissue surrounding an internal organ; fibers are continuous with those of surrounding tissues, providing support and stabilization. (24)

aerobic: Requiring oxygen.

aerobic metabolism: The complete breakdown of organic substrates into carbon dioxide and water; a process that yields large amounts of ATP but requires mitochondria and oxygen. (3, 10, 25)

afferent: Conducting toward a center.

afferent arteriole: An arteriole that carries blood to a glomerulus of the kidney. (26)

afferent fiber: An axon that carries sensory information to the central nervous system. (12)

agglutination: The aggregation of red blood cells due to interactions between surface antigens and plasma antibodies. (19, 22)

agglutinins: Immunoglobulins (antibodies) in plasma that react with antigens on the surfaces of foreign red blood cells when donor and recipient differ in blood type. (19)

agglutinogens: Genetically determined surface antigens on red blood cells that stimulate the formation of specific agglutinins. (19)

aggregated lymphoid nodules: Lymphoid nodules beneath the epithelium of the small intestine; also called *Peyer's patches*. (22)

agonist: A muscle responsible for a specific movement; also called a *prime mover*. (11)

agranular: Without granules; *agranular leukocytes* are monocytes and lymphocytes. (19)

AIDS: *See* **acquired immunodeficiency syndrome**. (22)

aldosterone: A mineralocorticoid produced by the zona glomerulosa of the adrenal cortex; stimulates the kidneys to conserve sodium and water; secreted in response to the presence of angiotensin II. (18, 26, 27)

alkalosis: The condition characterized by a blood pH greater than 7.45; associated with a relative deficiency of hydrogen ions or an excess of bicarbonate ions. (2, 27)

alpha (α) receptors: Membrane receptors sensitive to norepinephrine or epinephrine; stimulation normally results in target cell excitation. (16)

alveolar sac: An air-filled chamber at the terminal end of the alveolar duct that gives rise to the alveoli in the lung. (23)

alveolus/alveoli: Terminal pockets at the end of the respiratory tree, lined by a simple squamous epithelium and surrounded by a capillary network; sites of gas exchange with the blood (23); a bony socket that holds the root of a tooth. (24)

Alzheimer's disease: A disorder resulting from degenerative changes in populations of neurons in the cerebrum, causing dementia characterized by problems with attention, short-term memory, and emotions. (16)

amination: The attachment of an amino group to a carbon chain; performed by a variety of cells and important in the synthesis of amino acids. (25)
amino acids: Organic compounds made up of carbon, hydrogen, oxygen, and nitrogen; building block of protein; chemical structure can be summarized as R—$CHNH_2$—COOH. (2, 25)
amino group: —NH_2. (2)
amnion: One of the four extra-embryonic membranes; surrounds the developing embryo or fetus. (29)
amniotic fluid: Fluid that fills the amniotic cavity; cushions and supports the embryo or fetus. (4, 29)
amphiarthrosis: A joint (articulation) that permits a small degree of independent movement; *see* **interosseous membrane** (8) and **pubic symphysis**. (9)
ampulla/ampullae: A localized dilation in the lumen of a canal or passageway. (17, 24, 28)
amygdaloid body: A basal nucleus that is a component of the limbic system and acts as an interface between the limbic system, the cerebrum, and sensory systems; also called *amygdala*. (14)
amylase: An enzyme that breaks down polysaccharides; produced by the salivary glands and pancreas. (24)
anabolism: The synthesis of complex organic compounds from simpler precursors. (2, 25)
anaerobic: Without oxygen.
analgesic: A substance that relieves pain. (15)
anal triangle: The posterior subdivision of the perineum. (11)
anaphase: The mitotic stage in which the paired chromatids separate and move toward opposite ends of the spindle apparatus. (3)
anaphylaxis: A hypersensitivity reaction due to the binding of antigens to immunoglobulins (IgE) on the surfaces of mast cells; the release of histamine, serotonin, and prostaglandins by mast cells then causes widespread inflammation; a sudden decrease in blood pressure may occur, producing anaphylactic shock. (22)
anastomosis: The joining of two tubes, usually referring to a connection between two peripheral vessels without an intervening capillary bed. (21)
anatomical position: An anatomical reference position; the body viewed from the anterior surface with the palms facing forward. (1)
anatomy: The study of internal and external body structures and their physical relationships among other body parts. (1)
androgen: A steroid sex hormone mainly produced by the interstitial cells of the testis and manufactured in small quantities by the adrenal cortex in both sexes. (18, 28)
anemia: The condition marked by a decrease in the hematocrit, the hemoglobin content of the blood, or both. (19)
aneurysm: A weakening in the arterial wall causing an outpouching or enlargement of the artery. (21)
angiotensin-converting enzyme (ACE): A chemical that converts angiotensin I (a hormone) to angiotensin II (a vasoconstrictor), which causes an increase in blood pressure. (26)
angiotensin I: The hormone produced by the activation of angiotensinogen by renin (18); angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II in lung capillaries. (26)
angiotensin II: A hormone that causes an increase in systemic blood pressure, stimulates the secretion of aldosterone, promotes thirst, and causes the release of antidiuretic hormone (18); angiotensin-converting enzyme (ACE) in lung capillaries converts angiotensin I into angiotensin II. (21, 26)
angiotensinogen: The blood protein produced by the liver that is converted to angiotensin I by the enzyme renin. (18)
anion: An ion having a negative charge. (2, 27)
anoxia: Inadequate oxygen reaching body tissues. (23)
antagonist: A muscle that opposes the movement of an agonist. (11)
antebrachium: The forearm. (8)
anterior: On or near the front, or ventral surface, of the body.
antibiotic: A chemical agent that selectively kills pathogens, primarily bacteria. (20)
antibody: A globular protein produced by plasma cells that will bind to specific antigens and promote their destruction or removal from the body. (19, 22)
antibody-mediated immunity: The form of immunity resulting from the presence of circulating antibodies produced by plasma cells; also called *humoral immunity*. (22)
anticodon: Three nitrogenous bases on a tRNA molecule that interact with a complementary codon on a strand of mRNA. (3)
antidiuretic hormone (ADH): A hormone synthesized in the hypothalamus and secreted at the posterior lobe of the pituitary gland (neurohypophysis); causes the kidneys to retain water and an increase in blood pressure. (18, 21, 26, 27)
antigen: A substance capable of inducing an immune response that may include the production of antibodies. (22)
antigen–antibody complex: The combination of an antigen and a specific antibody. (22)
antigenic determinant site: A region of an antigen that can interact with an antibody molecule. (22)
antigen-presenting cell (APC): A cell that processes antigens and displays them, bound to class II MHC proteins; essential to the initiation of a normal immune response. (22)
antihistamine: A chemical that blocks the action of histamine on peripheral tissues. (22)
antrum: A chamber or pocket. (28)
anulus: A cartilage or bone shaped like a ring; also spelled *annulus*. (9)
anus: The external opening of the anal canal. (24)
aorta: The large, elastic artery that carries blood away from the left ventricle and into the systemic circuit. (20)
aortic bodies: Receptors in the aortic arch that are sensitive to changes in oxygen, carbon dioxide, and pH levels in the blood. (21)
aortic sinus: Space between the superior portion of each of the three aortic valve cusps and the dilated portion of the wall of the ascending aorta.(21)
apnea: Cessation of breathing. (23)
apocrine secretion: A mode of secretion in which the glandular cell sheds portions of its cytoplasm. (4, 5)
aponeurosis/aponeuroses: Broad tendinous sheet(s) that may serve as the origin or insertion of a skeletal muscle. (4, 6, 10)
apoptosis: Genetically programmed cell death. (3)
appendicular: Pertaining to the upper or lower limbs. (7, 8)
appendix: A blind sac connected to the cecum of the large intestine; also called *vermiform appendix*. (24)
appositional growth: The enlargement of a cartilage or bone by the addition of cartilage or bony matrix at its surface. (4, 6)
aqueous humor: A fluid similar to perilymph or cerebrospinal fluid that fills the anterior chamber of the eye. (17)
arachidonic acid: One of the essential fatty acids. (2, 18)
arachnoid granulations: Processes of the arachnoid mater that project into the superior sagittal sinus; sites where cerebrospinal fluid enters the venous circulation. (14)
arachnoid mater: The middle meninx (layer) that encloses cerebrospinal fluid and protects the central nervous system. (13, 14)
arbor vitae: The central, branching mass of white matter inside the cerebellum. (14)
arcuate: Curving.
areolar: Containing minute spaces, as in areolar tissue.
areolar tissue: Loose connective tissue with an open framework. (4)
arrector pili: Smooth muscles whose contractions force hairs to stand erect. (5)
arrhythmias: Abnormal patterns of cardiac contractions. (20)
arteriole: A small arterial branch that delivers blood to a capillary network. (21)
artery: A blood vessel that carries blood away from the heart and toward a peripheral capillary. (4, 20, 21)
articular: Pertaining to a joint.
articular capsule: The dense collagen fiber sleeve that surrounds a joint and provides protection and stabilization; also called *joint capsule*. (6, 9)
articular cartilage: The cartilage pad that covers the surface of a bone inside a joint cavity. (6, 9)
articulation: A joint. (9)
arytenoid cartilages: A pair of small cartilages in the larynx. (23)
ascending tract: A tract carrying information from the spinal cord to the brain. (13, 14)
association areas: Cortical areas of the cerebrum that are responsible for the integration of sensory inputs and/or motor commands. (14)
association neuron: *See* **interneuron**. (12)
astrocyte: One of the four types of neuroglia in the central nervous system; responsible for maintaining the blood brain barrier by the stimulation of endothelial cells. (12)
atherosclerosis: The formation of fatty plaques in the walls of arteries, restricting blood flow. (21)
atom: The smallest stable unit of matter. (1, 2)
atomic number: The number of protons in the nucleus of an atom. (2)
atomic weight: The average of the different atomic masses and isotope proportions of a particular element. (2)
atria: Thin-walled chambers of the heart that receive venous blood from the pulmonary or systemic circuit.
atrial natriuretic peptide (ANP): *See* **natriuretic peptides**. (20)
atrial reflex: The reflexive increase in heart rate after an increase in venous return; due to mechanical and neural factors; also called *Bainbridge reflex*. (20, 21)
atrioventricular (AV) bundle: Specialized conducting cells in the interventricular septum that carry the contracting stimulus from the AV node to bundle branches and then to Purkinjie fibers; also called *bundle of His*. (20)
atrioventricular (AV) node: Specialized cardiac muscle cells that relay the contractile stimulus to the atrioventricular bundle (bundle of His), the bundle branches, the Purkinje fibers, and the ventricular myocardium; located at the boundary between the atria and ventricles. (20)
atrioventricular (AV) valve: One of the valves that prevents backflow into the atria during ventricular systole (contraction). (20)
atrophy: The wasting away of tissues from a lack of use, ischemia, or nutritional abnormalities. (10)
auditory: Pertaining to the sense of hearing. (17)
auditory ossicles: The bones of the middle ear: malleus, incus, and stapes. (7, 17)
auditory tube: A passageway that connects the nasopharynx with the middle ear cavity; also called *Eustachian tube* or *pharyngotympanic tube*. (17)

auricle: A broad, flattened process that resembles the external ear; in the ear, the expanded, projecting portion that surrounds the external auditory meatus; also called *pinna* (17); in the heart, the externally visible flap formed by the collapse of the outer wall of a relaxed atrium (20).
autoantibodies: Antibodies that react with antigens on the surfaces of a person's own cells and tissues. (22)
autoimmunity: The immune system's sensitivity to one's own tissues, resulting in the production of autoantibodies. (22)
autolysis: The destruction of a cell due to the rupture of lysosomal membranes in its cytoplasm. (3)
automaticity: The spontaneous depolarization to threshold, characteristic of cardiac pacemaker cells. (10, 20)
autonomic ganglion: A collection of visceral motor neurons outside the central nervous system. (16)
autonomic nerve: A peripheral nerve consisting of preganglionic or postganglionic autonomic fibers. (16)
autonomic nervous system (ANS): Centers, nuclei, tracts, ganglia, and nerves involved in the unconscious regulation of visceral functions; includes components of the central nervous system and the peripheral nervous system. (12, 16)
autoregulation: Changes in activity that maintain homeostasis in direct response to changes in the local environment; does not require neural or endocrine control. (1, 21, 26)
autosome: A chromosome other than the X or Y sex chromosome. (29)
avascular: Without blood vessels. (4)
axilla: The armpit. (1, 8)
axolemma: The plasma membrane of an axon, continuous with the plasma membrane of the cell body and dendrites and distinct from any neuroglial coverings. (12)
axon: The elongated extension of a neuron that conducts an action potential. (4, 12)
axon hillock: In a multipolar neuron, the portion of the cell body adjacent to the initial segment. (12)
axoplasm: The cytoplasm within an axon. (12)

B

bacteria: Single-celled microorganisms, some pathogenic, that are common in the environment and in and on the body. (22)
Bainbridge reflex: The reflexive increase in heart rate after an increase in venous return; due to mechanical and neural factors; also called *atrial reflex*. (20, 21)
baroreception: The ability to detect changes in pressure. (15, 23)
baroreceptor reflex: A reflexive change in cardiac activity in response to changes in blood pressure. (21)
baroreceptors: The nerve endings that sense pressure changes. (15, 21)
basal nuclei: Nuclei of the cerebrum that are important in the subconscious control of skeletal muscle activity. (14, 15)
base: A compound whose dissociation releases a hydroxide ion (OH^-) or removes a hydrogen ion (H^1) from the solution. (2, 27)
basement membrane: A layer of filaments and fibers that attach an epithelium to the underlying connective tissue. (4)
basophils: Circulating granulocytes (white blood cells) similar in size and function to tissue mast cells. (19)
B cells: Lymphocytes capable of differentiating into plasma cells, which produce antibodies. (19, 22)
benign: Not malignant. (3)
beta (β) cells: Cells of the pancreatic islets that secrete insulin in response to increased blood sugar concentrations. (18)
beta-oxidation: Fatty acid catabolism that produces molecules of acetyl-CoA. (25)
beta (β) receptors: Membrane receptors sensitive to epinephrine; stimulation may result in the excitation or inhibition of the target cell. (16)
bicarbonate ion: HCO_3^-; anion component of the carbonic acid-bicarbonate buffer system. (26, 27)
bicuspid: Having two cusps or points; refers to a premolar tooth, which has two roots, or to the left AV valve, which has two cusps. (24)
bicuspid valve: *See* **mitral valve** (20).
bifurcate: To branch into two parts.
bile: The exocrine secretion of the liver; stored in the gallbladder and ejected into the duodenum. (24)
bile duct: The duct formed by the union of the cystic duct from the gallbladder and the common hepatic duct from the liver; terminates at the duodenal ampulla, where it meets the pancreatic duct. (24)
bile salts: Steroid derivatives in bile; responsible for the emulsification of ingested lipids. (2, 24)
bilirubin: A pigment that is the by-product of hemoglobin catabolism. (19)
biopsy: The removal of a small sample of tissue for pathological analysis. (4, 13)
bladder: A muscular sac that distends as fluid is stored and whose contraction ejects the fluid at an appropriate time; used alone, the term usually refers to the urinary bladder. (26)
blastocyst: An early stage in the developing embryo, consisting of an outer trophoblast and an inner cell mass. (29)
blockers/blocking agents: Drugs that block membrane pores or prevent binding to membrane receptors. (16)
blood brain barrier (BBB): The isolation of the central nervous system from the general circulation; primarily the result of astrocyte regulation of capillary permeabilities. (12, 14)
blood clot: *See* **clot**. (19)
blood CSF barrier: The isolation of the cerebrospinal fluid from the capillaries of the choroid plexus; primarily the result of specialized ependymal cells. (14)
blood pressure (BP): A force exerted against vessel walls by the blood in the vessels, due to the push exerted by cardiac contraction and the elasticity of the vessel walls; usually measured along one of the muscular arteries, with systolic pressure measured during ventricular systole (contraction) and diastolic pressure during ventricular diastole (relaxation). (21)
blood testis barrier: The isolation of the interior of the seminiferous tubules from the general circulation, due to the activities of the nurse (sustentacular) cells. (28)
Bohr effect: The increased oxygen release by hemoglobin in the presence of increased carbon dioxide levels. (23)
bolus: A compact mass; usually refers to compacted ingested material (food) on its way to the stomach. (23, 24)
bone tissue: A strong connective tissue containing specialized cells and a mineralized matrix of crystalline calcium phosphate and calcium carbonate; also called *osseous tissue*.
bony labyrinth: A series of cavities within the petrous part of the temporal bone that is filled with perilymph and in which the membranous labyrinth is suspended.(17)
bowel: The intestinal tract. (24)
Bowman's capsule: *See* **glomerular capsule**. (26)
brachial: Pertaining to the arm.
brachial plexus: A network formed by branches of spinal nerves C_5–T_1 en route to innervating the upper limb. (13)
brachium: The arm. (11)
bradycardia: An abnormally slow heart rate, usually below 50 bpm. (20)
brainstem: The brain minus the cerebrum, diencephalon, and cerebellum; midbrain, pons, and medulla oblongata. (14)
brevis: Short. (11)
Broca's area: The speech center of the brain, normally located on the neural cortex of the left cerebral hemisphere. (14)
bronchial tree: The trachea, bronchi, and bronchioles. (23)
bronchodilation: The dilation of the bronchial passages; can be caused by sympathetic stimulation. (23)
bronchus/bronchi: Branch/branches of the bronchial tree between the trachea and bronchioles. (23)
B-type natriuretic peptide (BNP): *See* **natriuretic peptides**. (27)
buccal: Pertaining to the cheeks. (24)
buffer: A compound that stabilizes the pH of a solution by removing or releasing hydrogen ions. (2, 27)
buffer system: Interacting compounds that prevent increases or decreases in the pH of body fluids; includes the carbonic acid–bicarbonate buffer system, the phosphate buffer system, and the protein buffer systems. (27)
bulbar: Pertaining to the brainstem. (14)
bulbo-urethral glands: Mucous glands at the base of the penis that secrete into the penile urethra; the equivalent of the greater vestibular glands of females; also called *Cowper's glands*. (28)
bundle branches: Specialized conducting cells in the ventricles that carry the contractile stimulus from the atrioventricular bundle (bundle of His) to the Purkinje fibers. (20)
bundle of His: *See* **atrioventricular (AV) bundle**. (20)
bursa: A small sac filled with synovial fluid that cushions adjacent structures and reduces friction. (9)

C

calcaneal tendon: The large tendon that inserts on the calcaneus; tension on this tendon produces extension (plantar flexion) of the foot; also called *Achilles tendon*. (8, 11)
calcaneus: The heel bone, the largest of the tarsal bones. (8)
calcification: The deposition of calcium salts within a tissue. (4, 6)
calcitonin (CT): The hormone secreted by C cells of the thyroid when calcium ion concentrations are abnormally high; restores homeostasis by increasing the rate of bone deposition (mostly in childhood) and the rate of calcium loss by the kidneys. (6, 18)
calculus/calculi: Solid mass/masses of insoluble materials that form within body fluids, especially the gallbladder, kidneys, or urinary bladder. (26)

callus: A localized thickening of the epidermis due to chronic mechanical stresses (5); a thickened area that forms at the site of a bone break as part of the repair process. (6)
calorigenic effect: The stimulation of energy production and heat loss by thyroid hormones. (18)
canaliculi: Microscopic passageways between cells; bile canaliculi carry bile to bile ducts in the liver (24); in bone, canaliculi permit the diffusion of nutrients and wastes to and from osteocytes. (4, 6)
cancer: An illness caused by mutations leading to the uncontrolled growth and replication of the affected cells. (3)
cannula: A tube that can be inserted into the body; commonly placed in blood vessels prior to transfusion or dialysis. (19)
capacitation: The activation process that must occur before a sperm can successfully fertilize an oocyte; occurs in the vagina after ejaculation. (28, 29)
capillary: A small blood vessel, located between an arteriole and a venule, whose thin wall permits the diffusion of gases, nutrients, and wastes between plasma and interstitial fluids. (4, 19, 20, 21)
capitulum: A general term for a small, elevated articular process; refers to the rounded distal surface of the humerus that articulates with the head of the radius. (8)
caput: The head. (7)
carbaminohemoglobin: Hemoglobin bound to carbon dioxide molecules. (19, 23)
carbohydrase: An enzyme that breaks down carbohydrate molecules. (24)
carbohydrate: An organic compound containing carbon, hydrogen, and oxygen in a ratio that approximates 1:2:1. (2, 25)
carbon dioxide: CO_2; a compound produced by the decarboxylation reactions of aerobic metabolism. (2, 23)
carbonic anhydrase: An enzyme that catalyzes the reaction $H_2O + CO_2 \rightarrow H_2CO_3$; important in carbon dioxide transport (23), gastric acid secretion (24), and renal pH regulation (26).
carcinogenic: Stimulating cancer formation in affected tissues. (3)
cardia: The region of the stomach surrounding its connection with the esophagus. (24)
cardiac: Pertaining to the heart. (10, 20)
cardiac cycle: One complete heartbeat, including atrial and ventricular systole and diastole. (20)
cardiac output (CO): The amount of blood ejected by the left ventricle each minute; normally about 5 liters. (20)
cardiac reserve: The potential percentage increase in cardiac output above resting levels. (20)
cardiac tamponade: A compression of the heart due to fluid accumulation in the pericardial cavity. (20)
cardiovascular: Pertaining to the heart, blood, and blood vessels. (19, 20, 21)
cardiovascular (CV) centers: Poorly localized area in the reticular formation of the medulla oblongata of the brain; includes cardioacceleratory, cardioinhibitory, and vasomotor centers. (14, 21)
carotene: A yellow-orange pigment, found in carrots, sweet potatoes, and other vegetables, that the body can convert to vitamin A. (5)
carotid artery: The main artery of the neck, servicing cervical and cranial structures; one branch, the internal carotid, provides a major blood supply to the brain. (21)
carotid body: A group of receptors, adjacent to the carotid sinus, that are sensitive to changes in the carbon dioxide levels, pH, and oxygen concentrations of arterial blood. (15, 21)
carotid sinus: A dilated segment at the base of the internal carotid artery whose walls contain baroreceptors sensitive to changes in blood pressure. (21)
carotid sinus reflex: Reflexive changes in blood pressure that maintain homeostatic pressures at the carotid sinus, stabilizing blood flow to the brain. (21)
carpus/carpal: The wrist. (8, 11)
cartilage: A connective tissue with a gelatinous matrix that contains an abundance of fibers. (4)
catabolism: The breakdown of complex organic molecules into simpler components, accompanied by the release of energy. (2, 25)
catalyst: A substance that accelerates a specific chemical reaction but that is not altered by the reaction. (2)
catecholamines: Epinephrine, norepinephrine, dopamine, and related compounds. (18)
catheter: A tube surgically inserted into a body cavity or along a blood vessel or excretory passageway for the collection of body fluids, monitoring of blood pressure, or introduction of medications or radiographic dyes. (20)
cation: An ion having a positive charge. (2, 27)
cauda equina: Bundle of spinal nerve roots arising from the lumbosacral enlargement and medullary cone of the adult spinal cord; they extend caudally inside the vertebral canal en route to lumbar and sacral segments. (13)
caudal/caudally: Closest to or toward the tail (coccyx).
caudate nucleus: One of the basal nuclei involved with the subconscious control of skeletal muscular activity. (14)
cell: The smallest living structural unit in the human body. (1, 3)
cell body: The body of a neuron; also called *soma*. (4, 12)
cell-mediated immunity: Resistance to disease by sensitized T cells that destroy antigen-bearing cells by direct contact or through the release of lymphotoxins; also called *cellular immunity*. (22)
center of ossification: The site in a connective tissue where bone formation begins. (6)
central canal: Longitudinal canal in the center of an osteon that contains blood vessels and nerves; also called *Haversian canal* (6); a passageway along the longitudinal axis of the spinal cord that contains cerebrospinal fluid. (13, 14)
central nervous system (CNS): The brain and spinal cord. (12, 13)
centriole: A cylindrical intracellular organelle composed of nine groups of microtubules, three in each group (9 + 0 array); functions in mitosis or meiosis by organizing the microtubules of the spindle apparatus. (3)
centromere: The localized region where two chromatids remain connected after the chromosomes have replicated; site of spindle fiber attachment. (3)
centrosome: A region of cytoplasm that contains a pair of centrioles oriented at right angles to one another. (3)
cerebellum: The posterior portion of the metencephalon, containing the cerebellar hemispheres; includes the arbor vitae, cerebellar nuclei, and cerebellar cortex. (14, 15)
cerebral cortex: An extensive area of neural cortex covering the surfaces of the cerebral hemispheres. (14)
cerebral hemispheres: A pair of expanded portions of the cerebrum covered in neural cortex. (14)
cerebrospinal fluid (CSF): Fluid bathing the internal and external surfaces of the central nervous system; secreted by the choroid plexus. (12, 13, 14)
cerebrovascular accident (CVA): The occlusion of a blood vessel that supplies a portion of the brain, resulting in damage to the dependent neurons; also called *stroke*. (14)
cerebrum: The largest portion of the brain, composed of the cerebral hemispheres; includes the cerebral cortex, the basal nuclei, and the internal capsule. (14)
cerumen: The waxy secretion of the ceruminous glands along the external acoustic meatus. (5, 17)
ceruminous glands: Integumentary glands that secrete cerumen. (5, 17)
cervix: The inferior portion of the uterus. (28)
chemoreception: The detection of changes in the concentrations of dissolved compounds or gases (mainly CO_2 and O_2). (15, 17, 21, 23, 25)
chemotaxis: The attraction of phagocytic cells to the source of abnormal chemicals in tissue fluids. (22)
chemotherapy: The treatment of illness through the administration of specific chemicals.
chief cells: Gastric cells near the base of gastric glands that secrete pepsinogen. (24)
chloride shift: The movement of plasma chloride ions into red blood cells in exchange for bicarbonate ions generated by the intracellular dissociation of carbonic acid. (23, 27)
cholecystokinin (CCK): A duodenal hormone that stimulates the contraction of the gallbladder and the secretion of enzymes by the exocrine pancreas. (24)
cholesterol: A steroid component of plasma membranes and a substrate for the synthesis of steroid hormones and bile salts. (2, 25)
choline: A breakdown product or precursor of acetylcholine. (12)
cholinergic synapse: A synapse where the presynaptic membrane releases acetylcholine on stimulation. (12, 16)
chondrocyte: A cartilage cell. (4)
chondroitin sulfate: The predominant proteoglycan in cartilage, responsible for the gelatinous consistency of the matrix. (4)
chordae tendineae: Fibrous cords that stabilize the position of the AV valves in the heart, preventing backflow during ventricular systole (contraction). (20)
chorion/chorionic: An extra-embryonic membrane, consisting of the trophoblast and underlying mesoderm, that forms the placenta. (29)
choroid: The middle, vascular layer in the wall of the eye. (17)
choroid plexus: The vascular complex in the roof of the third and fourth ventricles of the brain, responsible for the production of cerebrospinal fluid. (14)
chromatid: One complete copy of a DNA strand and its associated nucleoproteins. (3, 28, 29)
chromatin: A histological term referring to the grainy material visible in cell nuclei during interphase; the appearance of the DNA content of the nucleus when the chromosomes are uncoiled. (3)
chromosomes: Dense structures, composed of tightly coiled DNA strands and associated histones, that become visible in the nucleus when a cell prepares to undergo mitosis or meiosis; normal human somatic cells each contain 46 chromosomes. (3, 28, 29)
chronic: Habitual or long term.

chylomicrons: Relatively large droplets that may contain triglycerides, phospholipids, and cholesterol in association with proteins; synthesized and released by intestinal cells and transported to the venous blood by the lymphatic system. (24, 25)
ciliary body: A thickened region of the choroid that encircles the lens of the eye; includes the ciliary muscle and the ciliary processes that support the *ciliary zonule* (suspensory ligament) of the lens. (17)
cilium/cilia: Slender organelle/organelles that extends above the free surface of an epithelial cell. Multiple *motile cilia* generally undergo cycles of movement and are composed of a basal body and microtubules in a 9 + 2 array; a nonmotile, solitary *primary cilium* acts as an environmental sensor, and has microtubules arranged in a 9 + 0 array. (3)
circulatory system: The network of blood vessels and lymphatic vessels that facilitate the distribution and circulation of extracellular fluid. (21, 22)
circumduction: A movement at a synovial joint in which the distal end of the bone moves in a circular direction, but the shaft does not rotate. (9)
cisterna: An expanded or flattened chamber derived from and associated with the endoplasmic reticulum. (3, 10)
citric acid cycle: The reaction sequence that occurs in the matrix of mitochondria; in the process, organic molecules are broken down, carbon dioxide molecules are released, and hydrogen molecules are transferred by coenzymes to the electron transport chain. (3, 10, 25)
clot: A network of fibrin fibers and trapped blood cells; also called a *thrombus* if it occurs within blood vessels. (19)
clotting factors: Plasma proteins, synthesized by the liver, that are essential to the clotting response. (19)
clotting response: The series of events that result in the formation of a clot. (19)
coccygeal ligament: The fibrous extension of the dura mater and filum terminale; provides longitudinal stabilization to the spinal cord. (13)
coccyx: The terminal portion of the spinal column, consisting of relatively tiny, fused vertebrae. (7)
cochlea: The spiral portion of the bony labyrinth of the internal ear that surrounds the organ of hearing. (17)
cochlear duct: *See* **scala media**. (17)
codon: A sequence of three nitrogenous bases along an mRNA strand that will specify the location of a single amino acid in a peptide chain. (3)
coelom: The body cavity lined by a serous membrane and subdivided during fetal development into the pleural, pericardial, and peritoneal cavities.
coenzymes: Complex organic cofactors; most are structurally related to vitamins. (2, 25)
cofactor: Ions or molecules that must be attached to the active site before an enzyme can function; examples include mineral ions and several vitamins. (2)
collagen fibers: Strong, insoluble protein fibers common in connective tissues. (4)
collateral ganglion: A sympathetic ganglion located anterior to the spinal column and separate from the sympathetic chain. (12, 16)
colliculus/colliculi: Little mound/mounds; in the brain, refers to one of the thickenings in the roof of the mesencephalon; the superior colliculi are associated with the visual system, and the inferior colliculi with the auditory system. (14, 15, 17)
colloid/colloidal suspension: A solution containing large organic molecules in suspension. (2, 26)
colon: The large intestine from the cecum to the rectum. (24)
coma: An unconscious state from which an individual cannot be aroused, even by strong stimuli. (16)
comminuted: Broken or crushed into small pieces.
commissure: A crossing over from one side to another.
common pathway: The final clotting pathway that begins with the activation of clotting factor X by enzyme complexes from either the extrinsic or intrinsic pathways. The common pathway ends with the formation of a blood clot when the enzyme thrombin converts soluble fibrinogen to insoluble fibrin. (19)
compact bone: Dense bone that contains parallel osteons. (6)
complement system: A group of distinct plasma proteins that interact in a chain reaction after exposure to activated antibodies or the surfaces of certain pathogens; complement proteins promote cell lysis, phagocytosis, and other defense mechanisms. (22)
compliance: Expandability; the ability of certain organs to tolerate changes in volume; indicates the presence of elastic fibers and smooth muscles. (23)
compound: A pure chemical substance made up of atoms of two or more different elements in a fixed proportion, regardless of the type of chemical bond joining them. (2)
concentration: The amount (in grams) or number of atoms, ions, or molecules (in moles) per unit volume. (2, 3, 25, 26)
concentration gradient: Regional differences in the concentration of a particular substance. (3, 25, 26)
conception: Fertilization. (29)
concha/conchae: Three pairs of thin, scroll-like bones that project into the nasal cavities; the superior and middle conchae are part of the ethmoid, and the inferior nasal conchae articulate with the ethmoid, lacrimal, maxilla, and palatine bones; also called *turbinate(s)*. (7)
condyle: A rounded articular projection on the surface of a bone. (8)
cone: A photoreceptor responsible for sharp vision and color vision. (17)
congenital: Present at birth.
congestive heart failure (CHF): The failure to maintain adequate cardiac output due to cardiovascular problems or myocardial damage. (23)
conjunctiva: A layer of stratified squamous epithelium that covers the inner surfaces of the eyelids and the anterior surface of the eye to the edges of the cornea. (17)
connective tissue: One of the four primary tissue types; provides a structural framework that stabilizes the relative positions of the other tissue types; includes connective tissue proper, cartilage, bone, and blood; contains cell products, cells, and ground substance. (4)
continuous propagation: The propagation of an action potential along an unmyelinated axon or a muscle plasma membrane, wherein the action potential affects every portion of the membrane surface. (12)
contractility: The ability to contract; possessed by skeletal, smooth, and cardiac muscle cells. (4, 20)
contralateral reflex: A reflex that affects the opposite side of the body from the stimulus. (13)
conus medullaris: The conical tip of the spinal cord that gives rise to the filum terminale. (13)
convergence: In the nervous system, the innervation of a single neuron by axons from several neurons; most common along motor pathways. (13)
coracoid process: A hook-shaped process of the scapula that projects above the anterior surface of the capsule of the shoulder joint. (8)
Cori cycle: The metabolic exchange of lactate from skeletal muscle for glucose from the liver; occurs during the recovery period after muscular exertion. (10)
cornea: The transparent portion of the fibrous layer of the anterior surface of the eye. (17)
corniculate cartilages: A pair of small laryngeal cartilages. (23)
cornu: Horn-shaped.
coronoid: Hooked or curved. (8)
corpora quadrigemina: The superior and inferior colliculi of the mesencephalic tectum (roof) in the brain. (14)
corpus/corpora: Body/bodies.
corpus callosum: A large bundle of axons that links centers in the left and right cerebral hemispheres. (14)
corpus luteum: The progesterone-secreting mass of follicle cells that develops in the ovary after ovulation. (18, 28)
cortex: The outer layer or region of an organ (5) or bone. (6)
corticobulbar tracts: Descending tracts that carry information or commands from the cerebral cortex to nuclei and centers in the brainstem. (15)
corticospinal tracts: Descending tracts that carry motor commands from the cerebral cortex to the anterior gray horns of the spinal cord. (15)
corticosteroid: A steroid hormone produced by the adrenal (suprarenal) cortex. (2, 18)
corticosterone: A corticosteroid secreted by the zona fasciculata of the adrenal (suprarenal) cortex; a glucocorticoid. (18)
corticotropin-releasing hormone (CRH): The releasing hormone, secreted by the hypothalamus, that stimulates secretion of adrenocorticotropic hormone (ACTH) by the anterior lobe of the pituitary gland (adenohypophysis). (18)
cortisol: A corticosteroid secreted by the zona fasciculata of the adrenal (suprarenal) cortex; a glucocorticoid. (18)
cortisone: A glucocorticoid produced by the adrenal cortex that exerts its effects after it is converted to cortisol. (18)
costa/costae: Rib/ribs. (7, 23)
cotransport: The membrane transport of a nutrient, such as glucose, in company with the movement of an ion, normally sodium; transport requires a carrier protein but does not involve direct ATP expenditure and can occur regardless of the concentration gradient for the nutrient. (3, 24, 26)
countercurrent exchange: The transfer of heat, water, or solutes between two fluids that travel in opposite directions. (25, 26)
countercurrent multiplication: Active transport between two limbs of a loop that contains a fluid moving in one direction in which the effect of the transport increases; responsible for the concentration of urine in the kidney tubules. (26)
covalent bond: A chemical bond between atoms that involves the sharing of electrons. (2)
coxal bone: Hip bone. (7, 8)
cranial: Pertaining to the head. (7)
cranial nerves: Peripheral nerves originating at the brain. (12)
craniosacral division: The parasympathetic division of the autonomic nervous system. (16)
cranium: The braincase; the skull bones that surround and protect the brain. (7)
creatine: A nitrogenous compound, synthesized in the body, that can form a high-energy bond by connecting to a phosphate group and that serves as an energy reserve. (10)

creatine phosphate (CP): A high-energy compound in muscle cells; during muscle activity, the phosphate group is donated to ADP, regenerating ATP; also called *phosphorylcreatine*. (10)
creatinine: A breakdown product of creatine metabolism. (26)
crenation: Cellular shrinkage due to an osmotic movement of water out of the cytoplasm. (3)
cribriform plate: A portion of the ethmoid that contains the foramina used by the axons of olfactory receptors en route to the olfactory bulbs of the cerebrum. (7)
cricoid cartilage: A ring-shaped cartilage that forms the inferior margin of the larynx. (23)
crista/cristae: A ridge-shaped collection of hair cells in the ampulla of a semicircular duct; the crista and cupula form a receptor complex sensitive to movement along the plane of the semicircular canal. (3, 17)
cross-bridge: The binding of a myosin head that projects from the surface of a thick filament at the active site of a thin filament in the presence of calcium ions. (10)
cuneiform cartilages: A pair of small cartilages in the larynx. (23)
cupula: A gelatinous mass that is located in the ampulla of a semicircular duct in the internal ear and whose movement stimulates the hair cells of the crista. (17)
Cushing disease: A condition caused by the oversecretion of adrenal steroids. (18)
cutaneous membrane: The epidermis and papillary layer of the dermis. (4, 5)
cuticle: The layer of dead, keratinized cells that surrounds the shaft of a hair; for nails, *see* **eponychium**. (5)
cyanosis: An abnormal bluish coloration of the skin due to the presence of deoxygenated blood in vessels near the body surface. (5)
cystic duct: A duct that carries bile between the gallbladder and the common bile duct. (24)
cytochrome: A protein-pigment component of the electron transport chain; a structural relative of heme. (25)
cytokinesis: The cytoplasmic movement that separates two daughter cells at the completion of mitosis. (3)
cytology: The study of the internal structures, physiology, and chemistry of cells. (1, 3)
cytoplasm: The material between the plasma membrane and the nuclear membrane; cell contents. (3)
cytosine (C): A pyrimidine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)
cytoskeleton: A network of microtubules and microfilaments in the cytoplasm. (3)
cytosol: The fluid portion of the cytoplasm; also called *intracellular fluid*. (3, 27)
cytotoxic: Poisonous to cells. (22)
cytotoxic T cells: Lymphocytes involved in cell-mediated immunity that kill target cells by direct contact or by the secretion of lymphotoxins; also called *killer T cells* and T_C *cells*. (22)

D

daughter cells: Genetically identical cells produced by somatic cell division. (3, 28)
deamination: The removal of an amino group from an amino acid. (25, 26)
decomposition reaction: A chemical reaction that breaks a molecule into smaller fragments. (2)
decussate: To cross over to the opposite side, usually referring to the crossover of the descending tracts of the corticospinal pathway on the ventral surface of the medulla oblongata. (15)
defecation: The elimination of fecal wastes. (24)
degradation: Breakdown, catabolism. (2, 25)
dehydration: A reduction in the water content of the body that threatens homeostasis. (27)
dehydration synthesis reaction: The joining of two molecules associated with the removal of a water molecule. (2)
demyelination: The loss of the myelin sheath of an axon, normally due to chemical or physical damage to Schwann cells or oligodendrocytes. (12)
denaturation: A temporary or permanent change in the three-dimensional structure of a protein. (2)
dendrite: A sensory process of a neuron. (4, 12)
deoxyribonucleic acid (DNA): A nucleic acid consisting of a double chain of nucleotides that contains the sugar deoxyribose and the nitrogenous bases adenine, guanine, cytosine, and thymine. (2)
deoxyribose: A five-carbon sugar resembling ribose but lacking an oxygen atom. (2)
depolarization: A change in the membrane potential from a negative value toward 0 mV. (12, 20)
depression: Inferior (downward) movement of a body part. (9)
dermatitis: An inflammation of the skin. (5)
dermatome: A sensory region monitored by the dorsal rami of a single spinal segment. (13)
dermis: The connective tissue layer beneath the epidermis of the skin. (5)
detrusor: Collectively, the three layers of smooth muscle in the wall of the urinary bladder. (26)
detumescence: The loss of a penile erection. (28)
development: Growth and the acquisition of increasing structural and functional complexity; includes the period from conception to maturity. (29)
diabetes insipidus: Disorder of the pituitary gland characterized by polyuria (excessive urination) and polydipsia (excessive thirst) that results from inadequate production of antidiuretic hormone (ADH). (18)
diabetes mellitus: Disorder characterized by polyuria (excessive urination) and glycosuria (glucose in the urine), most commonly due to the inadequate production or diminished sensitivity to insulin with a resulting increase of blood glucose levels. (18)
diapedesis: The movement of white blood cells through the walls of blood vessels by migration between adjacent endothelial cells. (19, 22)
diaphragm: Any muscular partition; the respiratory muscle that separates the thoracic cavity from the abdominopelvic cavity. (1, 11, 23)
diaphysis: The shaft of a long bone. (6)
diarthrosis: A synovial joint. (9)
diastole: A period of relaxation in a chamber of the heart, as part of the cardiac cycle. (20)
diastolic pressure: Pressure measured in the walls of a muscular artery when the left ventricle is in diastole (relaxation). (21)
diencephalon: A division of the brain that includes the epithalamus, thalamus, and hypothalamus. (14)
differential count: An estimate of the number of each type of white blood cell on the basis of a random sampling of 100 white blood cells. (19)
differentiation: The gradual appearance of characteristic cellular specializations during development as the result of gene activation or repression. (3, 29)
diffusion: Passive molecular movement from an area of higher concentration to an area of lower concentration. (3, 21, 23, 26)
digestion: The chemical breakdown of ingested food into simple molecules that can be absorbed by the cells of the digestive tract. (24)
digestive system: The digestive tract and associated glands. (24)
digestive tract: An internal passageway that begins at the mouth, ends at the anus, and is lined by a mucous membrane; also called *gastrointestinal(GI) tract* or *alimentary canal*. (24)
dilate: To increase in diameter; to enlarge or expand.
disaccharide: A compound formed by the joining of two simple sugars by dehydration synthesis. (2)
dissociation: *See* **ionization**. (2)
distal: A direction away from the point of attachment or origin; for a limb, away from its attachment to the trunk. (1, 8)
distal convoluted tubule (DCT): The segment of the nephron closest to the connecting tubules and collecting duct; an important site of active secretion. (26)
diuresis: Fluid loss by the kidneys; the production of unusually large volumes of urine. (26)
divergence: In nervous tissue, the spread of information from one neuron to many neurons; an organizational pattern common along sensory pathways of the central nervous system. (13)
diverticulum: A sac or pouch in the wall of the colon or other organ. (24)
DNA molecule: Two DNA strands wound in a double helix and held together by hydrogen bonds between complementary nitrogenous base pairs. (3)
dopamine: An important neurotransmitter in the central nervous system. (12)
dorsal: Toward the back, posterior.
dorsal root ganglion: *See* **posterior root ganglion**. (13)
dorsiflexion: Upward movement of the foot through flexion at the ankle. (9)
Down syndrome: A genetic abnormality resulting from the presence of three copies of chromosome 21; people with this condition have characteristic physical and intellectual deficits; also called *trisomy 21*. (16, 29)
duct: A passageway that delivers exocrine secretions to an epithelial surface. (4)
ductus arteriosus: A vascular connection between the pulmonary trunk and the aorta that functions throughout fetal life; normally closes at birth or shortly thereafter and persists as the ligamentum arteriosum. (21, 23)
ductus deferens: A passageway that carries sperm from the epididymis to the ejaculatory duct; also called the *vas deferens*. (28)
duodenal ampulla: A chamber that receives bile from the common bile duct and pancreatic secretions from the pancreatic duct. (24)
duodenal papilla: A conical projection from the inner surface of the duodenum that contains the opening of the duodenal ampulla. (24)
duodenum: The proximal 25 cm (9.8 in.) of the small intestine that contains short villi and submucosal glands. (24)
dura mater: The outermost membrane of the cranial and spinal meninges. (13, 14)

E

eccrine sweat glands: Sweat glands of the skin that produce a watery secretion. (5)
ectoderm: One of the three primary germ layers; covers the surface of the embryo and gives rise to the nervous system, the epidermis and associated glands, and a variety of other structures. (29)
ectopic: Outside the normal location.
effector: A peripheral gland or muscle cell innervated by a motor neuron. (1, 12)

efferent: Conducting a fluid or nerve impulse away from an organ or structure.
efferent arteriole: An arteriole carrying blood away from a glomerulus of the kidney. (26)
efferent fiber: An axon that carries impulses away from the central nervous system. (12)
ejaculation: The ejection of semen from the penis as the result of muscular contractions of the bulbospongiosus and ischiocavernosus muscles. (28)
ejaculatory ducts: Short ducts that pass within the walls of the prostate gland and connect the ductus deferens with the prostatic urethra. (28)
elastase: A pancreatic enzyme that breaks down elastin fibers. (24)
elastin: Connective tissue fibers that stretch and recoil, providing elasticity to connective tissues. (4, 5)
electrical coupling: A connection between adjacent cells that permits the movement of ions and the transfer of graded or propagated changes in the membrane potential from cell to cell. (12)
electrocardiogram (ECG, EKG): A graphic record of the electrical activities of the heart, as monitored at specific locations on the body surface. (20)
electroencephalogram (EEG): A graphic record of the electrical activities of the brain. (14)
electrolytes: Soluble inorganic compounds whose ions will conduct an electrical current in solution. (2, 27)
electron: One of the three fundamental subatomic particles; has a negative charge and normally orbits the protons of the nucleus. (2, 25)
electron transport chain (ETC): The system made up of four respiratory protein complexes, coenzyme Q, and electron carriers made up of a series of cytochrome molecules responsible for aerobic energy production in cells; bound to the inner mitochondrial membrane. (25)
element: All the atoms with the same atomic number. (2)
elevation: Movement in a superior, or upward, direction. (9)
elimination: The ejection of wastes from the body through urination or defecation. (24, 26)
embolism: The obstruction of a vessel, typically by a blood clot. (19)
embolus: An air bubble, fat globule, or blood clot drifting in the bloodstream. (19)
embryo: The developmental stage beginning at fertilization and ending at the start of the third developmental month. (28, 29)
embryology: The study of embryonic development, focusing on the first 2 months after fertilization. (1, 28, 29)
endocardium: The simple squamous epithelium that lines the heart and is continuous with the endothelium of the great vessels. (20)
endochondral ossification: The replacement of a cartilaginous model with bone; the characteristic mode of formation for skeletal elements other than the bones of the cranium, the clavicles, and sesamoid bones. (6)
endocrine gland: A gland that secretes hormones into the blood. (4, 18)
endocrine system: The endocrine (ductless) glands and organs of the body. (18)
endocytosis: The movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface; includes pinocytosis and phagocytosis. (3)
endoderm: One of the three primary germ layers; the layer on the undersurface of the embryonic disc; gives rise to the epithelia and glands of the digestive system, the respiratory system, and portions of the urinary system. (29)
endogenous: Produced within the body.
endolymph: The fluid contents of the membranous labyrinth (the saccule, utricle, semicircular ducts, and cochlear duct) of the internal ear. (17)
endometrium: The mucous membrane lining the uterus. (28)
endomysium: A delicate network of connective tissue fibers that surrounds individual muscle cells. (10)
endoneurium: A delicate network of connective tissue fibers that surrounds individual nerve fibers. (13)
endoplasmic reticulum: A network of membranous channels in the cytoplasm of a cell that function in intracellular transport, synthesis, storage, packaging, and secretion. (3)
endorphins: Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)
endosteum: An incomplete cellular lining on the inner (medullary) surfaces of bones. (6)
endothelium: The simple squamous epithelial cells that line blood and lymphatic vessels. (4, 19, 21)
enkephalins: Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)
enteric nervous system (ENS): One of the three main divisions of the nervous system; it is an extensive nerve network in the walls of the digestive tract that initiates and coordinates digestive motility and secretions. (16)
enterocrinin: A hormone secreted by the lining of the duodenum after exposure to chyme; stimulates the secretion of the submucosal glands. (24)
enteroendocrine cells: Endocrine cells scattered among the epithelial cells that line the digestive tract. (24)
enterogastric reflex: The reflexive inhibition of gastric secretion; initiated by the arrival of chyme in the small intestine. (24)
enterohepatic circulation: The excretion of bile salts by the liver, followed by the absorption of bile salts by intestinal cells for return to the liver by the hepatic portal vein. (24)
enteropeptidase: An enzyme in the lumen of the small intestine that activates the proenzymes secreted by the pancreas; formerly called *enterokinase*. (24)
enzyme: A protein that catalyzes a specific biochemical reaction. (2)
eosinophil: A type of white blood cell with a lobed nucleus and red-staining granules; participates in the immune response and is especially important during allergic reactions. (19)
ependymal cells: The layer of cells lining the ventricles and central canal of the central nervous system. (12)
epicardium: A serous membrane covering the outer surface of the heart; also called *visceral pericardium*. (20)
epidermis: The epithelium covering the surface of the skin. (5)
epididymis: A coiled duct that connects the rete testis to the ductus deferens; site of functional maturation of sperm. (28)
epidural space: The space between the spinal dura mater and the walls of the vertebral foramen; contains blood vessels and adipose tissue; a common site of injection for regional anesthesia. (13)
epiglottis: A blade-shaped flap of tissue, reinforced by cartilage, that is attached to the posterior and superior surface of the thyroid cartilage; folds over the entrance to the larynx during swallowing. (23)
epimysium: A dense layer of collagen fibers that surrounds a skeletal muscle and is continuous with the tendons/aponeuroses of the muscle and with the perimysium. (10)
epineurium: A dense layer of collagen fibers that surrounds a peripheral nerve. (13)
epiphyseal cartilage: The cartilaginous region between the epiphysis and diaphysis of a growing bone; also called *epiphyseal plate*. (6)
epiphysis: The head of a long bone. (6)
epithelium: One of the four primary tissue types; a layer of cells that forms a superficial covering or an internal lining of a body cavity or vessel. (4, 24)
eponychium: A narrow zone of stratum corneum that extends across the surface of a nail at its exposed base; also called the *cuticle*. (5)
eponym: A commemorative name for a structure or clinical condition that was originally named for a real or mythical person. (1)
equilibrium: A dynamic state in which two opposing forces or processes are in balance. (1, 15, 17)
erection: The stiffening of the penis due to the erectile tissues of the corpora cavernosa and corpus spongiosum filling with blood. (28)
erythema: Redness and inflammation at the surface of the skin. (5, 22)
erythrocyte: A red blood cell (RBC); has no nucleus and contains large quantities of hemoglobin. (4, 19)
erythropoiesis: The formation of red blood cells. (19)
erythropoietin (EPO): A hormone released by most tissues, and especially by the kidneys, when oxygen levels decrease; stimulates erythropoiesis (red blood cell formation) in red bone marrow. (18, 19, 21)
Escherichia coli: A normal bacterial resident of the large intestine. (24)
esophagus: A muscular tube that connects the pharynx to the stomach. (24)
essential amino acids: Amino acids that cannot be synthesized in the body in adequate amounts and must be obtained from the diet. (25)
essential fatty acids: Fatty acids that cannot be synthesized in the body and must be obtained from the diet. (25)
estrogens: A class of steroid sex hormones that includes estradiol. (2, 18, 28)
evaporation: A movement of molecules from the liquid state to the gaseous state. (25)
eversion: A turning outward. (9)
excitable membranes: Membranes that propagate action potentials, a characteristic of muscle cells and nerve cells. (10, 12)
excitatory postsynaptic potential (EPSP): The depolarization of a postsynaptic membrane by a chemical neurotransmitter released by the presynaptic cell. (12)
excretion: The removal of wastes from the blood, tissues, or organs. (24)
exocrine gland: A gland that secretes onto the body surface or into a passageway connected to the exterior. (4)
exocytosis: The ejection of cytoplasmic materials by the fusion of a membranous vesicle with the plasma membrane. (3)
expiration: Exhalation; breathing out.
extension: An increase in the angle between two articulating bones; the opposite of flexion. (8, 9)
external acoustic meatus: A passageway in the temporal bone that leads to the tympanic membrane of the middle ear. (7, 17)
external ear: The auricle, external acoustic meatus, and tympanic membrane. (17)

external nares: The nostrils; the external openings into the nasal cavity. (23)
external respiration: The diffusion of gases between the alveolar air and the alveolar capillaries and between the systemic capillaries and peripheral tissues. (23)
exteroceptors: General sensory receptors in the skin, mucous membranes, and special sense organs that provide information about the external environment and about our position within it. (12)
extracellular fluid (ECF): All body fluids other than that contained within cells; includes plasma and interstitial fluid. (3, 27)
extra-embryonic membranes: The yolk sac, amnion, chorion, and allantois. (29)
extrafusal muscle fibers: Contractile muscle fibers (as opposed to the sensory intrafusal fibers, or muscle spindles). (13)
extrinsic pathway: A clotting pathway that begins with damage to blood vessels or surrounding tissues and ends with the formation of tissue factor complex. (19)
eyelids: Movable folds that cover the front of the eyeballs. *See* **palpebrae.** (17)

F

fabella: A sesamoid bone commonly located in the gastrocnemius. (11)
facilitated: Brought closer to threshold, as in the depolarization of a nerve plasma membrane toward threshold; making the cell more sensitive to depolarizing stimuli. (12)
facilitated diffusion: The passive movement of a substance across a plasma membrane by means of a protein carrier. (3, 24, 26)
falciform ligament: A sheet of mesentery that contains the ligamentum teres, the fibrous remains of the umbilical vein of the fetus. (24, 29)
falx: Sickle shaped.
falx cerebri: The curving sheet of dura mater that extends between the two cerebral hemispheres; encloses the superior sagittal sinus. (7, 14)
fasciae: Connective tissue fibers, primarily collagen, that form sheets or bands beneath the skin to attach, stabilize, enclose, and separate muscles and other internal organs. (4)
fasciculus: A small bundle; usually refers to a collection of nerve axons or muscle fibers. (10, 15)
fatty acids: Hydrocarbon chains that end in a carboxyl group. (2)
fauces: The passage from the mouth to the pharynx, bounded by the palatal arches, the soft palate, and the uvula. (24)
febrile: Characterized by or pertaining to a fever. (22, 25)
feces: Waste products eliminated by the digestive tract at the anus; contains indigestible residue, bacteria, mucus, and epithelial cells. (24)
fenestra/fenestrae: Opening(s).
fertilization: The fusion of a secondary oocyte and a sperm to form a zygote. (28, 29)
fetus: The developmental stage lasting from the start of the third developmental month to delivery. (28, 29)
fibrin: Insoluble protein fiber that forms the basic framework of a blood clot. (19)
fibrinogen: A plasma protein that is the soluble precursor of the insoluble protein fibrin. (19)
fibroblasts: Cells of connective tissue proper that produce extracellular fibers and secrete the organic substances of the extracellular matrix. (4)
fibrocartilage: Cartilage containing an abundance of collagen fibers; located around the edges of joints, in the intervertebral discs, and the menisci of the knee; also referred to as *fibrous cartilage*. (4)
fibrocytes: Mature fibroblasts; maintain connective tissue fibers of connective tissue proper. (4)
fibrous layer: The outermost layer of the eye, composed of the sclera and cornea; also called *fibrous tunic*. (17)
fibula: The lateral, slender bone of the leg. (8)
filariasis: A condition resulting from infection by mosquito-borne parasites; can cause elephantiasis. (21, 22)
filiform papillae: Slender conical projections from the dorsal surface of the anterior two-thirds of the tongue. (17)
filtrate: The fluid produced by filtration at a glomerulus in the kidney. (26)
filtration: The movement of a fluid across a membrane whose pores restrict the passage of solutes on the basis of size. (21, 26)
filtration pressure: The hydrostatic pressure responsible for filtration. (21, 26)
filum terminale: A fibrous extension of the spinal cord, from the conus medullaris to the coccygeal ligament. (13)
fimbriae: Fringes; the fingerlike processes that surround the entrance to the uterine tube. (28)
fissure: An elongated groove or opening. (7, 14)
fistula: An abnormal passageway between two organs or from an internal organ or space to the body surface.
flaccid: Limp, soft, flabby; a muscle without muscle tone.
flagellum/flagella: An organelle that is structurally similar to a motile cilium but is used to propel a cell through a fluid; found on sperm. (3, 28)
flatus: Intestinal gas. (24)
flexion: A movement that decreases the angle between two articulating bones; the opposite of extension. (8, 9)
flexor: A muscle that produces flexion. (11)
flexor reflex: A reflex contraction of the flexor muscles of a limb in response to a painful stimulus. (13)
flexure: A bending.
folia: Leaflike folds; the slender folds in the surface of the cerebellar cortex. (14)
follicle: A small secretory sac or gland.
follicle-stimulating hormone (FSH): A hormone secreted by the adenohypophysis (anterior lobe of the pituitary gland); stimulates oogenesis (female) and spermatogenesis (male). (18, 28)
fontanelle: A relatively soft, flexible, fibrous region between two flat bones in the developing skull; also spelled *fontanel*. (7)
foramen/foramina: Opening/openings or passage/passages through a bone. (7, 20)
forearm: The distal portion of the upper limb between the elbow and wrist. (8)
forebrain: The cerebrum. (14)
fornix: An arch or the space bounded by an arch; in the brain, an arching tract that connects the hippocampus with the mammillary bodies (14); in the eye, a slender pocket located where the epithelium of the ocular conjunctiva folds back on itself as the palpebral conjunctiva (17); in the vagina, the shallow recess surrounding the protrusion of the cervix. (28)
fossa: A shallow depression or furrow in the surface of a bone. (8, 20)
fourth ventricle: An elongated ventricle of the metencephalon (pons and cerebellum) and the myelencephalon (medulla oblongata) of the brain; the roof contains a region of choroid plexus. (14)
fovea centralis: The portion of the retina within the macula that provides the sharpest vision because it has the highest concentration of cones; also called *fovea*. (17)
fracture: A break or crack in a bone. (6)
frenulum: A bridle; usually referring to a band of tissue that restricts movement, e.g., *lingual frenulum*. (24)
frontal (coronal) plane: A vertical plane that divides the body into anterior and posterior portions. (1)
fructose: A hexose (six-carbon simple sugar) in foods and in semen. (2, 28)
fundus: The base of an organ such as the stomach, uterus, or gallbladder.

G

gallbladder: The pear-shaped reservoir for bile after it is secreted by the liver. (24)
gametes: Reproductive cells (sperm or oocytes) that contain half the normal chromosome complement. (28, 29)
gametogenesis: The formation of gametes. (28)
gamma-aminobutyric acid (GABA): A neurotransmitter of the central nervous system whose effects are generally inhibitory. (12)
gamma motor neurons: Motor neurons that adjust the sensitivities of muscle spindles (intrafusal fibers). (13)
ganglion/ganglia: A collection of neuron cell bodies in the peripheral nervous system. (12, 16)
gangliosides: Glycolipids that are important components of plasma membranes in the central nervous system. (12)
gap junctions: Connections between cells that permit electrical coupling. (4)
gaster: The stomach (24); the body, or belly, of a skeletal muscle. (11)
gastric: Pertaining to the stomach. (24)
gastric glands: The tubular glands of the stomach whose cells produce acid, enzymes, intrinsic factor, and hormones. (24)
gastrointestinal (GI) tract: *See* **digestive tract**. (24)
gene: A portion of a DNA strand that functions as a hereditary unit, is located at a particular site on a specific chromosome, and codes for a specific protein or polypeptide. (3, 29)
genetic engineering: Research and experiments involving the manipulation of the genetic makeup of an organism. (29)
genetics: The study of heredity and genetic variations. (29)
geniculate body: The medial geniculate body and the lateral geniculate body are in the thalamus of the brain. (14)
genitalia: The reproductive organs. (28)
genotype: Genetic makeup of an organism. (29)
germinal centers: Pale regions in the interior of lymphoid tissues or lymphoid nodules, where cell divisions occur that produce additional lymphocytes. (22)
gestation: The period of intrauterine development; pregnancy. (29)
gland: Cells that produce exocrine or endocrine secretions. (4)
glenoid cavity: A rounded depression that forms the articular surface of the scapula at the shoulder joint. (8)
glial cells: *See* **neuroglia**. (4, 12)
globular proteins: Proteins whose tertiary structure makes them rounded and compact. (2)
glomerular capsule: The expanded initial portion of the nephron that surrounds the glomerulus; also called *Bowman's capsule*. (26)

glomerular filtration rate (GFR): The rate of filtrate formation at the glomerulus. (26)
glomerulus: A knot of capillaries that projects into the enlarged, proximal end of a nephron; the site of filtration, the first step in the production of urine. (26)
glossopharyngeal nerve: Cranial nerve IX that provides sensations to the pharynx and posterior third of the tongue; it also carries motor fibers to the stylopharyngeus muscle. (14)
glottis: Structure within the larynx that consists of the vocal folds and the rima glottidis. (23)
glucagon: A hormone secreted by the alpha cells of the pancreatic islets; increases blood glucose concentrations. (18)
glucocorticoids: Hormones secreted by the zona fasciculata of the adrenal (suprarenal) cortex to modify glucose metabolism; cortisol and corticosterone are important examples. (18)
gluconeogenesis: The synthesis of glucose from noncarbohydrate precursors (e.g., lactate, glycerol, or amino acids). (25)
glucose: A six-carbon sugar, $C_6H_{12}O_6$; the preferred energy source for most cells and normally the only energy source for neurons. (2, 10, 18, 25)
glycerides: Lipids composed of glycerol bound to fatty acids. (2)
glycogen: A polysaccharide that is an important energy reserve; a polymer consisting of a long chain of glucose molecules. (2, 10, 25)
glycogenesis: The synthesis of glycogen from glucose molecules. (25)
glycogenolysis: Glycogen breakdown and the liberation of glucose molecules. (25)
glycolipids: Compounds created by the combination of carbohydrate and lipid components. (2)
glycolysis: The anaerobic cytosolic breakdown of glucose into two 3-carbon molecules of pyruvate, with a net gain of 2 ATP molecules. (3, 10, 25)
glycoprotein: A compound containing a relatively small carbohydrate group attached to a large protein. (2, 18)
glycosuria: The presence of glucose in urine; also called *glucosuria*. (18, 26)
goblet (mucous) cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts; they are called goblet cells in the mucosa of the small intestine, large intestine, terminal bronchioles, and conjunctiva; they are called mucous cells when they are found in the stomach mucosa, respiratory mucosa, and salivary glands; (4, 23, 24)
Golgi apparatus: A cellular organelle consisting of a series of membranous plates that give rise to lysosomes and secretory vesicles. (3)
gomphosis: A fibrous synarthrosis that binds a tooth to the bone of the jaw; *see* **periodontal ligament**. (24)
gonadotropin-releasing hormone (GnRH): A hypothalamic releasing hormone that causes the secretion of both follicle-stimulating hormone and luteinizing hormone by the anterior lobe of the pituitary gland (adenohypophysis). (18, 28)
gonadotropins: Follicle-stimulating hormone and luteinizing hormone, hormones that stimulate gamete development and sex hormone secretion. (18, 28)
gonads: Reproductive organs that produce gametes and sex hormones. (28)
granulocytes: White blood cells containing granules that are visible with the light microscope; includes eosinophils, basophils, and neutrophils; also called *granular leukocytes*. (19)
gray matter: Areas in the central nervous system that are dominated by neuron cell bodies, neuroglia, and unmyelinated axons. (12, 13, 14)
gray ramus communicans: A bundle of postganglionic sympathetic nerve fibers distributed to effectors in the body wall, skin, and limbs by way of a spinal nerve. (13)
greater omentum: A large fold of the dorsal mesentery of the stomach; hangs anterior to the intestines. (24)
groin: The inguinal region. (11)
gross anatomy: The study of the structural features of the body without the aid of a microscope; also called *macroscopic anatomy*. (1)
growth hormone (GH): An adenohypophysis (anterior lobe of the pituitary gland) hormone that stimulates tissue growth and anabolism when nutrients are abundant and restricts tissue glucose dependence when nutrients are in short supply. (18)
growth hormone–inhibiting hormone (GH–IH): A hypothalamic regulatory hormone that inhibits growth hormone secretion by the anterior lobe of the pituitary gland (adenohypophysis); also called *somatostatin*. (18)
growth hormone–releasing hormone (GH–RH): A peptide released by the hypothalamus that causes the release of growth hormone from the anterior pituitary gland. (18)
guanine (G): A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)
gustation: Sense of taste. (15, 17)
gyrus: A prominent fold or ridge of neural cortex on the surfaces of the cerebral hemispheres. (14)

H

hair: A keratinous strand produced by epithelial cells of the hair follicle. (5)
hair cells: Sensory cells of the internal ear. (17)
hair follicle: An accessory structure of the integument; a tube lined by a stratified squamous epithelium that begins at the surface of the skin and ends at the hair papilla. (5)
hallux: The big toe; also called the *great toe*. (8)
haploid: Possessing half the normal number of chromosomes; a characteristic of gametes. (28, 29)
hard palate: The bony roof of the oral cavity, formed by the maxillae and palatine bones. (23, 24)
helper T cells: Lymphocytes whose secretions and other activities coordinate cell-mediated and antibody-mediated immunities; also called T_H *cells*. (22)
hematocrit: The percentage of formed elements in a sample of blood; also called *volume of packed red cells (VPRC)* or *packed cell volume (PCV)*. (19)
hematoma: A tumor or swelling filled with blood.
hematuria: The abnormal presence of red blood cells in urine. (19, 26)
heme: A porphyrin ring containing a central iron atom that can reversibly bind oxygen molecules; a component of the hemoglobin molecule. (19)
hemocytoblasts: Stem cells whose divisions produce each of the various populations of blood cells; also called *hematopoietic stem cells*. (19)
hemoglobin (Hb or Hgb): A protein composed of four globular subunits, each bound to a heme molecule; gives red blood cells the ability to transport oxygen in the blood. (5, 19, 23, 27)
homozygous: Having identical alleles at corresponding sites on a chromosome pair. (29)
hemolysis: The breakdown of red blood cells. (3)
hemopoiesis: Blood cell formation and differentiation. (19)
hemorrhage: Blood loss; to bleed. (21)
hemostasis: The stoppage of bleeding. (19)
heparin: An anticoagulant released by activated basophils and mast cells. (4, 19)
hepatic duct: The duct that carries bile away from the liver lobes and toward the union with the cystic duct. (24)
hepatic portal vein: The vessel that carries blood from the intestinal capillaries to the sinusoids of the liver. (21)
hepatocyte: A liver cell. (24)
heterozygous: Possessing two different alleles at corresponding sites on a chromosome pair; a person's phenotype is determined by one or both of the alleles. (29)
hexose: A six-carbon simple sugar. (2)
hiatus: A gap, cleft, or opening.
high-density lipoprotein (HDL): A lipoprotein with a relatively small lipid content; responsible for the movement of cholesterol from peripheral tissues to the liver. (25)
hilum: A localized region where blood vessels, lymphatic vessels, nerves, and/or other anatomical structures are attached to an organ. (22, 23, 26)
hippocampus: A region, deep to the floor of a lateral ventricle, involved with emotional states and the conversion of short-term to long-term memories. (12, 14)
histamine: The chemical released by stimulated mast cells or basophils to initiate or enhance inflammation. (4, 12)
histology: The study of tissues. (1, 4)
histones: Proteins associated with the DNA of the nucleus; the DNA strands are wound around them. (3)
holocrine secretion: A form of exocrine secretion in which the secretory cell becomes swollen with vesicles and then ruptures. (4)
homeostasis: The maintenance of a relatively constant internal environment. (1)
hormone: A chemical that is secreted by one cell and travels through the bloodstream to affect the activities of cells in another part of the body. (2, 4, 6, 18, 21, 24, 28, 29)
human chorionic gonadotropin (hCG): The placental hormone that maintains the corpus luteum for the first 3 months of pregnancy. (29)
human immunodeficiency virus (HIV): The infectious agent that causes acquired immunodeficiency syndrome (AIDS). (22)
human leukocyte antigen (HLA): *See* **MHC protein**. (22)
human placental lactogen (hPL): The placental hormone that stimulates the functional development of the mammary glands. (29)
humoral immunity: *See* **antibody-mediated immunity**. (22)
hyaluronan: A carbohydrate component of proteoglycans in the matrix of many connective tissues; also called *hyaluronic acid*. (4)
hyaluronidase: An enzyme that breaks down the bonds between adjacent follicle cells; produced by some bacteria and found in the acrosome of a sperm. (29)
hydrogen bond: A weak interaction between the hydrogen atom on one molecule and a negatively charged portion of another molecule. (2)
hydrogen ion: A hydrogen atom that has lost an electron; a proton. (2)
hydrolysis reaction: The breakage of a chemical bond through the addition of a water molecule; the reverse of dehydration synthesis. (2)
hydrophilic: Freely associating with water; readily entering into solution; water loving. (2)
hydrophobic: Incapable of freely associating with water molecules; insoluble; water fearing. (2)
hydrostatic pressure: Fluid pressure. (3, 21, 26)
hydroxide ion: OH^-. (2)

hypercapnia: High blood carbon dioxide concentrations, commonly as a result of hypoventilation or inadequate tissue perfusion. (23, 27)
hyperextension: Extension of a body part past the anatomical position. (9)
hyperplasia: An abnormal increase in the number of cells in a tissue or organ. (3)
hyperpolarization: The movement of the membrane potential away from the normal resting potential and farther from 0 mV. (12)
hypersecretion: The overactivity of glands that produce exocrine or endocrine secretions. (18)
hypertension: Abnormally high blood pressure. (21)
hypertonic: In comparing two solutions, the solution with the higher osmolarity. (3)
hypertrophy: An increase in tissue size without cell division. (10)
hyperventilation: A rate of respiration sufficient to decrease blood P_{CO_2} to levels below normal. (23, 27)
hypocapnia: An abnormally low blood P_{CO_2}; commonly results from hyperventilation. (23, 27)
hypodermic needle: A needle inserted through the skin to introduce drugs into the subcutaneous layer. (5)
hypodermis: The layer of loose connective tissue deep to the dermis; also called *subcutaneous layer* (4, 5)
hypophyseal portal system: The network of vessels that carries blood from capillaries in the hypothalamus to capillaries in the anterior lobe of the pituitary gland (adenohypophysis). (18)
hypophysis: *See* **pituitary gland**. (18)
hyposecretion: Abnormally low exocrine or endocrine secretion. (18)
hypothalamus: The floor of the diencephalon; the region of the brain containing centers involved with the subconscious regulation of visceral functions, emotions, drives, and the coordination of neural and endocrine functions. (14, 18)
hypothermia: An abnormally low body temperature. (25)
hypothesis: A prediction that can be subjected to scientific analysis and review.
hypotonic: In comparing two solutions, the solution with the lower osmolarity. (3)
hypoventilation: A respiratory rate that is insufficient to keep blood P_{CO_2} within normal levels. (23, 27)
hypoxia: A low tissue oxygen concentration. (19, 23)

I

ileum: The distal segment of the small intestine. (24)
ilium: The largest of the three bones whose fusion creates a coxal bone. (8)
immunity: Resistance to infection and disease caused by foreign substances, toxins, or pathogens. (22)
immunization: The production of immunity by the deliberate exposure to antigens under conditions that prevent the development of illness but stimulate the production of memory B cells. (22)
immunoglobulin (Ig): A circulating antibody. (19, 22)
implantation: The attachment of a blastocyst into the endometrium of the uterine wall. (29)
inclusions: Aggregations of insoluble pigments, nutrients, or other materials in cytoplasm. (3)
incus: The central auditory ossicle, located between the malleus and the stapes in the middle ear cavity. (17)
inducer: A stimulus that promotes the activity of a specific gene. (29)
inexcitable: Incapable of propagating an action potential. (12)
infarct: An area of dead cells that results from an interruption of blood flow. (19, 20)
infection: The invasion and colonization of body tissues by pathogens. (4)
inferior: Below, in reference to a particular structure, with the body in the anatomical position.
inferior vena cava (IVC): The vein that carries blood from the parts of the body inferior to the heart to the right atrium. (20, 21)
infertility: The inability to conceive; also called *sterility*. (28, 29)
inflammation: A nonspecific defense mechanism that operates at the tissue level; characterized by swelling, redness, heat (warmth), pain, and sometimes loss of function. (4, 22)
infundibulum: A tapering, funnel-shaped structure; in the brain, the connection between the pituitary gland and the hypothalamus (14, 18); in the uterine tube, the entrance bounded by fimbriae that receives the oocyte at ovulation. (28)
ingestion: The introduction of food into the digestive tract by way of the mouth; eating. (24)
inguinal canal: A passage through the abdominal wall that marks the path of testicular descent and that contains the testicular arteries, veins, and ductus deferens. (11, 28)
inguinal region: The area of the abdominal wall near the junction of the trunk and the thighs that contains the external genitalia; the groin. (28)
inhibin: A hormone, produced by nurse cells of the testes and follicular cells of the ovaries, that inhibits the secretion of follicle-stimulating hormone by the adenohypophysis (anterior lobe of the pituitary gland). (18, 28)
inhibitory postsynaptic potential (IPSP): A hyperpolarization of the postsynaptic membrane after the arrival of a neurotransmitter. (12)
initial segment: The proximal portion of the axon where an action potential first appears. (12)
injection: The forcing of fluid into a body part or organ.
inner cell mass: Cells of the blastocyst that will form the body of the embryo. (29)
innervation: The distribution of sensory and motor nerves to a specific region or organ. (11, 16)
insensible perspiration: Evaporative water loss by diffusion across the epithelium of the skin or evaporation across the alveolar surfaces of the lungs. (5, 27)
insertion: A point of attachment of a muscle; the end that is easily movable. (11)
insoluble: Incapable of dissolving in solution. (2)
inspiration: Inhalation; the movement of air into the respiratory system. (23)
insulin: A hormone secreted by beta cells of the pancreatic islets; causes a decrease in blood glucose concentrations. (18)
integument: The skin. (5)
intercalated discs: Regions where adjacent cardiac muscle cells interlock and where gap junctions permit electrical coupling between the cells. (4, 10, 20)
intercellular fluid: *See* **interstitial fluid**. (3)
interferons (IFNs): Peptides released by virus-infected cells, especially lymphocytes, that slow viral replication and make other cells more resistant to viral infection. (22)
interleukins: Peptides, released by activated monocytes and lymphocytes, that assist in the coordination of cell-mediated and antibody-mediated immunities. (22)
internal capsule: The collection of afferent and efferent fibers of the white matter of the cerebral hemispheres, visible on gross dissection of the brain. (14)
internal ear: The membranous labyrinth that contains the organs of hearing and equilibrium. (17)
internal respiration: The diffusion of gases between interstitial fluid and cytoplasm. (23)
interneuron: An association neuron; central nervous system neurons that are between sensory and motor neurons. (12)
interoceptors: Sensory receptors monitoring the functions and status of internal organs and systems. (12)
interosseous membrane: The fibrous connective tissue membrane between the shafts of the tibia and fibula and between the radius and ulna; an example of a fibrous amphiarthrosis. (8)
interphase: The stage in the life cycle of a cell during which the chromosomes are uncoiled and all normal cellular functions except mitosis are under way. (3, 29)
intersegmental reflex: A reflex that involves several segments of the spinal cord. (13)
interstitial fluid: The fluid in the tissues that fills the spaces between cells. (3)
interstitial growth: A form of cartilage growth in which the cartilage expands from within through the growth, mitosis, and secretion of chondrocytes in the matrix. (4)
interventricular foramen: The opening that permits fluid movement between the lateral and third ventricles of the brain. (14)
intervertebral disc: A fibrocartilage pad between the bodies of successive vertebrae that absorbs shocks. (7, 9)
intestinal gland: A tubular epithelial pocket that is lined by secretory cells and opens into the lumen of the digestive tract; also called *intestinal crypt*. (24)
intestine: The tubular organ of the digestive tract. (18, 24)
intracellular fluid (ICF): The cytosol. (27)
intrafusal muscle fibers: Muscle spindle fibers. (13)
intramembranous ossification: The formation of bone within a connective tissue without the prior development of a cartilaginous model. (6)
intrinsic factor: A glycoprotein secreted by the parietal cells of the stomach that facilitates the intestinal absorption of vitamin B_{12}. (19, 24, 25)
intrinsic pathway: A pathway of the clotting system that begins with the activation of platelets and ends with the formation of factor X activator complex. (19)
inversion: A turning inward. (9)
in vitro: Outside the body, in an artificial environment.
in vivo: In the living body.
involuntary: Not under conscious control.
ion: An atom or molecule having a positive or negative charge due to the loss or gain, respectively, of one or more electrons. (2, 26, 27)
ionic bond: A molecular bond created by the attraction between ions with opposite charges. (2)
ionization: the dissociation of an atom, molecule, or substance into ions; also called *dissociation*. (2)
ipsilateral: A reflex response that affects the same side as the stimulus. (13)
iris: A contractile structure made up of smooth muscle that forms the colored portion of the eye. (17)
ischemia: An inadequate blood supply to a region of the body. (11)
ischium: One of the three bones whose fusion creates a coxal bone. (8)
islets of Langerhans: *See* **pancreatic islets**. (18, 24)
isotonic: A solution with an osmolarity that does not result in water movement across plasma membranes. (3, 10)

isotopes: Forms of an element whose atoms contain the same number of protons but different numbers of neutrons (and thus differ in atomic mass). (2)
isthmus: A narrow band of tissue connecting two larger masses.

J

jejunum: The middle part of the small intestine. (24)
joint: An area where adjacent bones interact; also called *articulation*. (9)
juxtaglomerular cells: Modified smooth muscle cells between the walls of the distal convoluted tubule and the afferent and efferent arterioles adjacent to the glomerulus and the macula densa. (26)
juxtaglomerular complex (JGC): The macula densa, extraglomerular mesangial cells, and the juxtaglomerular cells; a complex responsible for the release of renin and erythropoietin. (26)

K

keratin: The tough, fibrous protein component of nails, hair, calluses, and the general integumentary surface. (5)
keto acid: The carbon chain that remains after the deamination or transamination of an amino acid. (25)
ketoacidosis: A condition characterized by a decrease in blood pH due to the presence of large numbers of ketone bodies. (25, 26, 27)
ketone bodies: Keto acids produced during the catabolism of lipids and ketogenic amino acids; specifically, acetone, acetoacetate, and beta-hydroxybutyrate. (25)
kidney: A component of the urinary system; an organ functioning in the regulation of blood composition, including the excretion of wastes and the maintenance of normal fluid and electrolyte balances. (18, 26)
killer T cells: *See* **cytotoxic T cells**. (22)
Krebs cycle: *See* **citric acid cycle**. (3, 10, 25)
Kupffer cell: *See* **stellate macrophage.** (22, 24)

L

labium/labia: Lip/lips; the labia majora and labia minora are structures of the female external genitalia. (28)
labrum: A lip or rim.
labyrinth: A maze of passageways; the structures of the internal ear. (17)
lacrimal gland: A tear gland on the dorsolateral surface of the eye. (17)
lactase: An enzyme that breaks down the milk sugar, lactose. (24)
lactate: An anion released by the dissociation of lactic acid, or formed from the reduction of pyruvate. (10)
lactation: The production of milk by the mammary glands. (28)
lacteal: A terminal lymphatic within an intestinal villus. (24)
lacuna/lacunae: A small pit or cavity. (4, 6, 29)
lambdoid suture: The synarthrosis between the parietal and occipital bones of the cranium. (7)
lamellae: Concentric layers; the concentric layers of bone within an osteon. (6)
lamellated corpuscle: A receptor sensitive to vibration. (15)
lamina: A thin sheet or layer.
lamina propria: The areolar tissue that underlies a mucous epithelium and forms part of a mucous membrane. (4, 23, 24)
Langerhans cells: Cells in the epithelium of the skin (15) and digestive tract (24) that participate in the immune response by presenting antigens to T cells; also called *dendritic cells*.
large intestine: The terminal portions of the intestinal tract, consisting of the colon, the rectum, and the anal canal. (24)
laryngopharynx: The division of the pharynx that is inferior to the epiglottis and superior to the esophagus. (23)
larynx: A complex cartilaginous structure that surrounds and protects the glottis and vocal cords; the superior margin is bound to the hyoid bone, and the inferior margin is bound to the trachea. (23)
latent period: The time between the stimulation of a muscle and the start of the contraction phase. (10)
lateral: Pertaining to the side.
lateral apertures: Openings in the roof of the fourth ventricle that permit the circulation of cerebrospinal fluid into the subarachnoid space. (14)
lateral ventricle: A fluid-filled chamber within a cerebral hemisphere. (14)
lens: The transparent refractive structure of the eye that is between the iris and the vitreous humor. (17)
lesion: A localized abnormality in tissue organization. (4)
lesser omentum: A double-layered peritoneal fold formed by the mesentery that connects the lesser curvature of the stomach to the liver. (24)
leukocyte: A white blood cell. (4, 19)
ligament: A dense band of connective tissue fibers that attaches one bone to another. (4, 9)
ligamentum arteriosum: The fibrous strand in adults that is the remnant of the ductus arteriosus of the fetal stage. (21)
ligamentum nuchae: An elastic ligament between the vertebra prominens and the occipital bone. (7)
ligamentum teres: The fibrous strand in the falciform ligament of adults that is the remnant of the umbilical vein; also called the *round ligament of the liver*. (24)
ligate: To tie off.
limbic system: The nuclei and centers in the cerebrum and diencephalon that are involved with emotional states, memories, and behavioral drives. (14)
lingual: Pertaining to the tongue. (17, 24)
lipid: An organic compound containing carbon, hydrogen, and oxygen in a ratio that does not approximate 1:2:1; includes fats, oils, and waxes. (2, 24, 25)
lipogenesis: The synthesis of lipids from nonlipid precursors. (25)
lipolysis: The catabolism of lipids as a source of energy. (25)
lipoprotein: A compound containing a relatively small lipid bound to a protein. (25)
liver: An organ of the digestive system that has varied and vital functions, including the production of plasma proteins, the excretion of bile, the storage of energy reserves, the detoxification of poisons, and the interconversion of nutrients. (24)
lobule: Histologically, the basic organizational unit of the liver. (24)
local hormone: *See* **prostaglandin**. (2, 18)
loop of Henle: *See* **nephron loop**. (26)
loose connective tissue: A loosely organized, easily distorted connective tissue that contains several fiber types, a varied population of cells, and a viscous ground substance. (4)
lumbar: Pertaining to the lower back. (7, 13)
lumen: The central space within a duct or other internal passageway. (4)
lungs: The paired organs of breathing enclosed by the pleural cavities. (23)
luteinizing hormone (LH): A hormone produced by the adenohypophysis (anterior lobe of the pituitary gland). In females, it assists FSH in follicle stimulation, triggers ovulation, and promotes the maintenance and secretion of endometrial glands. In males, it was formerly called *interstitial cell-stimulating hormone* because it stimulates testosterone secretion by the interstitial endocrine cells of the testes. (18, 28)
lymph: The fluid contents of lymphatic vessels, similar in composition to interstitial fluid. (4, 22)
lymphatic vessels: The vessels of the lymphatic system; also called *lymphatics*. (4, 22)
lymphedema: Sewlling as a result of lymphatic vessel obstruction. (22)
lymph nodes: Lymphoid organs that monitor the composition of lymph. (22)
lymphocyte: A cell of the lymphatic system that plays a role in the immune response. (4, 19, 22)
lymphokines: Chemicals secreted by activated lymphocytes. (22)
lymphopoiesis: The production of lymphocytes from lymphoid stem cells. (19, 22)
lymphotoxin: A secretion of lymphocytes that kills the target cells. (22)
lysis: The destruction of a cell through the rupture of its plasma membrane. (3)
lysosome: An intracellular vesicle containing digestive enzymes. (3)
lysozyme: An enzyme, present in some exocrine secretions, that has antibiotic properties. (17)

M

macrophage: A phagocytic cell of the monocyte–macrophage system. (4, 22)
macula: A receptor complex, located in the saccule or utricle of the internal ear, that responds to linear acceleration or gravity. (17)
macula (of retina)**:** The oval area in the retina whose center (the fovea centralis) is the region of sharpest vision; also called *macula lutea*. (17)
macula densa: A group of specialized secretory cells that is located in a portion of the distal convoluted tubule, adjacent to the glomerulus, extraglomerular mesangial cells, and the juxtaglomerular cells; a component of the juxtaglomerular complex. (26)
major histocompatibility complex: *See* **MHC protein**. (22)
malignant tumor: A form of cancer characterized by rapid cell growth and the spread of cancer cells throughout the body. (3)
malleus: An auditory ossicle, bound to the tympanic membrane and the incus. (17)
malnutrition: An unhealthy state produced by inadequate dietary intake or absorption of nutrients. (25)
mammillary bodies: Nuclei in the hypothalamus that affect eating reflexes and behaviors; a component of the limbic system. (14)
mammary glands: Milk-producing glands of the female breasts. (5, 28)
manus: The hand; manual. (8, 11)
marrow: A tissue that fills the internal cavities in bone; dominated by hemopoietic cells (red bone marrow) or by adipose tissue (yellow bone marrow). (6, 19)
mass: A physical property that determines the weight of an object in Earth's gravitational field; the amount of material in mater. (2)
mast cell: A connective tissue cell that, when stimulated, releases histamine, serotonin, and heparin, initiating the inflammatory response. (4)
mastication: Chewing. (11, 24)

mastoid sinus: Air-filled spaces in the mastoid process of the temporal bone. (7)
matrix: The extracellular fibers and ground substance of a connective tissue. (3, 4)
matter: Anything that takes up space and has mass. (2)
maxillary sinus: One of the paranasal sinuses; an air-filled chamber lined by a respiratory epithelium that is located in a maxilla and opens into the nasal cavity. (7)
meatus: An opening or entrance into a passageway. (23, 26)
mechanoreception: The detection of mechanical stimuli, such as touch, pressure, or vibration. (15)
medial: Toward the midline of the body.
mediastinum: The central tissue mass that divides the thoracic cavity into two pleural cavities. (1, 20)
medulla: The inner layer or core of an organ. (5)
medulla oblongata: The most caudal of the brain regions; also called the *myelencephalon*. (14)
medullary cavity: The space within a bone that contains the marrow. (6)
megakaryocytes: Bone marrow cells responsible for the formation of platelets. (19)
meiosis: Cell division that produces gametes with half the normal somatic chromosome complement. (3, 28)
melanin: The red-yellow or brown-black pigments produced by the melanocytes of the skin. (4, 5)
melanocyte: A specialized cell in the deeper layers of the stratified squamous epithelium of the skin; responsible for the production of melanin. (4, 5, 18)
melanocyte-stimulating hormone (MSH): A hormone, produced by the pars intermedia of the anterior lobe of the pituitary gland (adenohypophysis), that stimulates melanin production. (18)
melatonin: A hormone secreted by the pineal gland; inhibits secretion of MSH and GnRH. (14, 18)
membrane: Any sheet or partition; a layer consisting of an epithelium and the underlying connective tissue. (2)
membrane flow: The continuous movement and exchange of membrane segments. (3)
membrane potential: The potential difference, measured across a plasma membrane and expressed in millivolts, that results from the uneven distribution of positive and negative ions across the plasma membrane; also called *transmembrane potential*. (3, 10, 12)
membranous labyrinth: Endolymph-filled tubes that enclose the receptors of the internal ear. (17)
memory: The ability to recall information or sensations; can be divided into short-term and long-term memories. (16, 22)
memory T cells: T lymphocytes that provide immunologic memory, enabling an enhanced immune response when reexposed to a specific antigen. (22)
meninges: Three membranes that surround the surfaces of the central nervous system; the dura mater, the pia mater, and the arachnoid mater. (13)
meniscus: A fibrocartilage pad between opposing surfaces in a joint. (9)
menstruation: The phase of the uterine cycle in which the endometrial functional layer is shed; also called *menses*. (28)
merocrine secretion: A method of secretion in which the cell ejects materials from secretory vesicles through exocytosis. (4, 5)
mesencephalon: The midbrain; the region between the diencephalon and pons. (14)
mesenchyme: Embryonic or fetal connective tissue. (4)
mesentery: A double layer of serous membrane that supports and stabilizes the position of an organ in the abdominopelvic cavity and provides a route for the associated blood vessels, nerves, and lymphatic vessels. (24)
mesoderm: The middle germ layer, between the ectoderm and endoderm of the embryo. (29)
mesothelium: A simple squamous epithelium that lines the body cavities enclosing the lungs, heart, and abdominal organs. (4)
messenger RNA (mRNA): RNA formed at transcription to direct protein synthesis in the cytoplasm. (2, 3)
metabolic turnover: The continuous breakdown and replacement of organic materials within cells. (2, 25)
metabolism: The sum of all biochemical processes under way within the human body at any moment; includes anabolism and catabolism. (2, 25)
metabolites: Compounds produced in the body as a result of metabolic reactions. (2)
metacarpals: The five bones of the palm of the hand. (8)
metalloproteins: Proteins containing a metal ion cofactor; examples include plasma transport proteins, storage proteins, and enzymes. (19, 25)
metaphase: The stage of mitosis in which the chromosomes line up along the equatorial plane of the cell. (3)
metaphysis: The region of a long bone between the epiphysis and diaphysis, corresponding to the location of the epiphyseal cartilage of the developing bone. (6)
metastasis: The spread of cancer cells from one organ to another, leading to the establishment of secondary tumors. (3)
metatarsal: One of the five bones of the foot that articulate with the tarsal bones (proximally) and the phalanges (distally). (8)
metencephalon: The pons and cerebellum of the brain. (14)
MHC protein: A surface antigen that is important to the recognition of foreign antigens and that plays a role in the coordination and activation of the immune response; also called *major histocompatibility complex (MHC) protein* or *human leukocyte antigen (HLA)*. (22)
micelle: A droplet with hydrophilic portions on the outside; a spherical aggregation of bile salts, monoglycerides, and fatty acids in the lumen of the intestinal tract. (2, 24)
microfilaments: Fine protein filaments visible with the electron microscope; components of the cytoskeleton. (3)
microglia: Phagocytic neuroglia in the central nervous system. (12, 22)
microphages: Neutrophils and eosinophils. (4, 19, 22)
microtubules: Microscopic tubules that are part of the cytoskeleton and are a component in cilia, flagella, the centrioles, and spindle fibers. (3)
microvilli: Small, fingerlike extensions of the exposed plasma membrane of an epithelial cell. (3)
micturition: Urination. (26)
midbrain: The mesencephalon. (14)
middle ear: The space between the external and internal ears that contains auditory ossicles. (17)
midsagittal plane: A plane passing through the midline of the body that divides it into left and right halves. (1)
mineralocorticoids: Corticosteroids produced by the zona glomerulosa of the adrenal cortex; steroids such as aldosterone that affect mineral metabolism. (18)
mitochondrion: An intracellular organelle responsible for generating most of the ATP required for cellular operations. (3, 25)
mitosis: The division of a single cell nucleus that produces two identical daughter cell nuclei; an essential step in cell division. (3, 28)
mitral valve: The left atrioventricular (AV) valve, also called *bicuspid valve*. (20)
mixed gland: A gland that contains exocrine and endocrine cells, or an exocrine gland that produces serous and mucous secretions. (4)
mixed nerve: A peripheral nerve that contains sensory and motor fibers. (13)
mole: A quantity of an element or compound having a mass in grams equal to the element's atomic weight or to the compound's molecular weight. (2)
molecular weight: The sum of the atomic weights of all the atoms in a molecule or compound. (2, 3)
molecule: A chemical structure containing two or more atoms that are bonded together by shared electrons. (1, 2, 3)
monoclonal antibodies: Antibodies produced by genetically identical cells under laboratory conditions. (22)
monocytes: Phagocytic agranulocytes (white blood cells) in the circulating blood. (19)
monoglyceride: A lipid consisting of a single fatty acid bound to a molecule of glycerol. (2)
monokines: Secretions released by activated cells of the monocyte–macrophage system to coordinate various aspects of the immune response. (22)
monomer: A molecule that can be bonded to other identical molecules to form a polymer. (2)
monosaccharide: A simple sugar, such as glucose or ribose. (2, 24)
monosynaptic reflex: A reflex in which the sensory afferent neuron synapses directly on the motor efferent neuron. (13)
motor unit: All the muscle cells controlled by a single motor neuron. (10)
mucins: Proteoglycans responsible for the lubricating properties of mucus. (2, 24)
mucosa: A mucous membrane; the epithelium plus the lamina propria; also called *mucous membrane*. (4, 24)
mucosa-associated lymphoid tissue (MALT): The extensive collection of lymphoid tissues linked with the epithelia of the digestive, respiratory, urinary, and reproductive tracts. (22)
mucous (adjective)**:** Indicating the presence or production of mucus.
mucous (goblet) cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts; they are called mucous cells when they are found in the stomach mucosa, respiratory mucosa, and salivary glands; they are called goblet cells in the mucosa of the small intestine, large intestine, terminal bronchioles, and conjunctiva. (4, 23, 24)
mucous membrane: *See* **mucosa**. (4, 24)
mucus (noun)**:** A lubricating fluid that is composed of water and mucins and is produced by unicellular and multicellular glands along the digestive, respiratory, urinary, and reproductive tracts. (2, 4)
multipolar neuron: A neuron with many dendrites and a single axon; the typical form of a motor neuron. (12)
multiunit smooth muscle: A smooth muscle tissue whose muscle cells are innervated in motor units. (10)
muscarinic receptors: Membrane receptors sensitive to acetylcholine and to muscarine, a toxin produced by certain mushrooms; located at all parasympathetic neuromuscular and neuroglandular junctions and at a few sympathetic neuromuscular and neuroglandular junctions. (16)

muscle: A contractile organ composed of muscle tissue, blood vessels, nerves, connective tissues, and lymphatic vessels. (10, 11)
muscle tissue: A tissue characterized by the presence of cells capable of contraction; includes skeletal, cardiac, and smooth muscle tissues. (4, 10)
muscular layer: Concentric layers of smooth muscle responsible for peristalsis. (24)
muscularis mucosae: The layer of circular and longitudinal smooth muscle deep to the lamina propria; responsible for moving the mucosal surface. (24)
mutagens: Chemical agents that induce mutations and may be carcinogenic. (3)
mutation: A change in the nucleotide sequence of the DNA in a cell. (3)
myelencephalon: *See* **medulla oblongata**. (14)
myelin: An insulating sheath around an axon; consists of multiple layers of neuroglial membrane; significantly increases the nerve impulse propagation rate along the axon. (12)
myelination: The formation of myelin. (12)
myenteric plexus: Parasympathetic motor neurons and sympathetic postganglionic fibers located between the circular and longitudinal layers of the muscularis externa. (24)
myocardial infarction: A heart attack; damage to the heart muscle due to an interruption of regional coronary circulation. (20)
myocardium: The cardiac muscle tissue of the heart. (20)
myofibril: Organized collections of myofilaments in skeletal and cardiac muscle cells. (10)
myofilaments: Fine protein filaments composed primarily of the proteins actin (thin filaments) and myosin (thick filaments). (10)
myoglobin: An oxygen-binding pigment that is especially common in slow skeletal muscle fibers and cardiac muscle cells. (2, 10)
myogram: A recording of the tension produced by muscle fibers on stimulation. (10)
myometrium: The thick layer of smooth muscle in the wall of the uterus. (28)
myosatellite cells: Cells that are the precursors to skeletal muscle cells (fibers) (10)
myosin: The protein component of thick filaments. (3, 10)

N

nail: A keratinous structure produced by epithelial cells of the nail root. (5)
nasal cavity: A chamber in the skull that is bounded by the internal and external nares. (7, 17, 23)
nasolacrimal duct: The passageway that transports tears from the nasolacrimal sac to the nasal cavity. (7, 17)
nasolacrimal sac: A chamber that receives tears from the lacrimal ducts. (17)
nasopharynx: A region that is posterior to the internal nares and superior to the soft palate and ends at the oropharynx. (23)
natriuretic peptides: Hormones released by specialized cardiac muscle cells when they are stretched by an abnormally large venous return; promotes fluid loss and reductions in blood pressure and in venous return. Includes atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP). (18, 21, 26, 27)
natural killer (NK) cells: Type of lymphocyte that can kill target cells without previous sensitivity. (19)
N compound: An organic compound containing nitrogen atoms. (25)
necrosis: The death of cells or tissues from disease or injury. (4, 22)
negative feedback: A corrective mechanism that opposes or negates a variation from normal limits. (1, 18)
neonate: A newborn infant, or baby. (29)
neoplasm: A tumor, or mass of abnormal tissue. (3)
nephron: The basic functional unit of the kidney. (26)
nephron loop: The segment of the nephron that creates the concentration gradient in the renal medulla; also called *loop of Henle*. (26)
nerve impulse: An action potential in a neuron plasma membrane. (12)
net filtration pressure (NFP): The difference between the net hydrostatic pressure and the net osmotic pressure. (21, 26)
neural cortex: An area of gray matter at the surface of the central nervous system. (13)
neurofibrils: Microfibrils in the cytoplasm of a neuron. (12)
neurofilaments: Microfilaments in the cytoplasm of a neuron. (12)
neuroglandular junction: A cell junction at which a neuron controls or regulates the activity of a secretory (gland) cell. (12)
neuroglia: Cells of the central nervous system and peripheral nervous system that support and protect neurons; also called *glial cells*. (4, 12)
neurohypophysis: The posterior lobe of the pituitary gland, or pars nervosa; contains the axons of hypothalamic neurons, which release OXT and ADH. (18)
neurolemma: The outer surface of a Schwann cell that encircles an axon in the peripheral nervous system. (12)
neuromodulator: A compound, released by a neuron, that adjusts the sensitivities of another neuron to specific neurotransmitters. (12)
neuromuscular junction (NMJ): A synapse between a neuron and a muscle cell. (10, 12)
neuron: A cell in nervous tissue that is specialized for intercellular communication through (1) changes in membrane potential and (2) synaptic connections. (4, 12, 15, 16)
neuroplasticity: The ability of nerve cells to make new connections. (14)
neurotransmitter: A chemical compound released by one neuron to affect the membrane potential of another. (10, 12, 16)
neurotubules: Microtubules in the cytoplasm of a neuron. (12)
neutron: A fundamental particle that does not have a positive or a negative charge. (2)
neutrophil: A white blood cell that is very numerous and normally the first of the mobile phagocytic cells to arrive at an area of injury or infection. (19)
nicotinic receptors: Acetylcholine receptors on the surfaces of sympathetic and parasympathetic ganglion cells; respond to the compound nicotine. (16)
nipple: An elevated epithelial projection on the surface of the breast; contains the openings of the lactiferous sinuses. (28)
Nissl bodies: The ribosomes, Golgi apparatus, rough endoplasmic reticulum, and mitochondria of the perikaryon of a typical neuron. (12)
nitrogenous wastes: Organic waste products of metabolism that contain nitrogen, such as urea, uric acid, and creatinine. (25)
nociception: Pain perception. (15)
nodes: The areas between adjacent neuroglia where the myelin covering of an axon is incomplete; also called *nodes of Ranvier*. (12)
nodose ganglion: A sensory ganglion of cranial nerve X; also called *inferior ganglion*. (14)
noradrenaline: *See* **norepinephrine (NE)**. (12, 18)
norepinephrine (NE): A catecholamine neurotransmitter in the peripheral nervous system and central nervous system, released at most sympathetic neuromuscular and neuroglandular junctions, and a hormone secreted by the adrenal (suprarenal) medulla; also called *noradrenaline*. (12, 18)
nucleic acid: A polymer of nucleotides that contains a pentose sugar, a phosphate group, and one of four nitrogenous bases that regulate the synthesis of proteins and make up the genetic material in cells. (2)
nucleolus: The dense region in the nucleus that is the site of RNA synthesis. (3)
nucleoplasm: The fluid content of the nucleus. (3)
nucleoproteins: Proteins of the nucleus that are generally associated with DNA. (3)
nucleotide: A compound consisting of a nitrogenous base, a simple sugar, and a phosphate group. (2)
nucleus: The central region of an atom. (1) A cellular organelle that contains DNA, RNA, and proteins; in the central nervous system, a mass of gray matter. (3)
nucleus pulposus: The gelatinous central region of an intervertebral disc. (9)
nurse cells: Supporting cells of the seminiferous tubules of the testis; responsible for the differentiation of spermatids, the maintenance of the blood testis barrier, and the secretion of inhibin, androgen-binding protein, and Müllerian-inhibiting factor; also called *Sertoli cells*. (18, 28)
nutrient: An inorganic or organic substance that can be used by the body as a cofactor or to produce energy. (2, 25)
nystagmus: An unconscious, continuous movement of the eyes as if to adjust to constant motion. (17)

O

obesity: Body weight more than 20 percent above the ideal weight for a given individual. (25)
occlusal surface: The opposing surfaces of the teeth that come into contact when chewing food. (24)
ocular: Pertaining to the eye. (17)
oculomotor nerve: Cranial nerve III, which controls the extraocular muscles other than the superior oblique and the lateral rectus muscles. (14)
olecranon: The proximal end of the ulna that forms the prominent point of the elbow. (8)
olfaction: The sense of smell. (15, 17, 23)
olfactory bulb: The expanded ends of the olfactory tracts (17); the sites where the axons of the first cranial nerves (I) synapse on central nervous system interneurons that lie inferior to the frontal lobes of the cerebrum. (14)
oligodendrocytes: Central nervous system neuroglia that maintain cellular organization within gray matter and provide a myelin sheath in areas of white matter. (12)
oligopeptide: A short chain of amino acids. (2)
oocyte: A cell whose meiotic divisions will produce a single ovum and three polar bodies. (3, 28, 29)
oogenesis: Formation and development of an oocyte. (28)
opsonization: An effect of coating an object with antibodies; the attraction and enhancement of phagocytosis. (22)
optic chiasm: The crossing point of the optic nerves. (14, 17)

optic nerve: The second cranial nerve (II), which carries signals from the retina of the eye to the optic chiasm. (14)
optic tract: The tract over which nerve impulses from the retina are transmitted between the optic chiasm and the thalamus. (14)
orbit: The bony recess of the skull that contains the eyeball. (7)
organ: Combinations of tissues that perform complex functions. (1)
organelle: An intracellular structure with a specific function or group of functions. (3)
organic compound: A compound containing carbon, hydrogen, and in most cases oxygen. (2)
organogenesis: The formation of organs during embryonic and fetal development. (29)
organ systems: Groups of organs that function together in a coordinated manner. (1)
origin: In a skeletal muscle, the point of attachment that does not change position when the muscle contracts; usually defined in terms of movements from the anatomical position. (11)
oropharynx: The middle portion of the pharynx, bounded superiorly by the nasopharynx, anteriorly by the oral cavity, and inferiorly by the laryngopharynx. (23)
osmolarity: The total concentration of dissolved materials in a solution, regardless of their specific identities, expressed in moles; also called *osmotic concentration*. (3, 26, 27)
osmoreceptor: A receptor sensitive to changes in the osmolarity of plasma. (27)
osmosis: The movement of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. (3, 21, 26, 27)
osmotic pressure (OP): The force of osmotic water movement; the pressure that must be applied to prevent osmosis across a membrane. (3, 21, 26, 27)
osseous tissue: A strong connective tissue containing specialized cells and a mineralized matrix of crystalline calcium phosphate and calcium carbonate; also called *bone tissue*. (4, 6)
ossicles: Small bones; middle ear bones. (17)
ossification: The formation of bone; osteogenesis. (6)
osteoblast: A cell that produces the fibers and matrix of bone. (6)
osteoclast: A cell that dissolves the fibers and matrix of bone. (6)
osteocyte: A bone cell responsible for the maintenance and turnover of the mineral content of the surrounding bone. (4, 6)
osteogenic layer: The inner, cellular layer of the periosteum that aids in bone growth and repair. (6)
osteolysis: The breakdown of the mineral matrix of bone. (6)
osteon: The basic histological unit of compact bone, consisting of osteocytes organized around a central canal and separated by concentric lamellae. (6)
osteoporosis: A reduction in bone mass that causes brittle, fragile bones and compromises normal function. (6)
otic: Pertaining to the ear. (17)
otoliths: Calcium carbonate crystals embedded in a gelatinous matrix; located on each macula of the vestibule. (17)
oval window: An opening in the bony labyrinth where the stapes attaches to the membranous wall of the scala vestibuli (vestibular duct). (17)
ovarian cycle: The monthly process of the maturation, ovulation, and degeneration of a tertiary ovarian follicle. (28)
ovary: The female reproductive organ that produces oocytes (gametes). (18, 28)
ovulation: The release of a secondary oocyte, surrounded by cells of the corona radiata, after the rupture of the wall of a tertiary ovarian follicle. (28, 29)
ovum/ova: The functional product of meiosis II, produced after the fertilization of a secondary oocyte. (28, 29)
oxidation: The gain of oxygen, or the loss of hydrogen or electrons. (25)
oxytocin (OXT): A hormone produced by hypothalamic cells and secreted into capillaries at the posterior lobe of the pituitary gland (neurohypophysis); stimulates smooth muscle contractions of the uterus or mammary glands in females and the prostate gland in males. (18)

P

pacemaker cells: Cells of the sinoatrial node that set the pace of cardiac contraction. (4, 10, 20)
palate: The horizontal partition separating the oral cavity from the nasal cavity and nasopharynx; divided into an anterior bony (hard) palate and a posterior fleshy (soft) palate. (7, 23, 24)
palatine: Pertaining to the palate. (24)
palpate: To examine by touch.
palpebrae: *See* **eyelids**. (17)
pancreas: A digestive organ containing exocrine and endocrine tissues; the exocrine portion secretes pancreatic juice, and the endocrine portion secretes hormones, including insulin and glucagon. (18, 24)
pancreatic duct: A tubular duct that carries pancreatic juice from the pancreas to the duodenum. (18, 24)
pancreatic islets: Aggregations of endocrine cells in the pancreas; also called *islets of Langerhans*. (18, 24)
pancreatic juice: A mixture of buffers and digestive enzymes that is discharged into the duodenum under the stimulation of the enzymes secretin and cholecystokinin. (18, 24)
Papanicolaou test (Pap smear): A test for the detection of malignancies based on the cytological appearance of epithelial cells, especially those of the cervix and uterus. (28)
papilla: A small, conical projection.
paralysis: The loss of voluntary motor control over a portion of the body. (13)
paranasal sinuses: Bony chambers, lined by respiratory epithelium, that open into the nasal cavity; the frontal, ethmoidal, sphenoidal, and maxillary sinuses. (7)
parasagittal plane: A plane that parallels the midsagittal plane but that does not pass along the midline. (1)
parasympathetic division: One of the two divisions of the autonomic nervous system; generally responsible for activities that conserve energy and lower the metabolic rate; the "rest and digest" division; also called *craniosacral division*. (16)
parathyroid glands: Four small glands embedded in the posterior surface of the thyroid gland that secrete parathyroid hormone. (6, 18)
parathyroid hormone (PTH): A hormone secreted by the parathyroid glands when blood calcium levels decrease below the normal range; causes increased osteoclast activity, increased intestinal calcium uptake, and decreased calcium ion loss by the kidneys. (6, 18)
parenchyma: The cells of a tissue or organ that are responsible for fulfilling its functional role; distinguished from the stroma of that tissue or organ. (4)
paresthesia: A sensory abnormality that produces a tingling sensation.
parietal: Relating to the parietal bone (7); referring to the wall of a cavity. (23)
parietal cells: Cells of the gastric glands that secrete hydrochloric acid and intrinsic factor. (24)
parotid glands: Large salivary glands that secrete saliva with high concentrations of salivary (alpha) amylase. (24)
pars distalis: The large, anterior portion of the anterior lobe of the pituitary gland (adenohypophysis). (18)
pars intermedia: The portion of the anterior lobe of the pituitary gland (adenohypophysis) that is immediately adjacent to the posterior lobe of the pituitary gland (neurohypophysis) and the infundibulum. (18)
pars nervosa: The posterior lobe of the pituitary gland (neurohypophysis). (18)
pars tuberalis: The portion of the anterior lobe of the pituitary gland (adenohypophysis) that wraps around the infundibulum superior to the posterior lobe (neurohypophysis). (18)
patella: The sesamoid bone of the knee; also called the *kneecap*. (8)
pathogen: A disease-causing organism. (1, 22)
pathologist: A physician specializing in the identification of diseases on the basis of characteristic structural and functional changes in tissues and organs.
pelvic cavity: The inferior subdivision of the abdominopelvic cavity; encloses the urinary bladder, the sigmoid colon and rectum, and male or female reproductive organs. (1, 8)
pelvis: A bony complex created by the articulations among the coxal bones, the sacrum, and the coccyx. (8, 11)
penis: A component of the male external genitalia; a copulatory organ that surrounds the urethra and introduces semen into the female vagina; the developmental equivalent of the female clitoris. (28)
peptide: A chain of amino acids linked by peptide bonds. (2, 18)
peptide bond: A covalent bond between the amino group of one amino acid and the carboxyl group of another. (2)
perforating canals: Passageways within compact bone that extend perpendicular to the surface. (6)
pericardial cavity: The space between the parietal pericardium and the epicardium (visceral pericardium) that encloses the outer surface of the heart. (1, 20)
pericardium: The fibrous sac that surrounds the heart; its inner, serous lining is continuous with the epicardium. (4, 20)
perichondrium: The layer that surrounds a cartilage, consisting of an outer fibrous region and an inner cellular region. (4)
perikaryon: The cytoplasm that surrounds the nucleus in the cell body of a neuron. (12)
perilymph: A fluid similar in composition to cerebrospinal fluid; located in the spaces between the bony labyrinth and the membranous labyrinth of the internal ear. (17)
perimetrium: The incomplete serosa of the uterus. (28)
perimysium: A connective tissue partition that separates adjacent fasciculi in a skeletal muscle. (10)
perineum: The pelvic floor and its associated structures. (11)
perineurium: A connective tissue partition that separates adjacent bundles of nerve fibers in a peripheral nerve. (13)
periodontal ligament: Collagen fibers that anchor a tooth within its alveolus. (24)

periosteum: The layer that surrounds a bone, consisting of an outer fibrous region and inner cellular region. (4, 6)
peripheral nervous system (PNS): All nervous tissue outside the central nervous system and the enteric nervous system. (12, 13)
peripheral resistance: The resistance to blood flow; primarily caused by friction with the vessel walls. (21)
peristalsis: A wave of smooth muscle contractions that propels materials along the lumen of a tube such as the digestive tract (24), the ureters (26), or the ductus deferens. (28)
peritoneal cavity: The potential space within the abdominopelvic cavity lined by the peritoneum. (1)
peritoneum: The serous membrane that lines the peritoneal cavity. (4, 24, 28)
peritubular capillaries: A network of capillaries that surrounds the proximal and distal convoluted tubules of the kidneys. (26)
permeability: The ease with which dissolved materials can cross a membrane; if the membrane is freely permeable, any molecule can cross it; if impermeable, nothing can cross; most biological membranes are selectively permeable (allow some and restrict others). (3)
peroxisome: A membranous vesicle containing enzymes that break down hydrogen peroxide (H_2O_2). (3)
pes: The foot. (8, 11)
petrosal ganglion: A sensory ganglion of the glossopharyngeal nerve (N IX). (14, 15)
petrous: Stony; usually refers to the thickened portion of the temporal bone that encloses the internal ear. (17)
pH: The negative exponent (negative logarithm) of the hydrogen ion concentration, expressed in moles per liter. (2, 27)
phagocyte: A cell that performs phagocytosis. (22)
phagocytosis: The engulfing of extracellular materials or pathogens; the movement of extracellular materials into the cytoplasm by enclosure in a membranous vesicle. (3, 19, 22)
phalanx/phalanges: Bone(s) of the finger(s) or toe(s). (8)
pharmacology: The study of drugs, their physiological effects, and their clinical uses.
pharynx: The throat; a muscular passageway shared by the digestive and respiratory tracts. (11, 23, 24)
phasic response: A pattern of response to stimulation by sensory neurons that are normally inactive; stimulation causes a burst of neural activity that ends when the stimulus either stops or stops changing in intensity. (15)
phenotype: Physical characteristics that are genetically determined. (29)
phosphate group: PO_4^{3-}; a functional group that can be attached to an organic molecule; required for the formation of high-energy bonds. (2, 25, 27)
phospholipid: An important membrane lipid whose structure includes both hydrophilic and hydrophobic regions. (2, 3)
phosphorylation: The addition of a high-energy phosphate group to a molecule. (2, 25)
photoreception: Sensitivity to light. (17)
physiology: The study of how living organisms perform their functions. (1)
pia mater: The innermost layer of the meninges bound to the underlying nervous tissue. (13, 14)
pineal gland: Nervous tissue in the posterior portion of the roof of the diencephalon; secretes melatonin. (14, 18)
pinna: *See* **auricle**. (17)
pinocytosis: The introduction of fluids into the cytoplasm by enclosing them in membranous vesicles at the cell surface. (3)
pituitary gland: An endocrine organ that is located in the sella turcica of the sphenoid bone and is connected to the hypothalamus by the infundibulum; includes the posterior lobe (neurohypophysis) and the anterior lobe (adenohypophysis); also called the *hypophysis*. (14, 18)
placenta: A temporary structure in the uterine wall that permits diffusion between the fetal and maternal circulatory systems. (29)
plantar: Referring to the sole of the foot (1); muscles (11); plantar reflex. (13)
plantar flexion: Ankle extension; toe pointing. (8, 9, 11)
plasma: The fluid ground substance of whole blood; what remains after the cells have been removed from a sample of whole blood. (4, 19)
plasma cell: An activated B cell that secretes antibodies. (4, 19, 22)
plasma membrane: A cell membrane; also called a *plasmalemma*. (3)
platelets: Small packets of cytoplasm that contain enzymes important in the clotting response; manufactured in bone marrow by megakaryocytes. (4, 19)
pleura: The serous membrane that lines the pleural (lung) cavities. (4, 23)
pleural cavities: Body cavities of the thoracic region that surround the lungs. (1, 23)
plexus: A network or braid.
polar body: A nonfunctional packet of cytoplasm that contains chromosomes eliminated from an oocyte during meiosis. (28, 29)
polarized: Referring to cells that have regional differences in organelle distribution or cytoplasmic composition along a specific axis, such as between the basement membrane and free surface of an epithelial cell. (4)
pollex: The thumb. (8)
polymer: A large molecule consisting of a long chain of monomer subunits. (2)
polypeptide: A chain of amino acids strung together by peptide bonds; those containing more than 100 peptides are called *proteins*. (2)
polyribosome: Several ribosomes linked by their translation of a single mRNA strand. (3)
polysaccharide: A complex sugar, such as glycogen or a starch. (2)
polysynaptic reflex: A reflex in which interneurons are interposed between the sensory fiber and the motor neuron(s). (13)
polyunsaturated fats: Fatty acids containing carbon atoms that are linked by double bonds. (1, 2)
pons: The portion of the metencephalon that is anterior to the cerebellum. (14)
popliteal: Pertaining to the back of the knee. (9, 11, 21)
porphyrins: Ring-shaped molecules that form the basis of important respiratory and metabolic pigments, including heme and the cytochromes. (23)
positive feedback: A mechanism that increases a deviation from normal limits after an initial stimulus. (1)
postcentral gyrus: The primary sensory cortex, where touch, vibration, pain, temperature, and taste sensations arrive and are consciously perceived. (14)
posterior: Toward the back; dorsal.
posterior root ganglion: A peripheral nervous system ganglion containing the cell bodies of sensory neurons; *see* **dorsal root ganglion**. (13)
postganglionic neuron: An autonomic neuron in a peripheral ganglion, whose activities control peripheral effectors. (16)
postsynaptic membrane: The portion of the plasma membrane of a postsynaptic cell that is part of a synapse. (12)
potential difference: The separation of opposite charges; requires a barrier that prevents ion migration. (3, 12)
precentral gyrus: The primary motor cortex of a cerebral hemisphere, located anterior to the central sulcus. (14)
prefrontal cortex: The anterior portion of each cerebral hemisphere; thought to be involved with higher intellectual functions, predictions, and calculations. (14)
preganglionic neuron: A visceral motor neuron in the central nervous system whose output controls one or more ganglionic motor neurons in the peripheral nervous system. (16)
premotor cortex: The motor association area between the precentral gyrus and the prefrontal area. (14)
pre-optic body: The hypothalamic nucleus that coordinates thermoregulatory activities. (14)
presynaptic membrane: The synaptic surface where neurotransmitter release occurs. (12)
prevertebral ganglion: *See* **collateral ganglion**. (12, 16)
prime mover: A muscle that performs a specific action; also called an *agonist*. (11)
proenzyme: An inactive enzyme secreted by an epithelial cell. (19)
progesterone: The most important hormone secreted by the corpus luteum after ovulation. (18, 28)
prognosis: A prediction about the possible course or outcome from a specific disease.
projection fibers: Axons carrying information from the thalamus to the cerebral cortex. (14)
prolactin (PRL): The hormone that stimulates functional development of the mammary glands in females; a secretion of the anterior lobe of the pituitary gland (adenohypophysis). (18)
pronation: The rotation of the forearm that makes the palm face posteriorly. (9)
prone: Lying face down with the palms facing the floor. (1)
pronucleus: An enlarged ovum or sperm nucleus that forms after fertilization but before amphimixis. (29)
prophase: The initial phase of mitosis; characterized by the appearance of chromosomes, the breakdown of the nuclear membrane, and the formation of the spindle apparatus. (3)
proprioceptor: Sensory organ that monitors the position and movement of skeletal muscles and joints. (12)
proprioception: The awareness of the positions of bones, joints, and muscles. (15)
prostaglandin: A fatty acid secreted by one cell that alters the metabolic activities or sensitivities of adjacent cells; also called *local hormone*. (2, 18)
prostate gland: An accessory gland of the male reproductive tract, contributing about one-third of the volume of semen. (28)
prosthesis: An artificial substitute for a body part.
protease: An enzyme that breaks down proteins into peptides and amino acids. (2, 3, 24)
protein: A large polypeptide with a complex structure. (2, 25)
proteoglycan: A substance containing a large polysaccharide complex linked by polypeptide chains; examples include hyaluronan (hyaluronic acid) and chondroitin sulfate. (2, 4)
proton: A fundamental subatomic particle having a positive charge. (2)

protraction: Movement anteriorly in the horizontal plane. (9)
proximal: A direction toward the point of attachment or origin; for a limb, toward its attachment to the trunk. (1, 8)
proximal convoluted tubule (PCT): The segment of the nephron between the glomerular capsule (Bowman's capsule) and the nephron loop; the major site of active reabsorption from filtrate. (26)
pseudopodia: Temporary cytoplasmic extensions typical of mobile or phagocytic cells. (3)
pseudostratified epithelium: An epithelium that contains several layers of nuclei but whose cells are all in contact with the underlying basement membrane. (4)
puberty: A period of rapid growth, sexual maturation, and the appearance of secondary sexual characteristics; normally occurs at ages 10–15 years. (18, 28, 29)
pubic symphysis: The fibrocartilaginous amphiarthrosis between the pubic bones of the hip. (8, 9)
pubis: The anterior, inferior component of the hip bone. (8)
pudendum: The external genitalia. (28)
pulmonary circuit: Blood vessels between the pulmonary semilunar valve of the right ventricle and the entrance to the left atrium; the blood flow through the lungs. (20)
pulmonary ventilation: The movement of air into and out of the lungs. (23)
pulvinar nucleus: The thalamic nucleus involved in the integration of sensory information prior to projection to the cerebral hemispheres. (14)
pupil: The opening in the center of the iris through which light enters the eye. (17)
purine: A nitrogen compound with a double ring-shaped structure; examples include adenine and guanine, two nitrogenous bases that are common in nucleic acids. (2, 12)
Purkinje cell layer: A large, branching neuron of the cerebellar cortex. (14)
Purkinje fibers: Specialized conducting cardiac muscle cells in the ventricles of the heart. (20)
pus: An accumulation of debris, fluid, dead and dying cells, and necrotic tissue. (4, 20, 22)
pyloric part: The gastric region between the body of the stomach and the duodenum; includes the muscular pylorus and the pyloric sphincter. (24)
pyloric sphincter: A ring of smooth muscle that regulates the passage of chyme from the stomach to the duodenum. (24)
pyrimidine: A nitrogen compound with a single ring-shaped structure; examples include cytosine, thymine, and uracil, nitrogenous bases that are common in nucleic acids. (2)
pyruvate: The anion formed by the dissociation of pyruvic acid, a three-carbon compound produced by glycolysis. (25)

Q

quaternary structure: The three-dimensional protein structure produced by interactions between protein subunits. (2)

R

radiodensity: The relative resistance to the passage of x-rays. (1)
radiographic techniques: Methods of visualizing internal structures by using various forms of radiational energy. (1)
radiopaque: Having a high radiodensity. (1)
rami communicantes: Axon bundles that link the spinal nerves with the ganglia of the sympathetic chain. (13)
ramus/rami: Branch/branches.
raphe: A seam. (11, 28)
receptive field: The area monitored by a single sensory receptor. (15)
rectum: The inferior 15 cm (6 in.) of the digestive tract. (24)
rectus: Straight. (11)
red blood cell (RBC): *See* **erythrocyte**. (4, 19)
reduction: The loss of oxygen, or the gain of hydrogen or electrons. (25)
reductional division: The first meiotic division, which reduces the chromosome number from 46 to 23. (28)
reflex: A rapid, automatic response to a stimulus. (12, 13, 16, 18, 21)
reflex arc: The receptor, sensory neuron, motor neuron, and effector involved in a particular reflex; interneurons may be present, depending on the reflex considered. (13)
refractory period: The time between the initiation of an action potential and the restoration of the normal resting membrane potential; during this period, the membrane will not respond normally to stimulation. (12, 20)
regulatory T cells: Population of T lymphocytes that suppress the immune response. (22)
relaxation phase: The period after a contraction when the tension in the muscle fiber returns to resting levels. (10)
relaxin: A hormone that loosens the pubic symphysis; secreted by the placenta. (29)
renal: Pertaining to the kidneys. (26)
renal corpuscle: The initial segment of the nephron, consisting of an expanded chamber that encloses the glomerulus. (26)
renin: The enzyme released by cells of the juxtaglomerular complex when renal blood flow decreases; converts angiotensinogen to angiotensin I. (18, 26)
rennin: A gastric enzyme that breaks down milk proteins. (24)
replication: Duplication. (29)
repolarization: The movement of the membrane potential away from a positive value and toward the resting potential. (12, 20)
respiration: The exchange of gases between cells and the environment; includes pulmonary ventilation, external respiration, and internal respiration. (23, 27)
respiratory minute volume ($\dot{V}_E$): The amount of air moved into and out of the respiratory system each minute. (23)
respiratory pump: A mechanism by which changes in the intrapleural pressures during the respiratory cycle assist the venous return to the heart; also called *thoracoabdominal pump*. (21, 23)
respiratory rhythmicity center: The center in the medulla oblongata that sets the background pace of respiration; includes inspiratory and expiratory centers. (14, 23)
resting membrane potential: The membrane potential of a normal cell under homeostatic conditions. (3, 12)
rete: An interwoven network of blood vessels or passageways. (28)
reticular activating system (RAS): The midbrain portion of the reticular formation; responsible for arousal and the maintenance of consciousness. (16)
reticular formation: A diffuse network of gray matter that extends the entire length of the brainstem (medulla oblongata to the midbrain). (14)
reticulospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by neurons of the reticular formation. (15)
retina: The innermost layer of the eye, lining the vitreous chamber; also called *inner layer*. (17)
retinal: A visual pigment derived from vitamin A. (17)
retraction: Movement posteriorly in the horizontal plane. (9)
retroperitoneal: Behind or outside the peritoneal cavity. (1, 24)
reverberation: A positive feedback along a chain of neurons such that they remain active once stimulated. (13)
rheumatism: A general term used to describe pain in muscles, tendons, bones, or joints. (9)
Rh factor: A surface antigen that may be present (Rh positive) or absent (Rh negative) from the surfaces of red blood cells. (19)
rhodopsin: The visual pigment in the membrane discs of the distal segments of rods. (17)
ribonucleic acid: A nucleic acid consisting of a chain of nucleotides that contain the sugar ribose and the nitrogenous bases adenine, guanine, cytosine, and uracil. (2, 3)
ribose: A five-carbon sugar that is a structural component of RNA. (2, 3)
ribosome: An organelle that contains rRNA and proteins and is essential to mRNA translation and protein synthesis. (2, 3)
rod: A photoreceptor responsible for vision in dim lighting. (17)
rough endoplasmic reticulum (RER): A membranous organelle that is a site of protein synthesis and storage. (3)
round window: An opening in the bony labyrinth of the internal ear that exposes the membranous wall of the tympanic duct to the air of the middle ear cavity. (17)
rubrospinal tracts: Descending tracts of the lateral pathway that carry involuntary motor commands issued by the red nucleus of the midbrain. (15)
rugae: Mucosal folds in the lining of the empty stomach that disappear as gastric distension occurs (24); folds in the urinary bladder (26).

S

saccule: A portion of the vestibular apparatus of the internal ear; contains a macula important for providing sensations of gravity and linear acceleration in a vertical dimension. (17)
sagittal plane: A vertical plane that divides the body into left and right portions. (1)
salt: An inorganic compound consisting of a cation other than H^+ and an anion other than OH^-. (2)
saltatory propagation: The relatively rapid propagation of an action potential between successive nodes of a myelinated axon. (12)
sarcolemma: The plasma membrane of a muscle cell. (10)
sarcomere: The smallest contractile unit of a striated muscle cell. (10)
sarcoplasm: The cytoplasm of a muscle cell. (10)
scala media: The central membranous tube within the cochlea that is filled with endolymph and contains the spiral organ (*organ of Corti*); also called *cochlear duct*. (17)
scala tympani: The perilymph-filled chamber of the internal ear, adjacent to the basilar membrane; pressure changes there distort the round window; also called *tympanic duct*. (17)

scala vestibuli: The perilymph-filled chamber of the internal ear, adjacent to the vestibular membrane; pressure waves are induced by movement of the stapes at the oval window; also called *vestibular duct*. (17)
scar tissue: The thick, collagenous tissue that forms at an injury site. (5)
Schwann cells: Neuroglia responsible for the neurolemma that surrounds axons in the peripheral nervous system. (12)
sciatic nerve: A nerve innervating the posteromedial portions of the thigh and leg. (13)
scientific method: A system of advancing knowledge that begins by proposing a hypothesis to answer a question, and then testing that hypothesis with data collected through observation and experimentation. (1)
sclera: The fibrous, outer layer of the eye that forms the white area of the anterior surface; a portion of the fibrous layer of the eye. (17)
sclerosis: A hardening and thickening that commonly occurs secondary to tissue inflammation. (4)
scrotum: The loose-fitting, fleshy pouch that encloses the testes of the male. (28)
sebaceous glands: Glands that secrete sebum; normally associated with hair follicles. (5)
sebum: A waxy secretion that coats the surfaces of hairs. (5)
secondary sex characteristics: Physical characteristics that appear at puberty in response to sex hormones but are not involved in the production of gametes. (28)
secretin: A hormone, secreted by the duodenum, that stimulates the production of buffers by the pancreas and inhibits gastric activity. (24)
sectional plane: A view or slice along a two-dimensional flat surface. (1)
semen: The fluid ejaculate that contains sperm and the secretions of accessory glands of the male reproductive tract. (28)
semicircular ducts: The tubular components of the membranous labyrinth of the internal ear; respond to rotational movements of the head. (17)
semilunar valve: A three-cusped valve guarding the exit from one of the cardiac ventricles; the pulmonary and aortic valves. (20)
seminal glands: Glands of the male reproductive tract that produce roughly 60 percent of the volume of semen; also called *seminal vesicles*. (28)
seminiferous tubules: Coiled tubules where sperm production occurs in the testes. (28)
senescence: Aging. (29)
sensible perspiration: Water loss due to secretion by sweat glands. (5, 27)
septa: Partitions that subdivide an organ. (20, 22)
serosa: *See* **serous membrane**. (4, 24)
serotonin: A neurotransmitter in the central nervous system; a substance that enhances inflammation and is released by activated mast cells and basophils. (12, 19)
serous cell: A cell that produces a serous secretion. (4)
serous membrane: A squamous epithelium and the underlying loose connective tissue; the lining of the pericardial, pleural, and peritoneal cavities; also called a *serosa*. (4, 24)
serous secretion: A watery secretion that contains high concentrations of enzymes; produced by serous cells. (4)
Sertoli cells: *See* **nurse cells**. (18, 28)
serum: The ground substance of blood plasma from which clotting agents have been removed. (19)
sesamoid bone: A bone that forms within a tendon. (6)
sigmoid colon: The S-shaped region of the colon between the descending colon and the rectum. (24)
sign: The visible, objective evidence of the presence of a disease. (1)
simple epithelium: An epithelium containing a single layer of cells superficial to the basement membrane. (4)
sinoatrial (SA) node: The natural pacemaker of the heart; located in the wall of the right atrium. (20)
sinus: A chamber or hollow in a tissue; a large, dilated vein. (6, 7, 20)
sinusoid: An exchange vessel that is similar in general structure to a fenestrated capillary. The two differ in size (sinusoids are larger and more irregular in cross section), continuity (sinusoids have gaps between endothelial cells), and support (sinusoids have thin basement membranes, if present at all). (20, 21)
skeletal muscle: A contractile organ of the muscular system. (10)
skeletal muscle tissue: A contractile tissue dominated by skeletal muscle fibers; characterized as striated, voluntary muscle. (4, 10)
sliding-filament theory: The concept that a sarcomere shortens as the thick and thin filaments slide past one another. (10)
small intestine: The duodenum, jejunum, and ileum; the digestive tract between the stomach and the large intestine. (24)
smooth endoplasmic reticulum (SER): A membranous organelle in which lipid and carbohydrate synthesis and storage occur. (3)
smooth muscle tissue: Muscle tissue in the walls of many visceral organs; characterized as nonstriated, involuntary muscle. (4, 10, 24, 26)
soft palate: The fleshy posterior extension of the hard palate, separating the nasopharynx from the oral cavity. (24)
solute: Any materials dissolved in a solution. (2, 21, 26)
solution: A fluid containing dissolved materials. (2, 21)
solvent: The fluid component of a solution. (2, 21)
somatic: Pertaining to the body.
somatic nervous system (SNS): The efferent division of the nervous system that innervates skeletal muscles. (12, 15, 16)
somatomedins: Substances stimulating tissue growth; released by the liver after the secretion of growth hormone; also called *insulin-like growth factors*. (18)
somatotropin: Growth hormone (GH); produced by the anterior lobe of the pituitary gland (adenohypophysis) in response to growth hormone–releasing hormone (GH–RH). (18)
sperm: Male gamete(s). (3, 28, 29)
spermatic cord: Collectively, the spermatic vessels, nerves, lymphatic vessels, and the ductus deferens, extending between the testes and the proximal end of the inguinal canal. (28)
spermatocyte: A cell of the seminiferous tubules that is engaged in meiosis. (28)
spermatogenesis: Sperm production. (28)
sphincter: A muscular ring that contracts to close the entrance or exit of an internal passageway. (10, 11, 26)
spinal nerve: One of 31 pairs of nerves that originate on the spinal cord from anterior and posterior roots. (12, 13)
spindle apparatus: Microtubule-based structure that distributes duplicated chromosomes to opposite ends of a dividing cell during mitosis. (3)
spinocerebellar tracts: Ascending tracts that carry sensory information to the cerebellum. (15)
spinothalamic tracts: Ascending tracts that carry poorly localized touch, pressure, pain, vibration, and temperature sensations to the thalamus. (15)
spinous process: The prominent posterior projection of a vertebra; formed by the fusion of two laminae. (7)
spiral organ: A receptor complex in the scala media of the cochlea that includes the inner and outer hair cells, supporting cells and structures, and the tectorial membrane; provides the sensation of hearing; also called the *organ of Corti*. (17)
spleen: A lymphoid organ important for the phagocytosis of red blood cells, the immune response, and lymphocyte production. (22)
spongy bone: Bone that consists of an open network of struts and plates that resembles a three-dimensional garden lattice. (6)
squama: A broad, flat surface.
squamous: Flattened.
squamous epithelium: An epithelium whose superficial cells are flattened and platelike. (4)
stapes: The auditory ossicle attached to the tympanic membrane. (17)
stellate macrophage: Phagocytic cell of the liver sinusoids; also called *Kupffer cell*. (22, 24)
stenosis: A constriction or narrowing of a passageway.
stereocilia: Elongated microvilli characteristic of the epithelium of the epididymis, sections of the ductus deferens (28), and the internal ear. (17)
steroid: A ring-shaped lipid structurally related to cholesterol. (2, 18)
stimulus: An environmental change that produces a change in cellular activities; often used to refer to events that alter the membrane potentials of excitable cells. (15)
stratified epithelium: An epithelium containing several layers. (4)
stratum/strata: Layer/layers. (4)
stretch receptors: Sensory receptors that respond to stretching of the surrounding tissues. (13)
stretch reflex: Tonic muscle contraction in response to stimulation of muscle proprioceptors. (13)
stroke volume (SV): The amount of blood pumped out of one heart ventricle in a single heart beat. (20)
stroma: The connective tissue framework of an organ; distinguished from the functional cells (parenchyma) of that organ.
subarachnoid space: A meningeal space containing cerebrospinal fluid; the area between the arachnoid membrane and the pia mater. (13, 14)
subclavian: Pertaining to the region immediately posterior and inferior to the clavicle.
submucosa: The region between the muscularis mucosae and the muscularis externa. (23, 24)
subserous fascia: The loose connective tissue layer deep to the serous membrane that lines body cavities. (4)
substrate: A participant (product or reactant) in an enzyme-catalyzed reaction. (2)
sulcus: A groove or furrow. (14)
summation: The temporal or spatial addition of contractile force or neural stimuli. (10, 12)
superficial fascia: The layer of loose connective tissue below the dermis. (4, 5)
superior: Above, in reference to a portion of the body in the anatomical position.
superior vena cava (SVC): The vein that carries blood to the right atrium from parts of the body that are superior to the heart. (20, 21)
supination: The rotation of the forearm such that the palm faces anteriorly. (9)
supine: Lying face up, with palms facing anteriorly. (1)

suprarenal cortex: *See* **adrenal cortex**. (18)
suprarenal gland: *See* **adrenal gland**. (18)
suprarenal medulla: *See* **adrenal medulla**. (16)
surfactant: A lipid secretion that coats the alveolar surfaces of the lungs and prevents their collapse. (23)
sutural bones: Irregular bones that form in fibrous tissue between the flat bones of the developing cranium; also called *Wormian bones*. (6)
suture: A fibrous joint between flat bones of the skull. (7, 9)
sympathetic division: The division of the autonomic nervous system that is responsible for "fight or flight" reactions; primarily concerned with the elevation of metabolic rate and increased alertness; also called the *thoracolumbar division*. (12, 16)
symphysis: A fibrous amphiarthrosis, such as that between adjacent vertebrae or between the pubic bones of the coxal bones. (9)
symptom: An abnormality of function as a result of disease; subjective experience of patient. (1)
synapse: The site of communication between a nerve cell and some other cell; if the other cell is not a neuron, the term *neuromuscular junction* or *neuroglandular junction* is often used. (12, 16, 18)
synaptic delay: The period between the arrival of an impulse at the presynaptic membrane and the initiation of an action potential in the postsynaptic membrane. (12)
syncytium: A multinucleate mass of cytoplasm, produced by the fusion of cells or repeated mitoses without cytokinesis. (29)
syndrome: A discrete set of signs and symptoms that occur together.
synergist: A muscle that assists a prime mover in performing its primary action. (11)
synovial cavity: A fluid-filled chamber in a synovial joint. (4, 9)
synovial fluid: The substance secreted by synovial membranes that lubricates joints. (4, 9)
synovial joint: A freely movable joint where the opposing bone surfaces are separated by synovial fluid; a diarthrosis. (4, 9)
synovial membrane: An incomplete layer of fibroblasts confronting the synovial cavity, plus the underlying loose connective tissue. (4)
synthesis: Manufacture; anabolism. (23)
system: An interacting group of organs that performs one or more specific functions.
systemic circuit: The vessels between the aortic valve and the entrance to the right atrium; the system other than the vessels of the pulmonary circuit. (20)
systole: A period of contraction in a chamber of the heart, as part of the cardiac cycle. (20)
systolic pressure: The peak arterial pressure measured during ventricular systole. (20, 21)

T

tachycardia: Rapid heart beat, usually over 90 beats per minute. (20)
tactile: Pertaining to the sense of touch. (15)
tarsal bones: The bones of the ankle (the talus, calcaneus, navicular, and cuneiform bones). (8)
tarsus: The ankle. (8)
TCA (tricarboxylic acid) cycle: *See* **citric acid cycle**. (3, 10, 25)
T cells: Lymphocytes responsible for cell-mediated immunity and for the coordination and regulation of the immune response; includes cytotoxic T cells, helper T cells, regulatory T cells, and memory T cells. (19, 22)
tectospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by the colliculi. (15)
telodendria: Terminal axonal branches that end in axon terminals. (12)
telomeres: The distal ends of chromosomes. (3)
telophase: The final stage of mitosis, characterized by the disappearance of the spindle apparatus, the reappearance of the nuclear membrane, the disappearance of the chromosomes, and the completion of cytokinesis. (3)
temporal: Pertaining to time (temporal summation) or to the temples (temporal bone). (7)
tendon: A collagenous band that connects a skeletal muscle to an element of the skeleton. (4, 10)
teres: Round. (11)
terminal: Toward the end.
tertiary structure: The protein structure that results from interactions among distant portions of the same molecule; complex coiling and folding. (2)
testes: The male gonads, sites of gamete production and hormone secretion; also called *testicles*. (18, 28)
testosterone: The main androgen produced by the interstitial endocrine cells of the testes. (2, 18, 28)
tetraiodothyronine: T_4, or thyroxine, a thyroid hormone. (18)
thalamus: The walls of the diencephalon. (14)
therapy: The treatment of disease.
thermoreception: Sensitivity to temperature changes. (15)
thermoregulation: Homeostatic maintenance of body temperature. (1, 25)
thick filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; composed of myosin, with a core of titin. (3, 10)
thin filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; consists of actin, troponin, nebulin, and tropomyosin. (3, 10)
thoracolumbar division: The sympathetic division of the autonomic nervous system. (16)
thorax: The chest. (7)
threshold: The membrane potential at which an action potential begins. (12)
thrombin: The enzyme that converts soluble fibrinogen to insoluble fibrin. (19)
thymine (T): A pyrimidine; one of the nitrogenous bases in the nucleic acid DNA. (2)
thymosins: Thymic hormones essential to the development and differentiation of T cells. (18, 22)
thymus: A lymphoid organ, the site of T cell development and maturation. (18, 22)
thyroglobulin: A circulating transport globulin that binds thyroid hormones. (18)
thyroid gland: An endocrine gland whose lobes are lateral to the thyroid cartilage of the larynx. (18)
thyroid hormones: Thyroxine (T_4) and triiodothyronine (T_3), hormones of the thyroid gland; stimulate tissue metabolism, energy utilization, and growth. (18)
thyroid-stimulating hormone (TSH): The hormone, produced by the adenohypophysis (anterior lobe of the pituitary gland), that triggers the secretion of thyroid hormones by the thyroid gland. (18)
thyroxine: A thyroid hormone; also called T_4 or *tetraiodothyronine*. (18)
tidal volume (V_T): The volume of air moved into and out of the lungs during a normal quiet respiratory cycle. (23)
tight junction: Connection between cells formed by the fusion of membrane proteins. (4)
tissue: A collection of specialized cells and cell products that performs a specific function. (1, 4)
tonic response: An increase or decrease in the frequency of action potentials by sensory receptors that are chronically active. (15)
tonsil: A lymphoid nodule in the wall of the pharynx; the palatine, pharyngeal, and lingual tonsils. (22)
topical: Applied to the body surface.
toxic: Poisonous.
trabecula: A connective tissue partition that subdivides an organ. (22)
trachea: The windpipe; an airway extending from the larynx to the primary bronchi. (23)
tract: A bundle of axons in the central nervous system. (13, 14)
transamination: The reversible chemical reaction between an amino acid and a keto acid in which the amino group from the amino acid is transferred to the keto acid. (25)
transcription: The encoding of genetic instructions on a strand of mRNA. (3)
transection: The severing or cutting of an object in the transverse plane.
translation: The process of peptide formation from the instructions carried by an mRNA strand. (3)
transmembrane potential: *See* **membrane potential**. (3, 10, 12)
transudate: A fluid that diffuses across a serous membrane and lubricates opposing surfaces. (4)
transverse plane: A horizontal plane that divides the body into superior and inferior portions. (1)
transverse tubules: The transverse, tubular extensions of the sarcolemma that extend deep into the sarcoplasm, contacting cisternae of the sarcoplasmic reticulum; also called *T tubules*. (10)
tricuspid valve: The right atrioventricular valve, which prevents the backflow of blood into the right atrium during ventricular systole. (20)
trigeminal nerve: Cranial nerve V, which provides sensory information from the lower portions of the face (including the upper and lower jaws) and delivers motor commands to the muscles of mastication. (14)
triglyceride: A lipid that is composed of a molecule of glycerol attached to three fatty acids. (2, 25)
triiodothyronine: T_3, a thyroid hormone. (18)
trisomy: The abnormal possession of three copies of a chromosome; trisomy 21 is responsible for Down syndrome. (29)
trochanter: Large process near the head of the femur. (8)
trochlea: A pulley; the spool-shaped medial portion of the condyle of the humerus. (8)
trochlear nerve: Cranial nerve IV, controlling the superior oblique muscle of the eye. (14)
tropomyosin: Fibrous muscle protein that covers active sites on G actin and prevents actin-myosin interaction. (10)
troponin: Globular muscle protein that binds to tropomyosin. (10)
trunk: The thoracic and abdominopelvic regions (1); a large bundle of spinal nerve axons (13); a major arterial branch (21).
T tubules: *See* **transverse tubules**.
tuberculum: A small, localized elevation on a bony surface. (7)
tuberosity: A large, roughened elevation on a bony surface. (6, 8)
tumor: A tissue mass formed by the abnormal growth and replication of cells. (3)
tunica: A layer or covering.
twitch: A single stimulus–contraction–relaxation cycle in a skeletal muscle fiber. (10)
tympanic duct: *See* **scala tympani**.

tympanic membrane: The membrane that separates the external acoustic meatus from the middle ear; the membrane whose vibrations are transferred to the auditory ossicles and ultimately to the oval window; also called *eardrum* or *tympanum*. (17)
Type A fibers: Large myelinated axons. (12)
Type B fibers: Small myelinated axons. (12)
Type C fibers: Small unmyelinated axons. (12)

U

umbilical cord: The connecting stalk between the fetus and the placenta; contains the allantois, the umbilical arteries, and the umbilical vein. (21, 29)
umbilicus: The navel. (29)
unicellular gland: Mucous cells. (4)
unipolar neuron: A sensory neuron whose cell body is in a dorsal root ganglion or a sensory ganglion of a cranial nerve. (12)
unmyelinated axon: An axon whose neurolemma does not contain myelin and across which continuous propagation occurs. (12)
uracil (U): A pyrimidine; one of the nitrogenous bases in the nucleic acid RNA. (2)
ureters: Muscular tubes, lined by transitional epithelium, that carry urine from the renal pelvis to the urinary bladder. (26)
urethra: A muscular tube that carries urine from the urinary bladder to the exterior. (26, 28)
urinary bladder: The muscular, distensible sac that stores urine prior to micturition. (26)
urination: The elimination of urine; also called *micturition*. (26)
uterus: The muscular organ of the female reproductive tract in which implantation, placenta formation, and fetal development occur. (28)
utricle: The largest chamber of the vestibular apparatus of the internal ear; contains a macula important for providing sensations of gravity and linear acceleration in a horizontal dimension. (17)

V

vagina: A muscular tube extending between the uterus and the vestibule. (28)
vallate papilla: One of the large, dome-shaped papillae on the superior surface of the tongue that forms a V, separating the body of the tongue from the root. (17)
vascular: Pertaining to blood vessels. (19)
vas deferens: *See* **ductus deferens.** (28)
vasoconstriction: A reduction in the diameter of arterioles due to the contraction of smooth muscles in the tunica media; increases peripheral resistance; may occur in response to local factors, through the action of hormones, or from the stimulation of the vasomotor center. (21)
vasodilation: An increase in the diameter of arterioles due to the relaxation of smooth muscles in the tunica media; decreases peripheral resistance; may occur in response to local factors, through the action of hormones, or after decreased stimulation of the vasomotor center. (21)
vasomotion: Rhythmic changes in the pattern of blood flow through a capillary bed due to the alternate contraction and relaxation of precapillary sphincters. (21)
vasomotor center: The center in the medulla oblongata whose stimulation produces vasoconstriction and an increase of peripheral resistance. (14)
vein: A blood vessel carrying blood from a capillary bed toward the heart. (20, 21)
vena cava: One of the major veins delivering systemic blood to the right atrium; superior and inferior venae cavae. (20, 21)
ventilation: Air movement into and out of the lungs. (23)
ventral: Pertaining to the anterior surface.
ventricle: A fluid-filled chamber; in the heart, one of the large chambers discharging blood into the pulmonary or systemic circuits (20); in the brain, one of four fluid-filled interior chambers. (14)
venule: Thin-walled veins that receive blood from capillaries. (21)
vermiform appendix: *See* **appendix**. (24)
vertebral canal: The passageway that encloses the spinal cord; a tunnel bounded by the neural arches of adjacent vertebrae. (7)
vertebral column: The cervical, thoracic, and lumbar vertebrae, the sacrum, and the coccyx. (7, 11)
vesicle: A membranous sac in the cytoplasm of a cell. (3)
vestibular duct: *See* **scala vestibuli**.
vestibular nucleus: The processing center for sensations that arrive from the vestibular apparatus of the internal ear, located near the border between the pons and the medulla oblongata. (14, 17)
vestibulospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by the vestibular nucleus to stabilize the position of the head. (15)
villus/villi: Slender, finger-shaped projection(s) of a mucous membrane. (24, 29)
virus: A noncellular pathogen. (22)
viscera: Internal organs of the thoracic and abdominopelvic cavities. (1)
visceral: Pertaining to viscera (internal organs) or their outer coverings. (1)
visceral smooth muscle: A smooth muscle tissue that forms sheets or layers in the walls of visceral organs; the cells may not be innervated, and the layers often show automaticity (rhythmic contractions). (10, 24)
viscosity: The resistance to flow that a fluid exhibits as a result of molecular interactions within the fluid. (21)
viscous: Thick, syrupy.
vitamin: An essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. (24, 25)
vitreous humor: The fluid component of the vitreous body, the gelatinous mass in the posterior cavity (vitreous chamber) of the eye. (17)
voluntary: Controlled by conscious thought processes.

W

white blood cells (WBCs): The granulocytes and agranulocytes of whole blood; also called *leukocytes*. (4, 19)
white matter: Regions in the central nervous system that are dominated by myelinated axons. (12, 13, 14)
white ramus communicans: A nerve bundle containing the myelinated preganglionic axons of sympathetic motor neurons en route to the sympathetic chain or to a collateral ganglion. (13)
Wormian bones: *See* **sutural bones**. (6)

X

X chromosome: One of two sex chromosomes; females have two X chromosomes. (29)
xiphoid process: The slender, inferior extension of the sternum. (7)

Y

Y chromosome: The sex chromosome whose presence indicates that the individual is a genetic male. (29)

Z

zona fasciculata: The region of the adrenal cortex that secretes glucocorticoids. (18)
zona glomerulosa: The region of the adrenal cortex that secretes mineralocorticoids. (18)
zona reticularis: The region of the adrenal cortex that secretes androgens. (18)
zygote: The fertilized ovum, prior to the start of cleavage. (28, 29)

A bands, 344
ABCD mnemonic, for melanoma, 210
Abdominal aorta, 809–810
Abdominal cavity, 64
Abdominal thrust, 929
Abdominopelvic cavity, 60, 61, 812, 817–821
Abdominopelvic quadrants, 57
Abdominopelvic regions, 57
Abdominoplasty, 207
Abducens nerve (VI), 544, 551
Abduction, 317, 320, 388
Abductor (muscle name), 388, 392
Abductor digiti minimi muscle, 419, 427
Abductor hallucis muscle, 427
Abductor pollicis muscle, brevis/longus, 417, 419
ABO blood types, 712, 714–715
Abortion, 1169
Abrasion, 218
Abscess, 192, 851
Absolute refractory period, 457, 458, 756
Absorption
- carbohydrates, 973–975
- definition, 932
- ions, 976–977, 978
- in large intestine, 969–970
- lipids, 974, 975–976
- monosaccharides, 975
- nucleic acids, 976
- proteins, 974, 976
- in stomach, 951
- vitamins, 977, 978
- water, 976

Absorptive state, 1004, 1006
Accessory glands, male reproductive system, 1107–1109
Accessory nerve (XI), 550, 551
Accessory organs, digestive system, 931, 932
Accessory pancreatic duct, 954
Accessory respiratory muscles, 899, 900, 901
Accessory structures
- eye, 618–620
- glands. *See* Gland(s)
- hair. *See* Hair
- integument, 199, 200, 201
- nails, 217, 224
- synovial joints, 315–316

Acclimatization, 1016
Accommodation, vision, 628, 630
Accommodation curves, 274
ACE inhibitors, 690
Acetabular labrum, 329
Acetabular ligament, transverse, 327
Acetabular notch, 298, 330
Acetabulum, 298, 299, 307
Acetate, 464
Acetoacetate, 1004
Acetone, 1004
Acetylcholine (ACh)
- in cholinergic synapses, 464, 465, 589
- location, 468
- mechanism of action, 468
- muscle activity and, 349, 350–351
- in parasympathetic division, 592
- structure, 468
- in sympathetic division, 589

Acetylcholinesterase (AChE), 350–351, 353, 464, 592
Acetyl-CoA, 991
Acetyl group, 991
Achilles (calcaneal) tendon, 303, 426–427
Achondroplasia, 253
Acid(s), 90, 106, 1083–1084
Acid-base balance
- age-related changes, 1095, 1097
- definition, 1069
- overview, 1069
- pH control in, 1082, 1088
- regulation, 1087–1088
- renal compensation and, 1087–1088, 1090
- respiratory compensation and, 1087, 1090
- terminology, 1082

Acid-base disorders
- acute phase, 1091
- blood chemistry in, 1095
- causes, 1091
- combined respiratory and metabolic acidosis, 1095
- compensated phase, 1091
- detection and diagnosis, 1095, 1096
- metabolic acidosis, 1093–1094, 1095
- metabolic alkalosis, 1093, 1095
- respiratory acidosis, 1091, 1092, 1095
- respiratory alkalosis, 1091–1092, 1095

Acidemia, 1082
Acidic solution, 89
Acidity, 1068
Acidophils. *See* **Eosinophils**
Acidosis
- combined respiratory and metabolic, 1096
- definition, 89, 1082
- detection and diagnosis, 1095, 1096
- metabolic, 1093–1094, 1095, 1096
- renal responses, 1088, 1090
- respiratory, 1091, 1092, 1095, 1096
- respiratory responses, 1087, 1090

Acinar (alveolar) glands, 171
Acoustic meatus, external/internal, 259, 260, 261, 264, 265
Acoustic nerve. *See* **Vestibulocochlear nerve (VIII)**
Acquired immune deficiency syndrome (AIDS), 872, 873, 894
Acquired reflexes, 503
Acromegaly, 244, 691
Acromial end, clavicle, 292
Acromioclavicular joint, 292
Acromioclavicular ligament, 328
Acromion, 292
Acrosin, 1152
Acrosomal vesicle, 1116
Acrosome, 1116
Acrosome reaction, 1151
Actin, 118, 343
Actinic keratosis, 210
Actinins, 345
Action(s), muscle, 387–388, 392
Action potentials
- all-or-none principle, 455
- axon diameter and propagation speed, 465
- cardiac contractile cells, 755–757
- definition, 438, 455
- frequency, 474
- generation, 455–458
- vs. graded potentials, 458
- overview, 455
- propagation, 458–459
- rate of generation, 473–474
- refractory period, 453
- skeletal muscle cells, 341, 349, 350–351
- sodium–potassium exchange and, 458

Activated channels, 453
Activation, lymphocyte, 852–853
Activation energy, 85
Active immunity, 853, 854
Active (gated) ion channels, 117, 452–453
Active site
- enzyme, 101
- G-actin molecule, 345

Active transport, 142–143, 147, 1039
Acute, 72
Acute renal failure, 1037, 1060
Acute respiratory acidosis, 1091, 1096
Acute respiratory alkalosis, 1096
ADA deficiency, 1185
Adam's apple, 888
Adaptation
- light and dark, 635
- sensory receptors, 562–563

Adaptive (specific) immunity (adaptive defenses)
- antibody-mediated. *See* Antibody-mediated immunity
- antigens, 852
- cell-mediated. *See* Cell-mediated (cellular) immunity
- forms, 853, 854
- lymphocyte activation and clonal selection, 852–853

cerebrum, 532–534
characteristics, 444
medulla oblongata, 522
midbrain, 525
pons, 523
spinal cord, 486
White muscles, 370
White pulp, spleen, 842
White ramus communicans, 484, 491, 585
Whole blood, 704–705, 706. *See also* **Blood**
Wisdom teeth, 942
Withdrawal reflex, 501, 505
Word roots, 53
Work, 83
Wormian (sutural) bone, 228, 257
Wright's stain, 717
Wrist, 296

X

X chromosome, 1181
Xenograft, 879
Xenotransplant, 197
Xerosis, 203
Xiphoid process, 285
X-linked inheritance, 1181–1182
X-linked traits, 1182
X-rays, 62

Y

Y chromosome, 1181
Yellow bone marrow, 227, 235, 710
Yolk sac, 710, 1157, 1158, 1160
Yolk stalk, 1161

Z

Zika virus, 1139
Zinc, 1009
Z lines, 345
Zoloft (sertraline), 466
Zona fasciculata, 681, 682
Zona glomerulosa, 680, 681
Zona pellucida, 1129, 1151
Zona reticularis, 681, 682
Zone of overlap, 344
Zwitterions, 99, 1085
Zygomatic arch, 263, 264
Zygomatic bones, 269
Zygomaticofacial foramen, 269
Zygomatic process, 263
Zygomaticus muscle, major/minor, 395
Zygote, 1144, 1151

COMMON ABBREVIATIONS USED IN SCIENCE

ACh	acetylcholine
AChE	acetylcholinesterase
ACTH	adrenocorticotropic hormone
ADH	antidiuretic hormone
ADP	adenosine diphosphate
AIDS	acquired immunodeficiency syndrome
ALS	amyotrophic lateral sclerosis
AMP	adenosine monophosphate
ANP	atrial natriuretic peptide
ANS	autonomic nervous system
AP	arterial pressure
ARDS	adult respiratory distress syndrome
atm	atmospheric pressure
ATP	adenosine triphosphate
ATPase	adenosine triphosphatase
AV	atrioventricular
AVP	arginine vasopressin
BCOP	blood colloid osmotic pressure
BMR	basal metabolic rate
BPG	bisphosphoglycerate
bpm	beats per minute
BUN	blood urea nitrogen
C	large calorie; Celsius
CABG	coronary artery bypass graft
CAD	coronary artery disease
cAMP	cyclic-AMP
CAPD	continuous ambulatory peritoneal dialysis
CCK	cholecystokinin
CD	cluster of differentiation
CF	cystic fibrosis
CHF	congestive heart failure
CHP	capillary hydrostatic pressure
CsHP	capsular hydrostatic pressure
CNS	central nervous system
CO	cardiac output; carbon monoxide
CoA	coenzyme A
COMT	catechol-O-methyltransferase
COPD	chronic obstructive pulmonary disease
CP	creatine phosphate
CPK, CK	creatine phosphokinase
CPM	continuous passive motion
CPR	cardiopulmonary resuscitation
CRF	chronic renal failure
CRH	corticotropin-releasing hormone
CSF	cerebrospinal fluid; colony-stimulating factors
CT	computerized tomography; calcitonin
CVA	cerebrovascular accident
CVS	cardiovascular system
DAG	diacylglycerol
DC	Doctor of Chiropractic
DCT	distal convoluted tubule
DDST	Denver Developmental Screening Test
DIC	disseminated intravascular coagulation
DJD	degenerative joint disease
DMD	Duchenne's muscular dystrophy
DNA	deoxyribonucleic acid
DO	Doctor of Osteopathy
DPM	Doctor of Podiatric Medicine
DSA	digital subtraction angiography
E	epinephrine
ECF	extracellular fluid
ECG	electrocardiogram
EDV	end-diastolic volume
EEG	electroencephalogram
EKG	electrocardiogram
ELISA	enzyme-linked immunosorbent assay
EPSP	excitatory postsynaptic potential
ERV	expiratory reserve volume
ESV	end-systolic volume
ETS	electron transport system
FAD	flavin adenine dinucleotide
FAS	fetal alcohol syndrome
FES	functional electrical stimulation
FMN	flavin mononucleotide
FRC	functional residual capacity
FSH	follicle-stimulating hormone
GABA	gamma aminobutyric acid
GAS	general adaptation syndrome
GC	glucocorticoid
GFR	glomerular filtration rate
GH	growth hormone
GH–IH	growth hormone–inhibiting hormone
GHP	glomerular hydrostatic pressure
GH–RH	growth hormone–releasing hormone
GIP	gastric inhibitory peptide
GnRH	gonadotropin-releasing hormone
GTP	guanosine triphosphate
Hb	hemoglobin
hCG	human chorionic gonadotropin
HCl	hydrochloric acid
HDL	high-density lipoprotein
HDN	hemolytic disease of the newborn
hGH	human growth hormone
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HMD	hyaline membrane disease
HP	hydrostatic pressure
hPL	human placental lactogen
HR	heart rate
Hz	Hertz
ICF	intracellular fluid
ICOP	interstitial fluid colloid osmotic pressure
IGF	insulin-like growth factor
IH	inhibiting hormone
IM	intramuscular
IP3	inositol triphosphate
IPSP	inhibitory postsynaptic potential
IRV	inspiratory reserve volume
ISF	interstitial fluid
IUD	intrauterine device
IVC	inferior vena cava
IVF	in vitro fertilization
kcal	kilocalorie
LDH	lactate dehydrogenase
LDL	low density lipoprotein
L-DOPA	levodopa
LH	luteinizing hormone
LLQ	left lower quadrant
LM	light micrograph
LSD	lysergic acid diethylamide
LUQ	left upper quadrant
MAO	monoamine oxidase
MAP	mean arterial pressure
MC	mineralocorticoid
MD	Doctor of Medicine
mEq	millequivalent; (10^{-3})
MHC	major histocompatibility complex
MI	myocardial infarction
mm Hg	millimeters of mercury
mmol	millimole
mOsm	milliosmole
MRI	magnetic resonance imaging
mRNA	messenger RNA
MS	multiple sclerosis
MSH	melanocyte-stimulating hormone
MSH–IH	melanocyte-stimulating hormone–inhibiting hormone
NAD	nicotinamide adenine dinucleotide
NE	norepinephrine
NFP	net filtration pressure
NHP	net hydrostatic pressure
NO	nitric oxide
NRDS	neonatal respiratory distress syndrome
OP	osmotic pressure
Osm	osmoles
OXT	oxytocin
PAC	premature atrial contraction
PAT	paroxysmal atrial tachycardia
PCT	proximal convoluted tubule
PCV	packed cell volume
PEEP	positive end-expiratory pressure
PET	positron emission tomography
PFC	perfluorochemical emulsion
PG	prostaglandin
PID	pelvic inflammatory disease
PIH	prolactin-inhibiting hormone
PIP	phosphatidylinositol
PKC	protein kinase C
PKU	phenylketonuria
PLC	phospholipase C
PMN	polymorphonuclear leukocyte
PNS	peripheral nervous system
PR	peripheral resistance
PRF	prolactin-releasing factor
PRL	prolactin
psi	pounds per square inch
PT	prothrombin time
PTA	post-traumatic amnesia; plasma thromboplastin antecedent
PTC	phenylthiocarbamide
PTH	parathyroid hormone
PVC	premature ventricular contraction
RAS	reticular activating system
RBC	red blood cell
RDA	recommended daily allowance
RDS	respiratory distress syndrome
REM	rapid eye movement
RER	rough endoplasmic reticulum
RH	releasing hormone
RHD	rheumatic heart disease
RLQ	right lower quadrant
RNA	ribonucleic acid
rRNA	ribosomal RNA
RUQ	right upper quadrant
SA	sinoatrial
SCA	sickle cell anemia
SCID	severe combined immunodeficiency disease
SEM	scanning electron micrograph
SER	smooth endoplasmic reticulum
SGOT	serum glutamic oxaloacetic transaminase
SIADH	syndrome of inappropriate ADH secretion
SIDS	sudden infant death syndrome
SLE	systemic lupus erythematosus
SNS	somatic nervous system
STD	sexually transmitted disease
SV	stroke volume
SVC	superior vena cava
T_3	triiodothyronine
T_4	tetraiodothyronine, or thyroxine
TB	tuberculosis
TBG	thyroid-binding globulin
TEM	transmission electron micrograph
TIA	transient ischemic attack
T_m	transport (tubular) maximum
TMJ	temporomandibular joint
t-PA	tissue plasminogen activator
TRH	thyrotropin-releasing hormone
tRNA	transfer RNA
TSH	thyroid-stimulating hormone
TSS	toxic shock syndrome
U.S.	United States
UTI	urinary tract infection
UTP	uridine triphosphate
UV	ultraviolet
$\dot{V}_A$	alveolar ventilation
V_D	anatomic dead space
$\dot{V}_E$	respiratory minute volume
V_T	tidal volume
VF	ventricular fibrillation
VLDL	very low-density lipoprotein
VPRC	volume of packed red cells
VT	ventricular tachycardia
WBC	white blood cell

FOREIGN WORD ROOTS, PREFIXES, SUFFIXES, AND COMBINING FORMS

Each entry starts with the commonly used form or forms of the prefix, suffix, or combining form followed by the word root (shown in italics) and its English translation. One example is also given to illustrate the use of each entry.

a-, *a-,* without: avascular
ab-, *ab,* from: abduct
-ac, *-akos,* pertaining to: cardiac
acr-, *akron,* extremity: acromegaly
ad-, *ad,* to, toward: adduct
aden-, adeno-, *adenos,* gland: adenoid
adip-, *adipos,* fat: adipocytes
aer-, *aeros,* air: aerobic metabolism
-al, *-alis,* pertaining to: brachial
alb-, *albicans,* white: albino
-algia, *algos,* pain: neuralgia
allo-, *allos,* other: allograft
ana-, *ana,* up, back: anaphase
andro-, *andros,* male: androgen
angio-, *angeion,* vessel: angiogram
ante-, *ante,* before: antebrachial
anti-, ant-, *anti,* against: antibiotic
apo-, *apo,* from: apocrine
arachn-, *arachne,* spider: arachnoid
arter-, *arteria,* artery: arterial
arthro-, *arthros,* joint: arthroscopy
astro-, *aster,* star: astrocyte
atel-, *ateles,* imperfect: atelectasis
aur-, *auris,* ear: auricle
auto-, *auto,* self: autonomic
baro-, *baros,* pressure: baroreceptor
bi-, *bi-* two: bifurcate
bio-, *bios,* life: biology
-blast, *blastos,* precursor: osteoblast
brachi-, *brachium,* arm: brachiocephalic
brachy-, *brachys,* short: brachydactyly
brady-, *bradys,* slow: bradycardia
bronch-, *bronchus*, windpipe, airway: bronchial
carcin-, *karkinos,* cancer: carcinoma
cardi-, cardio-, *kardia,* heart: cardiac
-cele, *kele,* tumor, hernia, or swelling: blastocele
-centesis, *kentesis,* puncture: thoracocentesis
cephal-, *cephalos,* head: brachiocephalic
cerebr-, *cerebrum,* brain: cerebral hemispheres
cerebro-, *cerebros,* brain: cerebrospinal fluid
cervic-, *cervicis,* neck: cervical vertebrae
chole-, *chole,* bile: cholecystitis
-chondrion, *chondrion,* granule: mitochondrion
chondro-, *chondros,* cartilage: chondrocyte
chrom-, chromo-, *chroma,* color: chromatin
circum-, *circum,* around: circumduction
-clast, *klastos,* broken: osteoclast
coel-, -coel, *koila,* cavity: coelom
colo-, *kolon,* colon: colonoscopy
contra-, *contra,* against: contralateral
corp-, *corpus,* body: corpuscle
cortic-, *cortex,* rind or bark: corticospinal
cost-, *costa,* rib: costal
cranio-, *cranium,* skull: craniosacral
cribr-, *cribrum,* sieve: cribriform
-crine, *krinein,* to separate: endocrine
cut-, *cutis,* skin: cutaneous
cyan-, *kyanos,* blue: cyanosis
cyst-, -cyst, *kystis,* sac: blastocyst
cyt-, *cyto-, kytos,* a hollow cell: cytology
de-, *de,* from, away: deactivation
dendr-, *dendron,* tree: dendrite
dent-, *dentes,* teeth: dentition
derm-, *derma,* skin: dermatome
desmo-, *desmos,* band: desmosome
di-, *dis,* twice: disaccharide
dia-, *dia,* through: diameter
digit-, *digit,* a finger or toe: digital
dipl-, *diploos,* double: diploid
dis-, *dis,* apart, away from: disability
diure-, *diourein,* to urinate: diuresis
dys-, *dys,* painful: dysmenorrhea
-ectasis, *ektasis,* expansion: atelectasis
ecto-, *ektos,* outside: ectoderm
-ectomy, *ektome,* excision: appendectomy
ef-, *ex,* away from: efferent
emmetro-, *emmetros,* in proper measure: emmetropia
encephalo-, *enkephalos,* brain: encephalitis
end-, endo-, *endon,* within: endometrium
entero-, *enteron,* intestine: enteric
epi-, *epi,* upon: epimysium
erythema-, *erythema,* flushed (skin): erythematosis
erythro-, *erythros,* red: erythrocyte
ex-, *ex,* out of, away from: exocytosis
extra-, *exter,* outside of, beyond, in addition: extracellular
ferr-, *ferrum,* iron: transferrin
fil-,*filum,*thread: filament
-form, *-formis,* shape: fusiform
gastr-, *gaster,* stomach: gastrointestinal
-gen, -genic, *gennan,* to produce: mutagen
genicula-, *geniculum,* kneelike structure: geniculates
genio-, *geneion,* chin: geniohyoid
gest-, *gesto,* to bear: gestation
glosso-, -glossus, *glossus,* tongue: hypoglossal
glyco-, *glykys,* sugar: glycogen
-gram, *gramma,* record: myogram
gran-, *granulum,* grain: granulocyte
-graph, -graphia, *graphein,* to write, record: electroencephalograph
gyne-, gyno-, *gynaikos,* woman: gynecologist
hem-, hemo-, *haima,* blood: hemopoiesis
hemi-, *hemi-,* one half: hemisphere
hepato-, *hepaticus,* liver: hepatocyte
hetero-, *heteros,* other: heterozygous
histo-, *histos,* tissue: histology
holo-, *holos,* entire: holocrine
homeo-, *homoios*, similar: homeostasis
homo-, *homos,* same: homozygous
hyal-, hyalo-, *hyalos,* glass: hyaline
hydro-, *hydros,* water: hydrolysis
hyo-, *hyoeides,* U-shaped: hyoid bone
hyper-, *hyper,* above: hyperpolarization
hypo-, *hypo,* under: hypothyroid
hyster-, *hystera,* uterus: hysterectomy
-ia, *-ia,* state or condition: insomnia
idi-, *idios,* one's own: idiopathic
in-, *in-,* in, within, or denoting negative effect: inactivate
infra-, *infra,* beneath: infra-orbital
inter-, *inter,* between: interventricular
intra-, *intra,* within: intracapsular
ipsi-, *ipse,* itself: ipsilateral
iso-, *isos,* equal: isotonic
-itis, *-itis,* inflammation: dermatitis

karyo-, *karyon,* body: megakaryocyte
kerato-, *keros,* horn: keratin
kino-, -kinin, *kinein,* to move: bradykinin
lact-, lacto-, -lactin, *lac,* milk: prolactin
lapar-, *lapara,* flank or loins: laparoscopy
-lemma, *lemma,* husk: sarcolemma
leuk-, leuko-, *leukos,* white: leukemia, leukocyte
liga-, *ligare,* to bind together: ligase
lip-, lipo-, *lipos,* fat: lipoid
lith-, *lithos,* stone: cholelithiasis
lys- lyso-, *lysis*, a loosening: hydrolysis
macr-, *makros,* large: macrophage
mal-, *mal,* abnormal: malabsorption
mammilla-, *mammilla,* nipple: mammillary
mast-, masto-, *mastos,* breast: mastoid
mega-, *megas,* big: megakaryocyte
melan-, *melas,* black: melanocyte
men-, *men,* month: menstrual
mero-, *meros,* part: merocrine
meso-, *mesos,* middle: mesoderm
meta-, *meta,* after, beyond: metaphase
micr-, *mikros,* small: microscope
mono-, *monos,* single: monocyte
morph-, morpho-, *morphe,* form: morphology
multi-, *multus,* much, many: multicellular
-mural, *murus,* wall: intramural
myelo-, *myelos,* marrow: myeloblast
myo-, *mys,* muscle: myofilament
narc-, *narkoun,* to numb or deaden: narcotics
nas-, *nasus,* nose: nasolacrimal duct
natri-, *natrium,* sodium: natriuretic
necr-, *nekros,* corpse: necrosis
nephr-, *nephros,* kidney: nephron
neur-, neuri-, neuro-, *neuron,* nerve: neuromuscular
oculo-, *oculus,* eye: oculomotor
odont-, *odontos,* tooth: odontoid process
-oid, *eidos,* form, resemblance: odontoid process
oligo-, *oligos,* little, few: oligopeptide
-ology, *logos,* the study of: physiology
-oma, *-oma,* swelling: carcinoma
onco-, *onkos,* mass, tumor: oncology
oo-, *oon,* egg: oocyte
ophthalm-, *ophthalmos,* eye: ophthalmic nerve
-opia, *ops,* eye: myopia
orb-, *orbita,* a circle: orbicularis oris
orchi-, *orchis,* testis: orchiectomy
orth-, *orthos,* correct, straight: orthopedist
-osis, *-osis,* state, condition: neurosis
ost-, oste-, osteo-, *osteon,* bone: osteocyte
oto-, *otikos,* ear: otolith
para-, *para,* two like parts or a pair: paraplegia
path-, -pathy, patho-, *pathos,* disease:pathology
pedia-, *paidos,* child: pediatrician
per-, *per,* through, throughout: percutaneous
peri-, *peri,* around: perineurium
phago-, *phago,* to eat: phagocyte
-phasia, *phasis,* speech: aphasia
-phil, -philia, *philos,* love: neutrophil
phleb-, *phleps,* a vein: phlebitis
-phobia, *phobos,* fear: claustrophobia
phot-, photo-, *phos,* light: photoreceptor
-phylaxis, *phylax,* a guard: prophylaxis
physio-, *physis,* nature: physiology
-plasia, *plasis,* formation: dysplasia
platy-, *platys,* flat: platysma
-plegia, *plege,* a blow, paralysis: hemiplegia
-plexy, *plessein,* to strike: apoplexy
pneum-, *pneuma,* air: pneumotaxic center
pod-, podo-, *podos,* foot: podocyte
-poiesis, *poiesis,* making: hemopoiesis
poly-, *polys,* many: polysaccharide
post-, *post,* after: postanal
pre-, *prae,* before: precapillary sphincter
presby-, *presbys,* old: presbyopia
pro-, *pro,* before: prophase
proct-, *proktos,* anus: proctology
pterygo-, *pteryx,* wing: pterygoid
pulmo-, *pulmo,* lung: pulmonary
pulp-, *pulpa,* pulp: pulpitis
pyel-, *pyelos,* trough or pelvis: pyelitis
quadr-, *quadrans,* one quarter: quadriplegia
re-, *re-,* back, again: reinfection
retro-, *retro,* backward: retroperitoneal
rhin-, *rhis,* nose: rhinitis
-rrhage, *rhegnymi,* to burst forth: hemorrhage
-rrhea, *rhein,* flow, discharge: diarrhea
sarco-, *sarkos,* flesh: sarcomere
scler-, sclero-, *skleros,* hard: sclera
-scope, *skopeo,* to view: colonoscope
-sect, *sectio,* to cut: transect
semi-, *semis,* half: semitendinosus
-septic, *septikos,* putrid: antiseptic
-sis, *-sis,* state or condition: metastasis
som-, -some, *soma,* body: somatic
spino-, *spina,* spine, vertebral column: spinothalamic pathway
stalsis, *staltikos,* contractile: peristalsis
sten-, *stenos,* a narrowing: stenosis
stomy, *stoma,* mouth, opening: colostomy
stylo-, *stylus,* stake, pole: stylohyoid
sub-, *sub,* below; subcutaneous
super-, *super,* above or beyond: superficial
supra-, *supra,* on the upper side: supraspinous fossa
syn-, *syn,* together: synthesis
tachy-, *tachys,* swift: tachycardia
telo-, *telos,* end: telophase
tetra-, *tettares,* four: tetralogy of Fallot
therm-, thermo-, *therme,* heat: thermoregulation
thorac-, *thorax,* chest: thoracentesis
thromb-, *thrombos,* clot: thrombocyte
-tomy, *tome,* to cut: appendectomy
tox-, *toxikon,* poison: toxemia
trans-, *trans,* through: transudate
tri-, *tres,* three: trimester
tropho-, *trophe,* nutrition: trophoblast
trophy, *trophikos,* nourishment: atrophy
-tropic, *trope,* turning: adrenocorticotropic
tropo-, *tropikos,* turning: troponin
uni-, *unus,* one: unicellular
uro-, -uria, *ouron,* urine: glycosuria
vas-, *vas,* vessel: vascular
zyg-, *zygotos,* yoke: zygote

GLOBAL EDITION

For these Global Editions, the editorial team at Pearson has collaborated with educators across the world to address a wide range of subjects and requirements, equipping students with the best possible learning tools. This Global Edition preserves the cutting-edge approach and pedagogy of the original, but also features alterations, customization, and adaptation from the North American version.

This is a special edition of an established title widely used by colleges and universities throughout the world. Pearson published this exclusive edition for the benefit of students outside the United States and Canada. If you purchased this book within the United States or Canada, you should be aware that it has been imported without the approval of the Publisher or Author.
